(2). It is a more permanent method than any other of preserving photographs if proper precaution is taken to obtain a cement of proper quality, free from acidity, as the picture is to a great extent hermetically sealed from the action of air and damp, and might be made absolutely so if the back of the paper is treated with suitable waterproof compound or varnish.

(3). For framing purposes it is far more economical in the weight and cost of glass, because a print only requires a glass support about half an inch larger each way than itself, which can be put direct into a “cut out” mount without any glazing of the frame, the area of glass for which (allowing a fair margin round the print) would be about three times the square measurement of the actual print. Hence, treble greater weight for transit and cost of glass for frames when glazed all over.

(4). If properly worked in the manner recently described by the Editor of this JOURNAL, the process is far easier and quicker to manipulate than mounting on surface of cards or mounts of any kind.

(5). But the prime advantage of all is the beautiful optical effect it has on the prints, which I cannot quite understand; it seems to harmonise the lights and shadows of the picture more perfectly than any other treatment. Artificial glazing by enamel does not produce the same effect, and becomes highly offensive to many—under glass the heavy shadows become more transparent, and details visible which were before sunk in oblivion, and the general effect is richer and more transparent. The only precaution necessary is, that prints intended to be so mounted ought to be purposely printed a shade or two deeper all over than those for mounting on surface of cards, and I do not know any better way of utilising over-printed copies than by mounting them in optical contact on glass.

I think I have shown five good reasons why this style of mounting prints (for framing) ought to be encouraged rather than the reverse, and if anyone can give good ones to the contrary, I am open to conviction. A little ventilation of public opinion on the point will be a good thing. Perhaps Mr. Rattray, as Secretary of the Dundee Association, will give us their reasons for tabooing this most exquisite process, and disqualifying pictures so mounted from competition for prizes.—I am, yours, &c.,
Lux.

PHOTOGRAPHIC EXHIBITION IN DUBLIN.—ENLARGEMENTS.

To the Editors.

GENTLEMEN,—In my last letter to you on this subject I inadvertently omitted to mention that the Committee had decided to offer, in addition to those in the prospectus, a special medal for enlargements *bond fide* the work of amateurs.

Pictures competing for this medal must be marked plainly on the label (preferably in red) “Amateur enlargement for special medal.”—I am, yours, &c.,
GREENWOOD PRM, Hon. Sec. Exhibition Committee.

Monkstown, Co. Dublin, September 20.

CORNWALL EXHIBITION.

To the Editors.

GENTLEMEN,—I wish to correct an error, in your last issue, with reference to my exhibits at the Cornwall Exhibition. They are criticised as enlargements, whereas they are all direct from life on twenty-five-inch plates. I am anxious to know if this is an error on the part of the Judges, or merely a mistake your correspondent has fallen into. Trusting you will, in justice to me, insert this in your next issue.—I am, yours, &c.,
W. CROOKE.

103, Princes-street, Edinburgh, September 19, 1887.

Exchange Column.

* * No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as “anything useful” will therefore understand the reason of their non-appearance.

Will exchange half-plate portrait lens for good exterior background or posing chair.—Address, A. TAYLOR, 77 and 79, Fore-street, Ipswich, Suffolk.

I will exchange a cabinet-maker’s first-class tool chest for a half-plate camera, lens, burnisher, or accessories.—Address, JOHN McPHER, 213, Links-street, Kirkcaldy.

I will exchange five years’ BRITISH JOURNALS OF PHOTOGRAPHY, up to August, 1887, for either half-plate or whole-plate view lens.—Address, C. CHAMBERS, 18, Tipping-street, Stafford.

Wanted, 12×10 tourist’s camera with double slide; exchange, lantern with four-inch condenser, half-plate rectilinear lens, and cabinet burnisher.—Address, MASON, 11, Sea View, Hartlepool.

Will exchange Martini-Henry rifle, '380 bore, and screwless revolver, for whole-plate camera and rectilinear lens or good half-plate portrait lens.—Address, J. THOMPSON, Rhine Studio, Youghal.

Will exchange three gem lenses for six whole-plate, twelve cabinet, and eighteen *carte-de-visite* portraits, unmounted.—Address, R. W. F., Alfoxton-villa, Laurel-road, Highfields, Leicester.

Three half-plate double slides, half-plate lens, home-made bellows camera, and tripod stand, will be given in exchange for studio camera, half-plate size or larger.—Address, W. R. FAIREY, Harrold, Bedford.

I will exchange 10×8 view lens and Steinheil enlarging lens for quarter-plate Dallmeyer's rapid rectilinear or Ross' rapid symmetrical, same size.—Address, J. D. EDWARD, 43, Great King-street, Edinburgh.

Will exchange good German-made microscope with two eye-pieces, three objectives, magnifying 20-550 diameters, for a camera and accessories not less than whole-plate.—Address, C. ROWLAND, 39, Cecil-street, Carlisle.

Wanted, a half-plate Rectigraph, Optimus, or other good lens, or a Knox harnesser, eight-inch roller; exchange, revolver, by Colt, in mahogany case.—Address, WILLIAM FOX, 15, Cumming-street, Harlhill, Stoke-on-Trent.

Will exchange a bellows-body, reversible back, whole-plate camera, fitted with three double backs, and rectilinear lens; wanted, a tricycle, latest pattern, centre geared, close folding, &c.—Address, MYLES GARNER, 293, Holloway-road, N.

I will exchange *carte* lens, by Squire, five-inch back focus, for a *carte* lens of shorter focus or half-plate rectilinear; also a sewing machine on stand for Victoria camera.—Address, H. M. ASHLEY, Photographie Studio, Eldade-hill, Plymouth.

I will exchange Marion's 3½×2½ pocket landscape camera with lens, three double dark slides, and three dozen rapid plates to fit, all new and unused, for a good quarter-plate camera with three or more double slides. Cash adjustment.—Address, P. C. WATT, Hingham, Attleborough.

For exchange, tripod and studio stands, several head rests, various lenses and cameras, large-size magic lantern, backgrounds, Victoria camera, nine lenses, studio table, chair, &c. Wanted, wide-angle lens to cover half-plate, backgrounds, and accessories.—Address, J. W. WALMSLEY, 262, Walton-road, Liverpool.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a NOM DE PLUME as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

B. C. C.—No satisfactory method. In ordinary landscape negatives there is none at all.

GEO. FERGIE (Copiapo, Chili).—Your letter received. It was indeed a curious coincidence.

COLESWEGEN.—Immerse the negative in bichloride of mercury, which will in some measure render it less dense. If we have time we shall treat the other subject next week.

EMERY asks: "Can I with safety take abroad pyro in one-pound tins? How long will it keep?"—The pyrogallie acid may be taken with safety. It keeps well in the dry state.

T. B. II. asks what kind of lens is the best for taking photographs of pottery ware.—No particular lens is necessary; any will answer. One of the rapid series is as good as any.

UTILITY.—I. We shall be glad to receive the communication.—2. Specify diameter and focus of lens.—3. Send us the details of the invention you wish to patent or obtain the necessary forms from the Patent Office.

C. P.—I. About what time? We have no recollection of the matter.—2. All that can be said upon the subject has appeared in our volumes for the last or previous years. We fear that "our thousands of readers" would not appreciate the space being devoted to a repetition of what has appeared so recently.

W. HALLETT writes: "Will one of your readers kindly help an amateur with a suggestion? I have always used an ordinary blow-through jet, but contemplate using a mixed jet in the Ethoxo form, using oxygen in compressed cylinder. If pumice cylinders are used in tubes is there any possibility of accident, as this seems the extreme of precaution?"

H. BENTLEY says he has broken a porcelain dish and mended it with one of the commercial cements, and asks if this cement will injure the silver solution.—As we do not know the composition of this particular cement, which, no doubt, the manufacturers keep as their trade secret, we are unable to say. The simple experiment of leaving a little solution in the vessel for a day or two will settle the question.

AN OPTICIAN.—If we correctly understand the Merchandise Marks Act, you render yourself liable to fine or imprisonment by selling opera and race glasses made abroad but bearing your own name engraved thereon as the reputed maker. The Act specifies very strictly that such articles must bear the name of the real manufacturer if any name is to appear at all. But we imagine that by engraving before your own name the words "warranted and sold by," or simply "warranted by," no action for fraudulent representation would be sustainable.

J. HAMPTON says: "Will you be kind enough to tell me how to neutralise with ammonia the following solution:—One ounce of sulphuric acid, water, one ounce; add one hundred and twenty grains of gelatine, then add five ounces of water? I have used the blue and red litmus papers; I cannot get the solution neutral with the papers."—Does our correspondent really imagine that the object of litmus paper is to neutralise an acid or alkaline solution? Its sole use is to indicate whether any solution is or is not neutral. To neutralise with ammonia, add this substance until the litmus paper, both red and blue, remains unaffected in colour.

A. W. C. writes a long letter, lamenting that England is so far behind the Continent and America in photo-mechanical work. He says that in Germany lichtdruck prints are produced at far less price than they are done here, and for this reason publishers are having their work executed abroad.

W. P. asks: "1. Cause of spot in background of enclosed print.—2. Best preventative.—3. Are slightly blistered albumen prints unsafe? i.e., do the small blisters harbour hypo in spite of washing?—4. Best preventative of last-named evil."—Reply: 1. An air bubble sticking to the print when immersed in the fixing bath.—2. Remedy obvious.—3. They are always suspicious. Sometimes they make themselves apparent after a time, though not always.—4. Avoid the use of paper that produces blisters; next to that add water gradually to the fixing bath after the prints are fixed, so as to avoid transferring them direct from the strong hypo solution into plain water.

J. E. GOWER writes: "1. Having made an instantaneous shutter, I wish to stain it, but as it is made in some places of very thin wood (one-eighth of an inch) I am afraid the stain might make the wood warp. Do you think this would be the case? I should use Judson's stains but do not know whether they are made up with water or spirit.—2. As my hypo fixings become used up I throw them all into a large glass jar, but find after a few days that a thick sediment falls to the bottom; is this silver in any form?"—In reply: 1. If an aqueous dye be employed, and it be applied to one side of the wood only, it would, in all probability, cause warping; but if it were applied to both sides equally and dried evenly this would be avoided. A spirituous dye would be the best to use.—2. The sediment contains some silver, no doubt, but not all that is in the solution. Add sulphide of potassium so long as a precipitate is produced. This precipitate is the sulphide of silver.

A. J. CORRIE writes: "I have been using the Eastman negative paper for some time and got quite satisfactory results with all exposures excepting those made with the drop shutter; in these the paper fogs always, more or less—generally more, as the enclosed negative will show you. The exposure was with a common drop shutter unaccelerated by any spring; aperture of lens, about f_{16} ; a wide sunlit view, early in forenoon; development, normal; result, the object failure enclosed; which, please bear in mind, is like to many others of various subjects, but all exposed with the shutter. The fog appears soon, but in the case of longer exposures the shadows and edges of the papers are perfectly clear. The shutter is certainly light-tight. I have specially examined it before writing. I should suspect my light were it not that other negatives are so clear in shadows and edges. Is the paper more unfitted for instantaneous work than glass?"—As our correspondent finds that when he does not use the instantaneous shutter his negatives develop free from fog, and when he uses it the pictures are fogged, it is clear that the shutter arrangement allows some light to pass the lens other than during the exposure. The enclosed example proves that light has reached the paper by some means or other, and doubtless through the shutter. The paper itself is as well suited for instantaneous work as plates.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting, September 28, 1887, will be on *Developers and Developing*. Saturday outing at Dagenham. Trains from Fenchurch-street near two o'clock.

The photographic public are cautioned against a man who tells a pitiful tale of having lost a situation in Scotland or in the West of England, and who says he has travelled to London on foot, and is starving, &c. He called on some firms here more than a year ago with this tale, and has within the past few days been repeating this story. There is more than an element of suspicion about this matter.

ERRATA.—Mr. W. E. Debenham writes: "I observe that you have reprinted from the *Photographic Times* an article of mine on *Permanent Intensification with Mercury*. There are, however, in it two *errata* which have been corrected in a later number of the *Photographic Times*. On the first line of the sixth paragraph the reading is "better forced negative;" the word "forced" should be deleted. The other misprint is in the twelfth line of the eighth paragraph, where it reads "one quart; fill a pint bottle." It should be "one quarter fill a pint bottle."

THE AMERICAN CONVENTION.—Whether this Convention was a success or not we are left in some doubt at present, owing to the conflicting statements that have appeared concerning it in American journals, one of which characterises it as having "proven the most discordant Convention in the history of the Photographers' Association of America." At any rate several papers were contributed, even if they were not all read. The meeting next year will be held in Minneapolis, Minn., under the presidency of E. Decker, of Cleveland, Ohio. The Vice-Presidents are C. W. Motes, Atlanta, Ga., and F. W. Guerin, St. Louis. W. H. Potter, Indianapolis, is Secretary, while the office of Treasurer will continue to be filled by G. M. Carlisle, Providence.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1430. VOL. XXXIV.—SEPTEMBER 30, 1887.

THE EFFECT OF MOISTURE IN PRINTING.

At the meeting of the London and Provincial Photographic Association of the 15th instant, an old and somewhat vexed question amongst silver printers was revived, namely, In printing from a thin negative will the best result be obtained by printing it in a strong or in a feeble light? Some of those present gave it as their experience that with a feeble negative the best result would accrue when it is exposed for a prolonged period to a dull light. Mr. W. England even mentioned that with thin negatives he sometimes placed them in such a subdued light that they took an entire day to print. Others expressed the opinion that weak negatives might be quite as successfully printed, and more so, in a strong light, while some said that it mattered little what kind of light was used. In the end the question, simple though it be, was left very much as it was a quarter of a century ago—opinions divided.

On one point the meeting appeared to be tolerably unanimous, and that was that a different coloured print is obtained when it is printed in a strong light to what it would have been if it were printed in a weak one. This fact can easily be demonstrated by exposing two pieces of the same paper, the one to a feeble light—say at the back of a room facing the window—when it will take a long time to darken, and the other out of doors or in sunlight. Under these conditions it will be found that the former will partake of a somewhat cold or slaty tone, while the latter will be much redder. The stronger the light, as a rule, the redder will be the tint assumed by the paper in printing, whether it be exposed behind a negative or not. In the toning bath also the two papers will be found to act differently.

There is one point in connexion with printing which is frequently overlooked, or to which no importance is attached by many operators, namely, the hygroscopic condition of the paper at the time of printing. This very materially influences the colour which the print takes in the frame and also affects the after toning, which a very simple experiment will prove. Let a piece of paper be sensitised in the ordinary way and dried to a normal condition. Then let it be divided into three portions. Now place one portion in a damp situation where it can absorb moisture, and let another portion be made "bone dry" or crisp by drying it by heat, while the third piece is retained in its original state. If these three pieces be now exposed to light, whether weak or strong, taking care that their hygroscopic condition is not altered, it will be seen that they each take a decidedly different tint as they darken. If they be afterwards toned it will be noticed that they will all behave differently; the bone dry one will tone the slowest of all and will rarely go beyond an unpleasant brown stage without becoming mealy,

while the other two will both tone quickly, though one quicker than the other, and to a deeper tint, and without mealiness.

Some years ago cases containing chloride of calcium were introduced for preserving sensitive paper for long periods. This they did by virtue of the calcium salt absorbing the whole of the moisture from the paper, and retaining it in an exceedingly dry state. It was soon found, however, that paper kept for any length of time under this condition could not be readily toned, and that it also produced mealy prints, hence the cases soon fell into disuse.

The effect of moisture in the paper during printing was first brought under our notice some years ago, and was duly treated upon in the JOURNAL at the time, and quite recently it has cropped up again in two or three instances where toning difficulties were met with. We shall quote one case which is typical of each of the others.

During the past summer, in the printing establishment of a London house where the paper is sensitised on the premises, a difficulty was experienced in toning the prints, and when they were toned they were always of a dirty colour and usually more or less mealy. Particularly was this the case if the toning was carried beyond a very warm brown stage. Different samples of paper, sensitised under different conditions of the bath, were tried, and also ready sensitised paper, but to no purpose. From our past experience we at once suspected that excessive dryness was at the root of the trouble, and this proved correct. We found that the printing was conducted in a small building of wood and glass, which became exceeding hot during the day, and in this room the printing frames were kept when out of use, consequently they and their pads became thoroughly desiccated with the great heat and the unusually dry state of the atmosphere. The paper was sensitised in a small closet partitioned off from the printing room, and, of course, it was equally as hot and dry.

We suggested that a certain number of the printing frames should be transferred to a damp cellar and allowed to remain there, with their pads and backboards exposed to the moist atmosphere for the night, and that in drying the paper it should not be allowed to reach a crisp condition. This was done, and the prints obtained in these frames on the following day were of a totally different colour from those printed in the others. In the toning bath there was a wide difference in the behaviour of the two series of prints. Those printed in the frames which had been kept in the damp toned easily and assumed a rich and brilliant tone, while the others were, as usual, of a dingy brown colour, with a tendency to mealiness, according to the depth the toning had been carried. Indeed, these prints very closely resembled those which used to be

obtained with paper which had been kept in the chloride of calcium cases. In fact, the pads and frames had become so abnormally dry that they absorbed what little moisture the paper may have retained in the same way as did the calcium in the cases.

The difficulty often met with in toning ready sensitised paper may in some instances arise from its excessive dryness at the time of printing. In more than one instance we have proved this to be the case.

LA NATURE, in its current number, gives its readers an illustrated account of the photographic excursions of a society of amateur photographers which is of a highly interesting, not to say exciting, character. The particular object of the first excursion was the securing a number of negatives of subjects of especial interest requiring instantaneous exposures, and from the present account some considerable amount of success attended their efforts. The first subject was the photographing the firing of a shot in a stone quarry, 50,000 cubic metres of rock being disintegrated by the shock. An engraving, from a photograph, is given of the sight immediately after the explosion, the broken masses of stone and dust filling a vast space, while in the foreground, apparently in a post of considerable danger, is shown a plucky photographer just in the act of exposing a plate upon the falling mass. After science came amusement, and the assembly of amateurs next trooped off to the circus to a specially arranged performance, and tested the capabilities of their plates upon equestrian and other subjects of the *ménage*.

MR. VERNON HARCOURT's standard light has been experimented upon by a committee of the British Association; but in the report given it was clearly stated that the experiments have been insufficient in number, and that therefore another year would have to pass before they could place the standards upon a proper footing. Meanwhile, the Board of Trade have not been idle, and their chemist, Mr. Dibdin, has issued his report upon this light standard. He recommends the Board to take steps at once to secure the adoption of Mr. Harcourt's invention—the pentane air gas standard—as the legal standard of light in this country. If such a standard were adopted, and copies of the instrument employed in the various towns of the country, it would be a very simple matter for every photographer to have a gas-burner tested at ordinary pressure and standardised for his own town, as it were, for use in experiments with comparative exposures. Thus if a certain burner, clean and in good condition, were marked to possess at ordinary pressure so many candle power, it would, when comparing a plate with results obtained with a light of different power, be a simple matter of calculation as to what distance to place the plate from the burner, so as to subject it to conditions exactly similar to those the comparison plate experienced.

INDEED, seeing the great value any process would possess that would enable a photographer readily to test the rapidity of a plate for himself without investing in an expensive sensitometer, it is somewhat surprising that there are not standardised burners commonly offered for sale, standardised, that is, as to amount of gas passing through them. The quality of a gas in a particular neighbourhood would not be likely to vary so much from one time to another as to vitiate the practical value of the results, and the illuminating value could easily be found for any one burner. Pressure of course varies: though here, again, not to any important extent when it is divided into day pressure and night pressure. Its amount at any moment is roughly formed, almost in an instant, by slipping a piece of glass tube into a length of indiarubber tubing attached to a gas connexion. The tube is perpendicularly dipped some inches into a vessel of water and the gas turned on, when it will be found that the gas will not allow the water in the tube to come up to the level of the surrounding portion. The distance in inches between the two levels—the outer and the inner—gives the number of inches pressure of gas.

THE subject of gaslight naturally leads to electric lighting and lamps, a curious experience with regard to the latter having recently been made public. One of the drawbacks to the use of electric glow lamps

(of little value for portraiture, though most valuable for general dark room and other illuminating purposes) is the repeated need for replacement of the lamps after a certain period of use, on account of the deterioration of the transparency of the glass globes, owing to a deposit of volatilised carbon that usually takes place. A thousand hours is usually given as the maximum "life" of such a lamp, which in practice means, perhaps, the renewal twice or three times a-year of all the lamps in an installation—a very serious expense. But, as against the reality of this maximum, it is stated that in the office of the *Toronto Globe* there is now a thirty-two-candle Edison lamp, which has been burning full power five hours every night, six nights a-week, ever since the installation of the system in November, 1884. The lamp was guaranteed for six hundred hours, but is still burning with undiminished power after nearly five thousand hours service.

A new antiseptic agent, which should be of some value in photography, has been discovered by Mr. William Thomson, F.R.S.E., F.C.S. He was engaged in trying to find such a substance which was not volatile and was not destroyed by oxidation. He tried various chemicals on flour paste, and found that those bodies which had the most remarkable antiseptic properties were the compounds of fluorine—hydrofluoric acid, the acid and neutral fluorides of sodium, potassium, and ammonium, and the fluosilicates of those bases. He considered fluosilicate of sodium to be the one which, for its powerful antiseptic and unobjectionable properties, was best suited for the general purposes of an antiseptic. It is non-poisonous, possesses no smell, and is sparingly soluble in water. A saturated solution contains only '61 per cent., and yet has a value equal to that of a solution one part of bichloride of mercury in a thousand of water—a solution which hitherto has, perhaps, been considered the best antiseptic known for general purposes. It is, however, clear that its use is entirely inapplicable in a mounting medium, while the new salt should be of the greatest use in that direction. Thymol is a favourite chemical for this purpose, but its smell is by many considered a bar to its employment.

THE LATE JAMES G. TUNNY.

It is with grief that we record the death of Mr. James Good Tunny, of Edinburgh, which took place at his residence, 19, Salisbury-place, Edinburgh, at half-past six o'clock on Saturday morning, the 24th inst.

Mr. Tunny was one of the oldest and most advanced photographers in this country, having been professionally engaged in the art long anterior to the introduction of the collodion process. He invariably claimed that he practised this process previous to its publication by F. Scott Archer, and he always gave the credit of its discovery to Le Gray. It is worthy of notice that Mr. Tunny from the very first employed protosulphate of iron as a developer, as suggested by Le Gray, and this at the time when Archer was advocating pyrogallie acid as one of the features of his collodion process. At that time, over thirty-five years ago, Mr. Tunny had numerous pupils among the Scottish gentry, many of whom were imbued with the enthusiasm which characterised the master, who was thorough and enthusiastic in everything he undertook.

When the Photographic Society of Scotland was formed in 1856, under the presidency of Sir David Brewster, Mr. Tunny was one of its most active members, and continued to be so until its demise. During its life he contributed largely to its efficiency both by papers on practical topics and *vis à voce* utterances. He subsequently became a member of the Edinburgh Photographic Society and his name is at present on its list of Council. He was also one of the Council of the Photographic Convention, although, owing to his illness, he was unable to attend its meetings.

Imbued with a deep feeling as to the desirableness of having photographs absolutely lasting, he felt a keen interest in all such processes as were characterised by permanence, and in vitro-enamels in particular, in the production of which he ultimately acquired great success. His skill in his avocation as a professional photographer not only brought him fame but substantial emoluments, and on several occasions he has been enabled to indulge his tastes for travel in distant lands, having

visited many parts of the Continent, Egypt, Palestine, and America, a graphic and interesting account of his last trip, that to California and other parts of the United States, having been given to the Edinburgh Society a few years ago.

Within the last two years paralysis attacked his lower extremities and gradually extended upwards. We last saw Mr. Tunny on the occasion of the excursion of the Photographic Convention from Glasgow to Edinburgh, and it was evident then that he was sinking rapidly.

He was buried on Wednesday, and his remains were followed to the grave by a large number of photographic friends, some of whom came from a distance even so far as from London, to render the last tribute of honour to the memory of one who was beloved and esteemed as a straightforward, honest, fearless man.

In consequence of Mr. Tunny's desire that his funeral should be as quiet as possible, only a few invitations were issued. Nevertheless, a large concourse assembled at the grave, among whom were noticed Mr. Forgan (President of the Edinburgh Photographic Society), Dr. Thompson, Mr. and Mrs. Stuart, of Glasgow, Messrs. J. Cox (of Mason & Co.), Henderson (Perth), A. L. Henderson (London), Marshal Wane, Crooke, Howie, J. Ross, and others of the Edinburgh photographers, together with members of the Town Council. The coffin was covered with wreaths, noticeably one sent by Mrs. Duncan McLaren, and another from London friends.

ON THINGS IN GENERAL.

If any young photographer were to ask me what was the best reading of a periodical character likely to improve him in photographic knowledge, I should say at once, "Read THE BRITISH JOURNAL OF PHOTOGRAPHY, and pay special attention to the reports of the London and Provincial Photographic Association meetings"—succinct accounts of the speeches of men of mark freely parting with their knowledge to the general fund of information, the amount of practical knowledge thus conveyed is most remarkable. But this very succinctness is, I take it, apt at times to lead to misapprehension. Thus, according to last week's JOURNAL, Mr. England's observation that "to get more vigour with thin negatives he sometimes placed them where they would take a whole day to print, and thereby obtained contrast," was replied to by Mr. W. E. Debenham, who stated that his experience did not support the last statement. Now I feel sure here that the report does not do justice to Mr. Debenham. I believe him to be a large employer whose actual practice is in all probability in the dark room, if he handles his chemicals at all, and not in the printing room; but I shrewdly suspect that he has a practical knowledge of all his processes. Hence, when I read of him apparently denying the benefit to be derived from a mode of practice which I, for example, who have a large personal experience of (in common with most processes) practical printing, look upon as such an undoubted benefit as to be beyond possibility of cavil, I take it the report is too brief to give us the exact meaning of the discussion. Mr. Cowan's suggestion that comparative experiments upon the point should be made was an excellent one to disarm controversy, but I really don't think he believed it necessary to find out whether a weak negative gives a better print in sun or in shade; for that in effect was the condition well within meaning of the discussion when pressed to its ultimate limits.

I recollect, when a boy at school, my tutor telling me about the battle of Waterloo, that all three combatants claimed to have won it. Englishmen believed they in the main won it; the Prussians that they were the sole means of victory; while the French said that they were the victors but the British did not know they were beaten. To apply the simile to a much more modest affair, the writer of the letters over the signature of "A Painter" in falling foul of Mr. Redmond Barrett does not know when he is beaten, but I do not think any one else believes that he has not had a fall. I notice a week or two ago he passes the charge of audacity and hurls it at me. This is most unfortunate for him; he should have kept to his original resolve of silence, for I will quickly show that his charge of audacity is an impertinence only.

I go to see an oil painting and, for reasons to me quite satisfactory, but which I do not detail, I quickly come to the conclusion that the painting of the face is done over a photograph attached to the canvas.

I try to avoid giving my opinion, but the owner presses me and I give it. Observe, I come to a certain conclusion for reasons not given. In years to come one visible proof of the correctness of my conclusion is available, but even had such visible manifestations not been produced how can I be blamed if I do not give the reasoning that dictated my conclusion? I was not writing a treatise on painting. But while the subject is still under discussion we may just hark back to a question bearing on a topic of considerable interest to professional photographers. "An Amateur" asks "A Painter" (I presume a house-painter, from his lack of practical acquaintance with the *technique* of oil painting as used by artists) how oil paintings will become discoloured after the manner I described though no photograph underlie them? I will reply, as "A Painter" cannot. I spoke of the *faces* going black. As the picture was a three-quarter length the hands were presumably included in it as I did not mention them; they were equally presumably not blackened. Now a picture in which the face by selective preference discoloured, while the hands were all right, would be almost a miracle. Certainly the face might blacken if it were placed over the end of a stovepipe—a position unusual, to say the least—but the factors given by the painter would none of them effect that selective action.

The simplest and most frequent cause of all for blackening of the caruations is not mentioned at all by him. It is simply that oil paintings kept in the dark are very liable to spontaneously discolour, the remedy being to hang them in the light for a time. All that verbiage about second painting in three months' time, and bleaching of oils for five and varnish for ten years, has not the slightest practical value. It is little better than non-sense. Let my readers picture to themselves a varnish-maker starting business and waiting ten years before he sold his wares! Finally, this painter says, "But 'how to restore them,' I must recommend him to consult some works written upon this subject—for example, such as Field's *Chromatography*." I leave this subject by saying that, so far from Field's work being one on picture restoring, it is a work of over four hundred pages, of which one chapter of twenty pages only is devoted to picture cleaning and restoring!

Apropos of the new Act on merchandise marks, several times referred to lately, it appears to me that all concerned are treating it with such a *cœur léger* as to lead to the impression either that they are ignorant of its provisions, or that they are under the impression that it will be in effect a dead letter. As to the latter, I am in no position to judge, but my idea is that the Bill is one of the most far-reaching character that has been passed for many a long year. When it is considered that the man who sells photographic lenses, or microscopic objectives, or cameras, or dry plates, or collodion, or chemicals—subjects affecting photographers—not to speak of others who sell watches, clothes, shoes, antibilious pills, perambulators, cattle food, hydraulic pumps, and any other equally incongruous articles, and by simply placing his name upon them represents them as his own make, is liable to be sent to gaol if the article be not his own make, there is room to wonder at the calm way in which the Act is looked upon.

Mr. Briginshaw made a pathetic point when he described one of the properties of a roller slide being the power of inducing the photographer who employed it to cut his best exposure exactly into two halves, and every one must pity the artist undergoing such experience. Nevertheless, he did make a point, and one that wants attention being drawn to it. I liked, too, the reference to the perishability of enamel photographs being disproved by a cart-wheel. It reminded me of the photographer years ago who had just received a painted carbon photograph, and who showed it to a lady client. *He*: "This is one of the new process permanent pictures." *She*: "Is it?" and she stroked the face with a damp finger to try the permanency. Tableau!

FREE LANCE.

COLOURING AS APPLIED TO PHOTOGRAPHY.

THE materials upon which photographs are produced nowadays are, indeed, numerous, and numerous though they be they are daily being added to. An artist, therefore, who wishes to be successful from the point of photographic colouring must be prepared to work upon any base that may be offered to him. The choice in this matter very seldom falls to the artist.

* Continued from page 598.

Of course, the "*principles of painting*" never change, no matter what the substance we may be obliged to work upon, but the treatments as regards the application of the colour must necessarily be greatly influenced by it. Although the *principles* remain the same throughout, our methods of carrying them out must differ very considerably both in their application to the material we are working with as well as in the preparation of the material we intend to work upon.

Photographs intended for painting in water colours are usually printed on one or other of the following materials, especially when the subjects are large, albumenised paper being good enough for the very small work. First comes the *plain salted or arrowroot paper*, once very generally in use; then follows the carbons, Woodburytypes, and platinotypes; collodion transfers; opals, often called porcelains, and ivory. Photographs can be placed upon the ordinary canvas or upon Whatman's drawing-paper. The latest addition to the above is a newly prepared paper, only very recently brought into prominence, which promises to be useful alike to painters in oils as well as water colours. This paper is termed bromo-argento-gelatine paper, and which, I feel sure, has a great future before it.

These materials are generally only used when the most highly-finished work is required, or when the heads to be painted approach at all towards life-size. For all the smaller sizes, and where the highest finish is not essential nor permanency at all an object, albumenised paper is the most usual material used. The surface of albumenised paper has always been a source of trouble to the beginner. There is always a kind of greasiness about it; the colour will not run evenly or easily over it, nor will it dry uniformly; and, as if all these troubles were not sufficient, it adds the facility of coming away, or "licking up," when the brush touches it with a fresh "wash" or application of colour.

There are many ways of preparing the surface—such as a very little ox-gall mixed with warm water, or a regular sizing preparation can be bought which will not only serve the purpose of giving a desirable surface to the albumenised paper, but will facilitate the application of the colouring afterwards, in addition to adding to their natural brilliancy. All preparations of this kind should be applied to the photograph with a good sized *camel-hair* brush, care being taken to spread it evenly over the surface, and then allowed to dry thoroughly. Generally one application of this kind will be sufficient. Mr. Newman has made a preparation which not only prepares the surface, but will allow of a *second* wash of colour being applied without in the least disturbing the first. This, it is not necessary to say, is a very considerable advantage, as it will enable the artist to get a depth and transparency of colour he could not otherwise hope to obtain. It will mix easily with water, and possesses that most important quality of becoming insoluble when dry. The great advantages of this quality must be apparent to any one who has attempted to colour a photograph. There are many advantages attaching to the use of this preparation, one of them being that you can *mix it with the colour* and repeat one wash after another, as they each, when dry, become quite hard. The colourist is therefore enabled to procure a depth and transparency akin to oils, and rivalling them in brilliancy. The brushes used in this treatment should be washed before they can become dry, otherwise they may be considerably injured.

Plain salted or arrowroot paper is a very favourite material for working upon in water colours, as they lend themselves to the treatment. They have a "*tooth*," and receive the colour very kindly. Then it is a very fine drawing-paper, and retains, as such, the qualities requisite for easy colouring. One can almost always work upon this material without any preparation whatever, but occasionally it partakes somewhat of the quality of blotting-paper. Now in such cases it should be washed over with a size. The one mentioned above will answer the purpose, and may be applied as directed for albumenised paper. Sometimes there may be a little trouble in this regard, the paper being unduly absorbent, when a second wash of the size would be advisable before beginning work. This, however, can be easily judged by trying the corner of the paper with a little colour. If it adheres easily and does not sink too much into the surface, it is ready for colouring; if, on the contrary, it is still too absorbent, it will be found advantageous to repeat the application.

Often it will be found to be as well, before starting on the colouring, to gently wash the surface with a brush and a little clean water, and then dry it. This done, it will be ready for colouring, and you can start ahead with your work.

Carbon photographs are, nowadays, "the correct thing" for colouring. They have very many advantages over the ordinary albumenised print, foremost among them being its permanence. This, needless to say, is a very serious consideration when we are selecting a basis whereon to place valuable work. The ordinary albumenised print, unless most carefully washed (not as work is generally turned out nowadays), is a very unsafe base for such a purpose, for no matter how good the work or how skilful the artist who may have painted it, when once the photograph underneath begins to fade the picture is practically lost. There is no way out of such a trouble, as no amount of patching or restoring will stem the tide of destruction once it has set in.

All *carbons*, *Woodburytypes*, or *autotypes* are all photographs bearing a very close resemblance, inasmuch as they have each a gelatine basis. They have generally a smooth, shiny, and non-absorbent surface; some, however, are produced with a dead or matt surface, and also on Whatman's paper, and these are certainly the most preferable. These latter are, however, *special*, and not the ones most likely to be handed to you by the photographer for colouring. I have not worked upon many Woodburytypes, and I may here say that I have no particular desire to do so.

The *platinotype* process produces, to my mind, very beautiful results. The surface is very pleasant to work upon and takes the colour very satisfactorily, but, all things considered, they are best for working up in monochrome. There is a certain coldness of tone pervading all platinotypes, which, however beautiful it may be in itself, must necessarily make them objectionable from the point of painting in water colours. Of course, for oils it is much less material than in water colours, as the black shadows can be so much more easily obliterated. It is very difficult to get life and warmth into the shadows, they are so cold and black. Of course it can be done, but it will entail considerable labour on the artist, and in most cases force him to the doubtful expedient of using body colours. This would be more or less a misfortune. Of course everybody has an *opinion* on this subject, and some stronger than others. Personally, I must say I prefer *pure colouring*, and as transparent as is possibly consistent with the painting of a picture, to the wholesale or even preponderant use of opaque or body colours. I have seen some very fine examples of both kinds of water-colour painting, as regards portraiture, and on them have based my own opinion. The paintings which recur to me while I write these lines I saw in Paris some years back, and were painted for M. Nadar, père. I have never since seen their equal. They were life-size, head and shoulders, but they really looked *alive*. There was one of M. Nadar himself, and any one coming hastily into the studio would think the living man and not the picture stood before them. M. Nadar, too, was a most difficult subject to treat with anything like success.

Although rather unfavourable for water-colour painting, as I said before, they are admirably adapted for working up in monochrome; they are so cool in tone and so grateful to the eye. If, however, you are obliged to paint on them, or even finish *very highly* in monochrome, I would recommend the passing of a "*sizing preparation*," such as I before mentioned, over the entire surface before applying any *colour*. Although platinotypes have a good surface for working upon, the paper is somewhat *too* absorbent for water colours without the application of a sizing preparation of some kind or another. But this done there is nothing more required to produce a perfect result in either direction but ability. It would be a great boon if this, like the "*sizing preparation*," could be bought in a bottle.

Porcelain, opal, or pot metal.—For the best class of water-colour painting and working in monochrome (up to a certain size) this material is quite the favourite of the present day. There are two kinds of it, smooth and plain. The former possesses the necessary qualities for working almost without further preparation, but for the latter the photograph must be taken on a collodion film; it is then varnished with a matt varnish, which imparts an absorbent surface to the picture as though it had been ground or smoothed by hand. A great quality with these porcelain pictures is the purity of the whites,

This alone will ensure brilliancy when placed in skilful hands, and give every facility for pure colouring.

Collodion transfers are almost entirely used for finishing in oils. They are simply collodion films transferred to paper. I have no doubt that all the readers of the JOURNAL have seen some very dreadful examples of this class of work. I also feel sure that very few of them will ever aspire to practise this particular line of photographic colouring.

Ivory is also a basis both for carbon and collodion photographs. In some cases the photograph is printed direct upon the ivory, but generally there is a carbon film placed upon it, as in the case of the porcelains. It is something difficult to secure the pureness and transparency of the plain ivory, but it can be very nearly arrived at by printing in red and rubbing down until you get the desired effect. Should the surface work at all greasy, give the entire surface a wash of weak ox-gall.

The *bromo-argento-gelatine paper* is a material only recently come into prominence, and is more generally used for finishing in oils rather than water colours. When used for water colour a sizing would be advisable.

Photographs are also made on *canvas*, drawing-paper, and, I may say, almost any material of suitable colour can be used as a base for a photograph.

REDMOND BARRETT.

(To be continued.)

SUPERIOR WORKMANSHIP.

THE letter of "H. A. S.," under the above heading, in a recent issue, does not appear to have elicited any information as to whether the experiences of that gentleman's brother amateurs, "of what is advertised as 'superior workmanship,' runs upon all fours with" his. This is rather strange, such complaints being common, *videlicet*, just now. One would have thought that the opportunity of ventilating a grievance of this nature would have been readily seized by many who, like "H. A. S.," have no redress but the discreetly curtailed publicity of a professional journal. They appear, however, to prefer suffering in silence, which is philosophical, but not calculated to mend their wrongs.

One can sympathise with "H. A. S." in being cursed with such slides as he describes. At the same time, he must admit that some portion of the blame should be awarded to himself; for an amateur who has satisfactorily worked a certain camera for several years, and then "in an evil moment," for the sake of a few ounces in weight, exchanges it for one of which he knows absolutely nothing, can have less cause for surprise than disgust if he meets with the annoying experiences detailed by "H. A. S." If I were Mr. Hare I should say, "Serve you right." But there's a providence in all things, and "H. A. S." has learned a useful lesson, at a handsome price. In an article entitled, *The Camera in the Field*, that appeared herein on August 26, I devoted a few critical lines to these "much advertised light cameras," and I stated "that actual experience proves that for every ten men who could make a good camera not one turns out a reliable dark slide." The letter of "H. A. S." bears out that statement, point for point, with singular emphasis. I did not think I should so soon have such a splendid confirmation of what, to the uninitiated, must appear almost paradoxical, and I hope I may be pardoned for metaphorically shaking hands with myself.

The war in these pages between the old style of camera and the new must, I suppose, of necessity be decided without editorial intervention. Neither "H. A. S." nor anybody else would, I opine, desire to cast the mantle of Photographic Mentor to all and sundry on the heavily burdened shoulders of the present occupant of the Chair. If such were done life in York-street would be simply frightful. Still "H. A. S." and his brother amateurs need not be victimised with their eyes shut. I trust few are so unwise as to remit for such an important article as a camera, whose acquaintance they only make through the advertisements—from which even manufacturers themselves allow us to deduct a good discount. It is unfair to vendor as well as purchaser. This was the second mistake of "H. A. S." (the first being the exchange of an old lamp for a new one); the third was that he did not test the camera and slides before going abroad. He should have inspected them before purchasing, or got a friend or a dealer to do so for him. "H. A. S." seems to have been at fault all through, and it is to be hoped that others will be warned by his mistakes.

Everybody admires these light cameras, but their ingenuity is wasted and their extreme portability and lightness are only arrived

at after a deplorable sacrifice of strength and simplicity of construction. That they are durable remains to be proved. "H. A. S." confesses to have had his Hare several years. I take leave to doubt whether any one of the light brigade will ever earn such praise. Reiterating the opinions expressed in the before-mentioned article, I question the practical efficacy of many of the new movements; I deny that any number of so-called improvements, patented or otherwise, compensate in any degree for the most trifling fault in construction, and I refuse to believe that a trustworthy instrument can be made by machinery. In short, I maintain that the form of camera of which that alluded to by "H. A. S." is the accepted type, is, with the single exception of lightness, in all practical respects the equal, and in many the superior, of all the race of what "H. A. S." designates the "much advertised light cameras." Amateurs who contemplate deserting a camera that has served them well for several years—as in the case of "H. A. S."—should look before they leap. That gentleman did not; hence his bad fall.

MARSTON MOORE.

RECOLLECTIONS OF EARLY DAYS IN PHOTOGRAPHY. II.

THE photographic studios very soon became numerous and caused a great stir among the trades that attempted to supply the increasing demands for frames, &c., and among the manufacturing opticians who undertook to produce lenses that would make sharp pictures and reduce the time of exposure. These difficulties were not overcome so long as the Daguerreotype held its sway. The glass used in making the lenses was partly of flint and partly of crown, and the method of obtaining the specific gravity of glasses was at that time unknown to the ordinary working optician.

Would it be out of place to cite an accident which occurred to a manufacturer of object lenses for opera glasses in Paris about this time? He was very neat and particular in his grinding and always turned out the best quality of opera glasses. I employed him to make for me, as a venture, one dozen quarter portrait lenses, double combination, which he thought he could do as he happened at that time to have a stock of both crown and flint glasses perfectly adapted for this purpose.

He soon made twelve of these instruments, that could not be surpassed for quickness and sharp definition. I sold them without trouble, and thereafter continued to give my increasing orders. The price I placed upon these lenses was twenty shillings each, and Andrew Ross, hearing from others of this extraordinarily cheap and good lens, obtained one from me and was quite surprised to find that the lens was all that was claimed for it. I had sold, up to this time, about one hundred of these lenses and was continuing to give my orders for them in large quantities. A batch soon arrived from Paris, however, and was tested (as every lot of lenses was before being placed upon the market), and to my surprise they were found to be greatly inferior in quality to those which I had previously had from this glass grinder. I wrote to my friend and found that a great accident had happened in his shop. He kept his glasses in two cupboards: one containing all of the discs for my quarter lenses, and the other the lenses for his opera glasses. An apprentice, who had been ordered to dust each cupboard, had gone beyond his order and taken the lenses from the two cupboards, and in the confusion of dusting had mixed them, so that when the workmen, who were ignorant of the density of glasses, attempted to make the combination they used the discs recklessly, just as they happened to come, without regard to their specific gravity or other differences. The result was that I could obtain no more correctly made lenses until he had obtained from a scientific optician the specific gravity of the mixed discs and had them placed in their proper cupboards again.

Scientific opticians were not numerous at that time, and when, in 1851, the great Universal Exhibition was held in London, I introduced M. Buron, of Paris, to Andrew Ross; but M. Buron could not speak English, nor could Ross, French. Soon after M. Buron took a pencil and presented to Ross a paper with some geometrical curves and lines with explanatory algebraic letters inscribed thereon, which Ross seemed to understand and answered by another with similar curves and lines. Both seem pleased; but I do not know to this day what those hieroglyphic marks indicated to those two men.

Some three months after the Great Exhibition of 1851 was opened, an old acquaintance, a lithographic artist of Paris, sent to the Exhibition about four photographs on paper, printed from glass negatives of about $8\frac{1}{2} \times 6\frac{1}{2}$ in dimensions. These were the only paper negatives in the entire Exhibition, and public curiosity was naturally aroused at their appearance.

Public curiosity was again excited by the first stereoscopic pictures

taken from natural objects by the clever Parisian optician, Dubosc. Sir Charles Wheatstone, the inventor of the stereoscope, which in form resembled the graphoscope, was a customer of mine some years before he died. He came to my house a few weeks before he went to France, and complained to me that his invention of the stereoscope had not been done justice to by the firm to whom he had entrusted the model. He said he had also invented something nearly allied to the stereoscope, but which showed a most pleasing and amusing optical illusion. When he returned from France, he said, he would reveal the secret to me, and bring it before the public; but, unfortunately, he never came back to England.

Dubosc invented the general form of the stereoscope as now used, but he did not benefit himself by the invention. He was the first to show that small-sized photographs could be enlarged, and I was shown by him the first enlarged photograph which he had made from a small glass image—the light used coming from an electric lamp of his own invention. The Exhibition closed to the public, and only purchasers of goods from the Exhibition when it was opened, and the owners and packers of goods, admitted. Dubosc sent to an agent in the palace stereoscopic pictures taken from natural objects on Daguerreotype plates. I was the first to whom the pictures and stereoscopes were shown, and I agreed to take all that he received at six francs each, and also pay for the stereoscopes. The agent tacitly agreed to sell all to me. Prince Albert visited the Exhibition daily, and the agent showed him the pictures. The agent did not keep his agreement with me, but sold the pictures and stereoscopes to the Prince and Queen.

But I soon found a very clever Daguerreotype artist named Laroche, of Oxford-street, London, for whom I purchased statues and other plaster of Paris objects, which he reproduced for me in stereoscopic slides. He soon became very clever in stereoscopic portraiture, and I have now two coloured portraits quite free from any fading and very artistic, which were made by him at that time by the stereoscopic process.

Laroche became quite prominent in Daguerreotype portraiture, and his ambition urged him to produce portraits by photography on collodionised glass. Talbot opposed his productions because they infringed his patent, and a meeting was called to aid Laroche in his opposition of Talbot; but the final verdict was partially in favour of Talbot. The public, however, was so strongly opposed to Talbot that he was obliged to yield to its opinion, and soon gave up all his rights to the public.

At that period the lenses which were in highest favour were those made by Voigtländer, although these lenses never gave correct images because the chemical and optical rays were not coincident. The eminent optician, Andrew Ross, soon used his knowledge to produce lenses perfect in this respect. Soon after, a young German, Dallmeyer, entered the employ of Ross, ultimately marrying his daughter, and, after the death of Ross, was taken in as partner of Thos. Ross, son of Andrew Ross. The two, however, soon quarrelled, and a separation of the firm took place.

In 1848 another great discovery in photography excited public curiosity. Schoenbein had made a very explosive compound from the innocent article of cotton wool. It was claimed that warfare would be entirely changed through this invention, but then a man named Maynard, of Boston, dissolved the gun cotton with ether and spirits of wine into a liquid jelly, and when dry the particles were found to be very valuable for surgical use in covering wounds. M. Le Gray, of Paris, a rising and clever photographer, gave it as his public opinion that this substance could be made serviceable for photographic purposes.

In the month of February, 1851, F. S. Archer, of London, first published in *Notes and Queries* that he had sensitised collodion, and had succeeded in pouring it upon glass on which he could make pictures. This new advance in photographic manipulation was at first scarcely successful in attracting photographers, who then, as now, were very slow in adopting new methods, however improved or worthy of acceptance they might be. Soon, however, the tide began to flow in the direction of collodionised glass plates.

In the year 1853, on my return journey from Scotland, I stopped at Newcastle-on-Tyne, and called on Mawson, a druggist, who had commenced supplying photographers with requisite materials, and among other articles I showed him a student's microscope. A young chemist, at that time an assistant to Mawson, showed him, by the aid of this microscope, the structure of collodion. Thomas, a druggist of Pall Mall, London, was one of the first who followed Archer in the manufacture and sale of collodion, and it was generally reported that Professor Pepper, a clever lecturer of the London Polytechnic Institute, gave the best method for producing a good-working collodion that immediately rose in reputation, and realised for Thomas a large

fortune. Mawson took into partnership his young chemist, Mr. Swan, and the firm of Mawson & Swan became the largest manufacturers of collodion in the world.

The London King's College had a most excellent professor of chemistry, Rev. S. T. Hardwich, who was a very ardent lover of photography. He published many excellent notes on any new discovery that aided in producing photographic pictures. In this he emulated the example of Hunt, of Cornwall, who was the founder, I believe, of the Falmouth Technical Institute, and who encouraged in every way the growth of photographic knowledge. Unfortunately for photography and science in general, Mr. Hardwich entered the Church, and is at present one of the hardest workers in Durham county.

Thomas Sutton, editor of *Photographic Notes*, followed Hardwich as professor of chemistry at the college for some short period. Sutton was a personal friend of mine, and we passed many agreeable hours together. He was most virulent when writing in opposition to an assailant, but in conversation one of the most attractive men one could meet, and was ever ready to help any photographer out of a difficulty. He was the inventor of the panoramic lens. Thos. Ross manufactured the lenses and cameras, and the pictures were good, but the dark slides were made to hold bent glasses. This difficulty stopped its success. Sutton lived in the Island of Jersey, from where he issued his journal, *Photographic Notes*. I will now relate the difficulty which the changes in photographic manipulation occasioned Daguerreotype artists in India and other colonies of Great Britain.

My friend, Frederick York, the eminent photographer, lived at the Cape of Good Hope. He was by trade a chemist and druggist, and went to the Cape of Good Hope to become its chief Daguerreotype artist, but when the change obliged him to adopt the collodion process he obtained, with great difficulty, the necessary chemicals. In 1854 he was obliged to redistil ether from an acid article imported from Holland—being only used for medicinal purposes—that, when it was made into collodion and iodised, it turned the colour of the collodion to that of port wine. Spirit of wine had to be redistilled also from a Cape brandy called Cape Smoke. Iodide of ammonium and pyroxyline he had to make also. All these difficulties placed in contrast to the present easy way by which photographers produce their pictures, emphasises both conditions by the contrast. Another great difficulty in collodion pictures in the colonies was that no ship would convey collodion on account of its easy combustion, so that collodion was only accepted by certain ships which carried gunpowder. Some ships took collodion as deck cargo, and on the most trifling accident occurring, the whole cargo was thrown overboard. J. SOLOMON.

(To be continued.)

LANDSCAPE: CHOICE OF SUBJECT.

A GREAT deal has been claimed for the extraordinary range of art, "from the hues of a cabbage leaf to the sufferings of a Christ." "Nay, there is nothing that man has ever dreamed, or hoped, or feared, suffered, enjoyed, or sinned in, which is not a subject matter for art," says Mr. Quilter, one of the most acute art critics of our time. But all who practise art must appreciate the limitations of the particular department of art which they practise. The painter in oils has the widest range, and an almost unlimited choice of subjects; the water colourist has a narrower scope, so also has the sculptor; but shall I be wide of the mark when I say it is left for the photographer to show the greatest ingenuity in the choice of subjects in which to show his skill as an artist? The photographer should try to understand, and be satisfied with, the limitations with which he is "cribbed, cabined, and confined," and endeavour to turn them to his use, or rather find in the very limitations a certain fitness and use, because it clears away a vast number of impossible subjects, confines his study in a narrower groove, and enables him to give more complete attention to "the things that are his." Do you get a glimmer of my meaning?

We are in the habit of claiming for photography an unlimited range of subjects, from the infinitely little to the infinitely remote; from the microscopic diatom dredged up from the depths of the ocean to the infinitely remote nebulae in star-packed space; but there are some things that may be possible which are yet unaccomplished. We may say we have no more worlds to conquer, but we talk like Alnascher.

In landscape photography, which is our present subject, there are one or two things that have not been done. For instance, have you ever seen a photograph in which one very common fact in nature is adequately represented? I mean the effect of storm and wind on an island landscape. I say island, because such effects are easy in sea pictures. The effect often seen in pictures by Salvator Rosa and

Gasper Poussin. The bending and swaying branches of the trees, the driven sky and the fluttering garments of the figures. The effect of wind is, unfortunately, too often to be found in photographs, always to the disfigurement of the picture, but no "lightning" or "special instantaneous" plate has yet been made that would enable us to do justice to the grand and pictorially fit effects I have suggested.

Then, again, I have never seen a photograph that gave me any proper idea of a mountain. Photographs of the Alps always remind me of toy mountains, and I want to see a child's Noah's Ark on the highest peaks. Perhaps it is because we nowadays make such fun of what were once inaccessible solitudes. We go up Ararat on a bicycle instead of waiting for the orthodox flood, as Noah did.

There is another effect that has never been quite properly captured. In a mountainous country when the sun has set to the observer it still shines on the mountains. The effect is often one of the most beautiful in nature, but the non-actinic colour of the sun's rays at that time of the evening has hitherto prevented anything like success in photographing this subject. As Milton says:

"Yet from these flames
No light, but rather darkness visible."

However, this is a difficulty that may soon be added to the many conquered in the past. Orthochromatic plates will solve this problem, and when you have obtained a really fine example of the effect, here is a title for it (there is a good deal in a title) from Tennyson's new *Locksley Hall*, but make the pictures worthy of the line:

"Cold upon the dead volcano sleeps the gleam of dying day."

This reminds me of another important thing. Never give your picture a title it cannot support. I like good titles. I don't mind even if there is a bit of sentiment, so that it is healthy in them, and the boundary between the sublime and the ridiculous be not overstepped, but beware of anything in the nature of an anti-climax. If you have a picture in an exhibition and the spectator, before seeing your poor little work, reads an ultra-poetical title, with perhaps a verse attached to it in the catalogue, his expectations will be so raised that when he sees the picture he may feel a cold fit of disillusionising pathos come over him that he may remember against you for some time.

While I am talking of titles I may just add an illustration of how it is possible to go wrong in naming even the simplest subjects. I am told that the cows in the photographs of which I gave a reduction in my last letter were not cows at all, but are what are called in Scotland "stirks." I am quite aware that the natives of that far country, with an independence which is perhaps praiseworthy but slightly puzzling, call things by names beyond the comprehension of other parts of the world, yet I believe I am almost wrong in calling these animals cows. Some of them may attain the dignity of cowhood just as some girls become women.

Now for subjects that are possible.

It is a true saying that each student must discover for himself what is beautiful. It is not every kind of scene that appeals to the feelings of all alike. Some of us delight in particular kinds of landscapes, some like grandeur, others are content with quiet simplicity. "Each of us is constituted," writes Mr. Hamerton, with, perhaps, not a few verbal impediments, "with a special idiosyncrasy related in some mysterious way to a certain class of natural scenery, and when we find ourselves in a scene answering to our idiosyncrasy, the mind feels itself at home there, and rapidly attaches itself by affection."

The student may be guided in his search for beauty, but it is not wise in a teacher to persist too strongly on what is picturesque or the reverse. Many painters will make good pictures out of subjects which would seem to be quite inadequate to others. Many of the greatest landscapes are of the most ordinary scenes. What could be more commonplace than the scenery of Gainsborough's *Market Cart*, Turner's *Frosty Morning*, or any of the pictures by De Wint and David Cox?

—*Photographic Times*.

FILM NEGATIVES.

[A Communication to the Birmingham Photographic Society.]

HAVING had a certain measure of success with Eastman stripping films, I have been requested by your Council to give a paper this evening dealing with the subject, and particularly with the method of working which my experience has found most successful. In according to their request I feel I have imposed upon myself a somewhat difficult task.

There is, undoubtedly, a strong prejudice in the minds of most photographers, both amateur and professional, against a negative in which paper is used as a permanent support, on account of the in-

separable "grain" and lack of brilliancy in the resulting prints, and the idea of the paper being used only as a temporary support does not seem to convey to their mind a correct impression of the true position of the matter.

It may be as well before entering into the technical details of the manipulation to consider briefly the advantages to be derived—which will be better appreciated after an actual trial.

My experience (which is at present limited) is that they are far superior to glass for all purposes except portraiture of the human form or instantaneous pictures where extreme rapidity is necessary, but for all ordinary cases of rapid exposure they are sufficiently quick. The first advantage, which I soon discovered, is their entire freedom from halation. This with glass plates is inseparable, and even when much labour has been bestowed on backing them the halation is painfully apparent.

These films never frill, being made of emulsion which has been made insoluble. Compare the respective weights of the two substances—one plate weighing more than a dozen films of the same size.

Again, on comparing a stripping film negative with one on glass of the same exposure and subject, it will be found there is a greater sharpness or clearness in the detail owing, I am of opinion, to the paper absorbing the light immediately it has penetrated the emulsion, the result being a brilliant negative. Landscapes on stripped films can be retouched or printed from on either side, and the advantage in this respect for carbon or mechanical printing is enormous.

Now imagine the tourist working with glass, and compare him to another working with films. The one works in harness, tugging, probably, a half-hundredweight of glass with him from place to place, paying extra carriage, extra tips, and in a continual state of anxiety as to possible breakage, difficulty of packing, and having to be continually on the look out for a dark place to change the plates, and, perhaps, on his return finds numbers of his plates damaged owing to friction on the surface; while the disciple of films, lightly burdened with only camera and slide, and his (say, 200) films in his pockets, for they lie so compact together. Then the advantages to the tourists abroad their name is "legion," not the least being the ease of guarding your exposed pictures from the custom-house officials, who almost always seek to make matters disagreeable in this respect; and lastly, though not least, the ease with which the negatives can be stowed away in envelopes or albums, &c., when reference to them is easy in the extreme.

Now, having come (rightly, I think, you will admit) to the conclusion that films have these advantages, you naturally ask, What are its disadvantages? Remembering, then, that I am only advocating stripping films, I consider they have but two disadvantages:—1st, They entail some additional outlay in the way of apparatus, &c. 2nd, They are a little more trouble to finish than the glass negatives, which sink into insignificance when the manifold advantages are considered.

I will now show how I work the roller slide (Eastman I use and prefer), and also note the indicator I have had made by Mr. Place, showing the exact position of the paper before and after exposure. My friend (J. H. Pickard) has fixed one on his slide which shows in addition the number of films exposed (automatically). I also show here the film carriers for the cut sheets. A substitute for these can be made of a piece of thin wood, and springing this strip in your dark slide over the paper and exposing in the usual way. The cut sheets can be used also in Pumphrey's and other changing slides. There is one fault, if it may be called a fault, for it lies more at the door of the operator and not the films or slides, viz., the number of exposures. Surely there is no necessity to expose twenty-four films in an hour or so because you have the power to do so.

In order to deal effectively with the second objection I mentioned, viz., the extra trouble and perseverance, I propose, with your permission, to carry a negative through the different stages from exposure to completion, and in so doing I shall endeavour to make the process clear to you, and hope to enlist your attention.

The developer I use is slightly different to that of the Eastman Company, and is as follows:—

A.

Sulphite of soda 4 ounces.

To be dissolved in 8 ounces of hot distilled water, then rendered slightly acid with citric acid, then add—

Pyrogalllic acid 1 ounce.

Water to make up to 10 ounces.

B.

Pure carbonate of soda 1 ounce.

Water to make up in all to 10 ounces.

C.	
Pure carbonate of potash	1 ounce.
Water to make up to 10 ounces.	
D.	
Bromide of potassium	1 ounce.
Water to make up to 10 ounces.	

I have here two half-plate films exposed at 8.30 a.m. to-day, one with five and one with six seconds exposure, subject chiefly middle distance. I take 90 minims A, 10 minims D, and 90 minims B, and make up to 2 ounces water. I do not soak the films in water. There is no need for it; in fact, it is prejudicial to do so. I place the films face uppermost in the dish, and pour on the developer on the centre of the films. You will observe they lie perfectly flat, and are free from air bubbles. Rock the dish continually during development, and when the high lights are out add from 10 to 90 minims C, and finish development and fix. The negatives being complete, I ask you to observe that both are of equal quality, proving the latitude of exposure permissible.

I now coat a piece of glass half an inch larger all round than the negative with indiarubber solution (see Eastman formula) and squeegee the negative face downwards upon the rubber, interposing a sheet of blotting-paper and oiled skin between the negative and squeegee to prevent injury to the exposed rubber surface, and then place the negative under pressure with blotting-paper interposed until moderately dry only.

I then pour hot water upon it, and gently rocking the dish you see the paper floats from the film without the necessity for pulling it with a pin, leaving the film negative on the glass. Now the instructions say remove the remaining soluble gelatine with camel-hair brush, but unless it requires intensifying, which no properly developed negative should require, you need not do so, but simply pour on the gelatine solution (see Eastman formula), well covering the edges of the film, and put on a level shelf to dry.

I will now take up a negative in this state on the glass, but dry, and carefully cut round the edges of the film, and you see I can readily pull off the film with its gelatine support. Having now passed through the whole of the process it behoves us to consider for a few minutes the causes of failure in the hands of beginners and their remedies. 1. The rubber will not flow over glass?—Solution too thick, glass greasy. 2. Rubber peels off on drying?—Dirty glass. 3. Negative not dense enough?—Use more bromide and longer development. 4. Gelatine cracks on being pulled off?—Add more glycerine. 5. Gelatine not thick enough?—Gelatine varnish too thin, not strong enough. 6. Does not dry sufficiently hard?—Too much glycerine.

E. H. JAKES.

ON THE FADING OF SILVER PHOTOGRAPHS.

III.

WE have already seen (page 553) how sulphur or sulphurous compounds may be communicated to and left in the silver prints during the ordinary course of their preparation. It is not my purpose to enter into details as to the best means of avoiding these pitfalls in practice, inasmuch as the principles which should guide the operator are now so well known, or ought to be, that any shortcomings in this respect must be discredited to sheer ignorance or culpable laziness. When any doubt exists as to the thorough washing of a batch of prints, a very delicate and easily applied test should always be called into requisition. This test is iodide of starch, made by adding a few drops of tincture of iodine to a thin solution of starch; sufficient iodine being added to confer an intensely blue colour. This test solution will keep in good condition for a long time if some camphor dissolved in alcohol be mixed with it. When the prints are supposed to be thoroughly washed, take a few of them from the last washing water and collect the last drops of the drainage from them in a clean test-tube, a similar tube being filled to the same height with fresh water from the same tap. Now add to each, say, two drops of the iodide solution, and watch the result. If the colour in the tube containing the print droppings is discharged or lessened in depth when compared with the other, the hyposulphite has not been completely removed from the prints. This is a very delicate test, and one which, I think, ought always to be applied.

Indeed, so far as the preparation of a silver print is concerned, the complete elimination of sulphurous or other injurious and soluble compounds is entirely within the photographer's power, with only one exception, and that is the existence of deleterious substances in the unsensitised paper with which he has to operate. Here he is at the mercy of the paper maker and the albumeniser. With respect to the latter, I need hardly say that the article supplied by him should never

have been tainted by decomposition, else a sulphurous silver compound, with the liberation of acid, is the inevitable result as soon as the albuminous surface comes in contact with the sensitising bath.

The next danger that the silver print has to encounter is in the mounting. If the mounting boards are suspected of containing a trace of the anti-chlor hypo, a portion of one should be macerated in pure water and some of the supernatant water tested with a drop or two of the usual iodo-starch solution, just as was previously recommended for the washed prints. I have not had occasion lately to test the modern mounting boards, but I know that some years ago many of them, especially the larger sizes, contained more than traces of hypo, so much so that "look to your mounting boards" became a cry of warning among photographers.

The next danger arises from the nature of the mountant or adhesive material used in attaching the prints to their final support. Starch paste is frequently employed for this purpose. The great objections to its use are its tendency to turn acid when the prints are exposed to a damp atmosphere and also to generate the starch fungus which, when once originated, overspreads the whole surface and is fatal to the prints.

Common glue contains many injurious impurities, and, although frequently employed as a mountant, is certainly open to grave objections. The finer kinds of gelatine may, probably, be used with impunity if, in the presence of moisture, they can be preserved from decomposition, still it is doubtful whether a slight decomposition would exercise any baneful influence, unless sulphur or acid be liberated.

But, of all mountants, I must give the preference to the best white gum arabic. A solution of this, of the proper consistency for mounting, is colourless, possesses great adhesive properties, may, by the addition of a little camphor, be kept fresh for a very long time, and is not liable to decompose, but, should it undergo change, it liberates neither free acid, sulphur, nor anything detrimental to a silver print. These, in my opinion, are advantages which should recommend its general adoption, even although its price (5s. per lb.) may, at first glance, seem a deterrent.*

Yet, when we consider the immense number of photographs which a pound of this gum would attach to their mounts, the additional cost of each mounted photograph would only be the fraction of a farthing. I am the more impressed with the importance of giving great attention to the securing of an inert mountant from the fact that, in the course of last autumn, I had occasion to examine very closely some photographs executed by Talbot in 1845. These were cemented to the mount only for about an inch along the edges. The portions of the pictures over the cement had almost entirely faded away, while the uncemented portions retained almost their pristine vigour.

I shall now conclude this short series of articles with a summary of what I consider the essential conditions required for the utmost longevity of auro-argentic photographs:—1st. That the photograph itself and its supporting medium should contain neither sulphur nor easily decomposed sulphur compounds. 2nd. That they should contain no free acid, nor any substance liable to generate it. 3rd. Silver prints should, when practicable, be kept in dry positions and protected from the action of impure air.

With respect to the latter point, I know of no easier and more efficient plan of securing this end than that fully described in a recent editorial article in this JOURNAL (page 561). The only improvement I would suggest on the method there described, would be to finally squeegee the back of the print with a solution of alum which would render the paper, to a great extent if not altogether, waterproof, and thus enable the print to resist successfully the influence of any noxious substances which may exist in the place of storage.

GEORGE DAWSON, M.A., PH.D.

THE ECONOMICAL PRODUCTION OF OXYGEN.

WHETHER there would be a large market for oxygen for use in industrial operations could it be supplied at a reasonable rate, is a question upon which a long debate might be raised; still it cannot be open to doubt that for many small operations it would find extensive

* Some difficulty may be experienced in obtaining the genuine article. The sample I have been testing was obtained from the firm of H. Cooper & Co., 24, Greek-street, Soho, London. It was made up into paste by a formula kindly furnished me by Mr. Ayers, who invariably uses it in his own practice. He showed me some of his stock, which had been kept in the fluid state for more than two years, and which still retained its good qualities unimpaired. The following is his formula:—

The best white gum arabic is dissolved in water sufficient to make a mucilage of the proper consistency. To this are added one ounce of lump sugar for every four ounces of gum used, and also a piece of camphor, both being anti-septics. The sugar also has the property of rendering the gum tougher and more elastic when dry. Gum contains no sulphur.

application. In a future article we shall endeavour to enumerate some of the uses to which a cheap supply of oxygen could be put, and from which it will be easy to see that the ordinary processes at present followed in laboratories are altogether out of the question.

The method usually followed for oxygen preparation in the laboratory, and even for oxyhydrogen work at theatres and the like, is to heat a mixture of chlorate of potash and peroxide of manganese, by which means oxygen is given off from the chlorate, the manganese remaining practically unchanged. The decomposition may be shown by the following formula:—

1000 cubic feet of pure oxygen weighs 89 lbs., so that allowing for manufacturing losses, 1000 cubic feet of oxygen would be produced from 245 lbs. of chlorate of potash, which would not cost the user less than 7d. per lb. at his works, making the cost of 1000 cubic feet of oxygen about 7l. 3s. Of course we should have the chloride of potassium remaining as a by-product, but this, even when refined to a white marketable salt, would not be worth more than 18s., the total amount of which would be swallowed up in the fuel, wages, and plant account. It will thus be seen that the industrial production of oxygen from chlorate of potash is, on account of its cost, practically impossible.

The next process by which oxygen has been prepared is by heating ordinary native peroxide of manganese, when the following decomposition takes place:—

or, in other words, supposing the decomposition to be complete, which it never is, it would require half a ton of 70 per cent. manganese to produce 1000 cubic feet of oxygen.

By reference to our prices current, this quantity of 70 per cent. manganese would not cost less than 25s., so that it becomes necessary to recover the manganese if there is any life at all in the process.

In order to increase the yield of oxygen from peroxide of manganese, and to enable the decomposition to take place at a lower temperature, it has been proposed to mix silica with it, when the following reaction is stated to take place:—

That is to say, it would take 7 ewt. of 70 per cent. manganese to produce 1000 cubic feet of oxygen, costing for raw material alone 17s. 6d. It is very probable, however, that this reaction would not take place so readily as the equation indicates, and the utilisation of the manganese silicate would perhaps not be so easy after all.

Another process has been much praised, but we believe it has never been put into general use, though patented by Kirkpatrick on May 6, 1870, No. 1300. By this method a strong solution of bleaching powder is treated with about three parts to the thousand of hydrated peroxide of cobalt, or of a cobalt solution; this determines the decomposition of the bleaching powder into oxygen and chloride of calcium, thus—

From this it will be seen that this process is more expensive than any, save that of the decomposition of chlorate of potash. It would require 1200 lbs. of bleaching powder of 35 per cent. to produce 1000 cubic feet of oxygen by this process, which would cost at the present price at least 80s., besides which the cost of manufacture would have to be reckoned in, as no by-product of sufficient importance is utilisable, and a certain working loss of cobalt preparations would inevitably occur.

Of the whole of the foregoing processes, that of simply heating peroxide of manganese seems the most hopeful, as if the same price could be realised for the manganese-manganic oxide (Mn_3O_4) as is paid for the peroxide, the cost per 1000 cubic feet of oxygen could be very materially reduced, and probably sold at a profit at 4s. per 1000 cubic feet, or one halfpenny per pound.

Another process which has tempted many is the electrolysis of water. The cheapness of the raw material has been the attraction, but up to the present time no headway has been made with the process.

Such advances have now, however, been made in plating dynamos, and they have been sufficiently long introduced into practice to enable us to form a very good estimate of what the cost of oxygen would be if manufactured by their aid.

A dynamo to deposit two tons of copper per 144 hours costs about 250l. This requires a 30-h.p. engine to drive it, say, with boiler, &c.,

another 400l. This boiler would require at least two tons of good coal per day. One man by day and another by night might possibly do all the work required. This machinery then would produce not more than half a ton of oxygen weekly, or about 12,000 cubic feet, so that the expenses would be:—

Coal, 12 tons at 8s.	96	0
Interest, &c., at 10 per cent. on 650l.	25	0
Wages	60	0
	181	0

As only 12,000 cubic feet of oxygen could be produced, the cost will not be less than 15s. 1d. per 1000 cubic feet.

Recapitulating, we find that the various methods we have described may be as follows:—

	Per 1000 cubic feet.
From chlorate of potash	£7 3 0
From bleaching powder	4 0 0
By electrolysis	0 15 1
By silica and manganese	0 5 0
From manganese alone	0 4 0

The last two instances are supposing that a sale is made of the residual oxide of manganese at a price equal to the peroxide purchased.

—*Chemical Trade Journal.*

AUTO-STEREOTYPIC PRINTING.

A NEW process of auto-stereotypic printing, especially adapted for the reproduction of books and engravings, has lately been invented in Switzerland, and is already used with advantage at the establishment of Orell, Fussli, & Co., at Zurich, a printing office of European fame.

The process will cheapen the reprinting of the works of foreign authors, which is done considerably here in this country. By this method the type setting and copying of engravings is saved, and an accurate stereotyped plate is obtained directly from the original. It is a transfer process, and for the reproduction two newly printed copies of the publication to be reproduced are necessary to insure complete success. It is done in the following manner:—Plaster of Paris, best quality, is mixed with water to make it a thin putty without lumps, and to this a little alum or salt is added to make it set quickly. To every five pounds of the plaster are then added:—

Silicate of potash or silicate of soda	3 ounces.
Phosphate of lime	2 "

The mixture thus obtained is then put upon a perfectly level piece of plate glass of the desired size, around which iron rods are placed, and left to get hard. The plaster cast ought to be at least type high, to prevent breakage. While the mass is setting, the back ought to be scraped level, and should remain undisturbed until it is perfectly dry and hard. After that it may be taken off, and it will be found to be as smooth as the glass itself.

The paper to be reproduced is next placed, with the side to be copied down, in a dish which contains the following transferring solution:—

Distilled water	16 ounces.
Alcohol, 90°	5 "
Acetic acid	½ ounce.
Phosphate of soda	¼ "

Care should be taken not to get the solution on the back of the paper, which is not to be transferred, as it is then liable to print through when it is drawn through the transferring press. Should the print to be copied have been printed for some time, it is desirable to warm the solution and float the paper longer on it. The sheets should be left on the solution for at least two hours to insure perfect action. In the meantime, the plaster of Paris plate, which was completely dried before, is prepared in a dark room.

A solution of five ounces of gelatine in twelve ounces of water is prepared by letting the former soak for half an hour and then heating it to about 190°. Care must be taken to prevent the boiling of the solution. To this, six drachms of citrate of iron and ammonia and two ounces of alcohol are added and well filtered. This is when still warm. Put into a flat dish covered to a depth of about a quarter of an inch. It is well to put this dish upon a hot metal plate, as it gets hard quickly when getting cold. The plaster of Paris plate, which itself is warmed first, is dipped in the solution on the smooth side for a moment, thus letting it take up some of it, whereupon it is taken out and dried in the dark. When dry, the copy is transferred upon it in the usual way, the plaster having been placed between rubber

sheets to prevent it from breaking. Of course, also, this has to be done in the dark room, that is, at lamp or gas light. The plate is then dried once more and exposed to direct sunlight for fifteen minutes. When taken out, the places where the light has acted will be found to be quite hard, while at the other places the plaster is soft and will fall off as fine powder as deep as the solution has penetrated if brushed with a hard brush. After that the plate is ready to be stereotyped.

—*Scientific American*.

HERMAN REINBOLD.

A FEW OPTICAL POINTS IN CONNEXION WITH THE ENLARGEMENT.

THE general optical principles involved in enlarging are, for the most part, simple enough when the action of a lens in forming an inverted image of any object is once understood.

We all know that in focussing any object on the ground-glass, as we come nearer the object the image becomes larger, and we have to increase the distance between the lens and the ground-glass. This process does not of necessity stop when the image becomes of the same size as the object, except for the reason that few cameras will allow of the necessary extension. The necessary extension provided for, we may keep coming nearer to the object and racking back our ground-glass till we get any size of image that we desire. This really includes the whole of the general principles of enlarging, further complications being necessary merely to facilitate adjustments and, in certain cases, to light the negative in a special way. Of the latter a few words will be said further on.

Although the general principle is the same in enlarging as in ordinary photography, there are one or two difficulties due to the fact that the object to be enlarged from—that is the negative—is all in one plane. Most or all of them hold good for copying as well as for enlarging.

In the first place, there is no need to use a stop to gain depths of focus, as we must in most kinds of direct photographic work. It may be necessary to use a stop for the purpose of gaining marginal definition, but not for gaining depth of focus. Even for marginal definition it will, in many cases, be unnecessary. If the lens be of the rapid landscape type, if its focal length be pretty long as compared with the plate to be enlarged from, and if the subject be a portrait, it will generally be found that there is no perceptible falling off of definition, even when full aperture is used. For architectural work, where microscopic definition to the edge of the plate is generally considered essential, a small stop may be necessary. I should mention that here I am speaking of direct enlargements by daylight where no condenser is used. I shall show presently that where a condenser is employed the conditions are totally different.

Another matter in connexion with the optical side of both enlarging and copying, a matter whose enunciation is often met with considerable incredulity, is that we get in both cases precisely the same *form* of image, however wide an angle we cause the negative or picture copied to subtend. In other words, if we use a long-focus lens, so that the negative is included in a very narrow angle, or if we use a short-focus lens, so that it occupies quite a wide angle, the image that we get is precisely the same in form. Granted that the lens is rectilinear, there is not a particle of distortion in either case, not even of the form, which is more correctly termed exaggerated perspective than distortion. This being the case, it may be asked, why is a long-focus lens particularly insisted on by most writers on the subject of enlargement? To this it may be replied that there are three reasons. The first and principle is merely a case of marginal definition. It is difficult, if anything like a wide angle be included, to get even tolerable definition unless a small stop be used, and that involves greatly prolonged exposures. A second reason is that a wide angle involves unequal lighting of the image given by the lens—a rapid falling off at the edges. A third is that if a wide angle is included, the difficulty of lighting the negative—of getting an evenly diffused light behind it—is considerably increased.

On the other hand, it might be pointed out that there are some advantages not quite imaginary in the use of a wide-angle lens. The principal of these is that the falling off of light in the *negative* may be compensated for by falling off of light in the enlargement. Thus, if we have a negative showing that comparative transparency around the edges which is due to the falling off of the light of the lens with which it was taken, we may so arrange that the enlarging lens will give a precisely similar falling off, and, of course, this, in the case of closet enlarging, means a *lightening*, not a darkening, of the edges. If, in enlarging, the negative is made to subtend the same angle that was included in photographing the object, the correction will be as nearly right as may be. This involves the use, in

enlarging, of a shorter focus lens than was used in photographing the object—unless the latter chanced to be very near the camera—because allowance must be made for increase in the lesser conjugal focus in the case of enlarging.

It is, of course, known that when artificial light is used it is practically always necessary to use a condenser in enlarging, and that, even when direct sunshine illuminates the negatives, a condenser is necessary for those kinds of enlargement which are generally known as "direct solar enlargement." In these sensitive films of the same nature as those used for contact printing are acted upon, and, with all the light that can be got from the sun, condensed by large lenses, the exposure is long.

The condenser is generally looked upon simply as an arrangement for lighting the negative more brilliantly than it can be lighted by diffused light either from the sky or from a white sheet of any substance behind it. This way of looking at the condenser is certainly, so far as it goes, correct; but the condenser does much more than merely illuminate the back of the negative in the ordinary sense of the word.

In enlarging from a negative which is lighted by diffused light the conditions are as nearly as possible the same as when a photograph is being taken in the ordinary way. Every part of the negative is in a certain sense a source of illumination, scattering light in every direction; a certain small portion of the scattered light enters the objective. As a matter of fact, it is the white diffusing screen behind which is the source of illumination, but as this sends light *in all directions* through the negative, it may be considered as if the light radiated from points of this latter. The consequences are that the objective performs just the same functions in direct enlargement as in taking a photograph, that the same qualities are demanded, and that the same faults will show the same defects in both cases.

In working with the condenser the conditions are entirely different. The condenser, if arrangements are as they should be, throws the whole of the light which passes through the negative into the objective. Indeed, could we have as a source of light an absolute print, and could we have an absolutely perfect condenser—one free, amongst other faults, from spherical and chromatic aberration—we should have no need of an objective at all. The condenser itself would form a perfect image at any desired distance from the negative. The function of the objective where a condenser is used is merely to compensate for the want of perfection in the source of light and in the condenser, for the fact that any kind of light that we can use has considerable dimensions, and that condensers are generally, from an optical point of view, very rough instruments indeed. Indeed, in some cases—for example, when certain forms of oil lamp form the source of light, and where condensers of the roughest form are used—the amount of compensation is so great that almost as much is called for on the part of the objective as in direct enlarging. When, on the other hand, we have such a source of light as the limelight, or as the electric light with a very short arc, and when the condenser is of high quality, the objective has but little to do. And now comes a curious result. All the rules, laws, &c., that we have been accustomed to with regard to relation between size of lens or diaphragm and length of exposure are upset. The light enters the objective as a cone whose apex should correspond with the optical centre of the objective. Were the source of light a point and the object perfect, the apex would be a point, and however small a stop were used the exposure required would remain the same.

As it is, the apex of the cone is always a disc of some diameter, and the introduction of a stop smaller than this will greatly increase the exposure. On the other hand, once the diameter of this disc increased, increase of the size of the stop will make no difference in the image either as regards brightness, marginal definition, or anything else; and, again, supposing the smallest of any set of lenses of the same focal length to be of diameter sufficient to admit the apex of the cone of light, all these lenses will act with equal rapidity, although used in this ordinary way one might be twenty times more rapid than another.

Another and curious result of the use of the condenser should be mentioned. It has often been observed that the qualities of negatives desirable when diffused light is used and that desirable when a condenser is employed are quite different. In the first one, the negative which serves for contact printing will serve for enlargement also. In this second case such a negative will probably give exceedingly heavy enlargements, and it is necessary, to get a luminous effect, to have a negative with clear shadows and very thin high lights. The fact has often been observed, but I am not aware that it has been explained. Let us consider this case of the condenser first. Here, as has already been said, this light which passes through the negative is sent directly into the objective. This statement, however, requires a little qualifi-

cation. It is true in the case of such light as passes through the transparent parts of the negatives; but it is not quite true, for that light which passes through the more or less opaque parts, these not being structureless, but consisting of a deposit of palpable particles, such light as is not obstructed is, to a certain extent, diffused or scattered, and consequently not the whole of it reaches the objective. Briefly put, all the light passing through a transparent part of the negative is thrown into the objective, only a portion of that passing through the denser parts is so thrown, and there is a consequent increase of contrast.

In this case of a negative lighted by diffused light the case is different. Here it is true, of course, that the denser parts of the film scatter light as before, and therefore that some rays which come from the source of light (the sheet, or white screen) to the negative, in this direction to the objective, are deflected, and never reach the latter; but on the other hand some rays coming to the negative in such a direction that they would not otherwise reach the objective are deflected into it, and the one action precisely counteracts the other.

Those who have followed the explanations just given will perceive that, when the source of light is small in rays, the amount of contrast between shadow and high light will be greater in the case of an image cut by a lens than in that which results from contact, there being in the latter case no chance for the light which passes the denser parts to scatter. This fact seems to me to introduce a possible factor of error in a remarkably ingenious method recently invented by Abney, for giving actual numerical realms to the densities of different parts of a negative—of stating, in fact, what fraction of all the light reaching a certain part of the negative was allowed to pass through it.

PROFESSOR DEWAR ON LIGHT AND ITS ACTION.

II.

PROFESSOR DEWAR gave the following figures as to the intensity of solar radiation as measured by a thermometer, and assuming a perfectly thermo-homogeneous atmosphere; the absorbing medium was a perfectly black body:—

SOLAR RADIATION.

Zenith Distance.	Thickness of Atmosphere.	Intensity of Radiation (Air Dry).
0	1000	2.403
10	1016	2.401
20	1065	2.395
30	1155	2.383
40	1305	2.364
50	1555	2.331
60	2000	2.275
70	2930	2.164
80	5700	1.868
90	35,000	0.359

He also gave the following as the most accurate measurements yet made in relation to the wave lengths and velocity of vibration of waves of light of different colours. The letters in the first column are those of the fixed lines of the spectrum:—

VISIBLE SPECTRUM.

	Wave Lengths (Centimetres).	Vibrations per second.
A	7.604×10^5	3.950×10^{14}
B	6.867	4.373
C	6.562	4.577
D ₂	5.895	5.097
D ₁	5.880	
E	5.269	5.700
F	5.183	6.179
G	4.860	
H	4.307	6.973
I	4.101	7.569
H ₁	3.968	
H ₂	3.933	7.636

He stated that the first effect of the influence of light upon a chemical substance is, to produce a result which it afterwards reverses, and this is seen in the case of gum guaiacum, which turns blue when long enough subjected to the influence of light, but which by further action is bleached. Often in phosphorescent bodies the same inversion of the effect is seen. Similar effects are produced upon guaiacum by ozone; at first ozone turns the gum blue, but afterwards bleaches it, for ozone will bleach anything.

Plants will not grow in a light filtered through a solution of chlorophyll; there is also a temperature at which the chlorophyll in living plants will not function under the action of sunlight. Something apparently of the same kind may take place with inorganic substances. He took a plate covered with luminous phosphide of calcium paint, and cooled it to

eighty degrees below the zero of the Centigrade scale by means of water containing solid carbonic acid; it then ceased to shine in the dark, and could be kept from shining so long as the low temperature was maintained, but upon removing it from the bath and breathing upon it, it glowed again. He had "looked up light" in this way for three weeks. He did not know the cause of the phenomenon, so would not attempt to give any explanation.

In some additional experiments he proved that chloride of gold is sensitive to the action of light because of the starch and other organic reducing substances in the paper. He also developed with ammonia a mercurial latent image, consisting of calomel, but did not state how he prepared the paper. Perhaps with bichloride of mercury. The developed image was brown.

In the course of experiments upon the opacity of glass to radiations from luminous sources, he proved that the thinnest microscopic glass cuts off twenty-five per cent. of the radiations from a Bunsen's flame; four plates of the same glass cut off but fifty per cent., most of those rays which do not readily pass through glass being stopped in the first instance. When a cube containing boiling water was substituted for the flame, a single piece of microscopic glass cut off seventy-five per cent. of the radiations. The measurements were made by means of a thermo-pile and a galvanometer. When the radiations from the electric arc were taken, a piece of transparent glass cut off from ten to fifteen per cent. of the total emission, and deep red glass cut off but little more, proving how very transparent red is to some of the radiations from luminous sources which are not visible to the eye. Blue glass, however, cut off fifty per cent. of the total radiation. The radiation in this case, he said, is partly from a gaseous and partly from a solid source. He accordingly arranged the slit in the diaphragm of the electric lantern so that it would permit only the rays from the incandescent gas between the carbons to pass; the radiation from the gas was then proved to amount to but ten per cent. of that of the electric light as a whole. There is more heat than light in the electric arc radiation, the relative values of heat and light in which, as compared with the radiation from the sun are here given:—

	Light.	Heat.	Total Radiation.
Sun	25	75	100
Electric arc	10	90	100

If we suppose the surface of the earth in this latitude to be black, and that the sun acts vertically, then a layer of water, half an inch deep, covering the surface, would be raised in temperature one degree Centigrade after one minute's exposure. A parabolic mirror a yard in diameter, exposed perpendicularly to the sun's rays, will concentrate at its focus as much radiant energy as is evolved by an ordinary fifty-cell Grove's battery. Although glass is so opaque to certain radiations from luminous sources, plates of rock salt let them pass freely; bad absorbers are bad radiators, hence when rock salt gets very hot it takes a long time to cool.

Professor Dewar exhibited a curious way of getting a low steady light from platinum. He poured an ounce or two of strong liquid ammonia into a large globular flask, then suspended over the liquid a spiral of platinum wire which had first been made red hot. In the flask it continued to glow steadily because of the heat generated, without flame, by the slow combustion of ammoniacal gas. Would this do for a developing room lamp?

Professor Dewar then spoke of bacteria used as the basis of a photometer. He said that Engelmann uses bacteria as reagents for discovering the assimilative power of the plant cell, containing chlorophyll, for carbon, when stimulated by different rays of the solar spectrum. The method depends upon the fact that certain bacteria only exhibit movements in the presence of free oxygen. If such organisms are examined under the microscope, only those next the edge of the cover glass show any motion. They further all tend to collect where they can get free oxygen. If a cell containing chlorophyll, such as a small alga, be placed under the cover glass along with the bacteria, then they instantly collect round it, provided the illumination is sufficiently intense to cause the evolution of oxygen by the chlorophyll. When such observations are made in a pure spectrum, it is found that the bacteria collect especially at the part of the spectrum between the solar lines B and C (junction of the orange and green), and to a smaller extent in the blue just beyond the line F. These positions in the spectrum coincide with the marked absorption bands of the chlorophyll spectrum, and this coincidence would seem to indicate that those rays which correspond to maximum absorption are most efficient in the decomposition of carbonic acid, or, what is the same thing, most active in producing free oxygen from the same gas.

Engelmann has shown that some kind of colouring matter is absolutely necessary in order to bring about this light decomposition by the plant cell. It is possible by Engelmann's method to estimate quantitatively the relative activity of the different rays of the spectrum with regard to the decomposition of carbonic acid by observing the width of the slit needed in each successive region of the spectrum to stimulate the bacteria into movement in the immediate vicinity of the alga. The curve showing the relation between the wave length of light and the intensity of carbon assimilation, or production of free oxygen from carbonic acid, follows very closely the form of the curve found by Lamansky and Langley, by the agency of the thermo-pile and the bolometer for the distribution of radiant energy in the solar spectrum.

The quantitative relation which exists between the amount of absorption

and assimilation is relatively a simple fraction, and may be stated as follows:—The ratio of the amount of luminous energy which has disappeared as such, to the chemical potential energy produced, is for each wave length and all chlorophylls the same, and equal the one to the other.

PRINTING PLATES FROM PHOTOGRAPHS.

A METHOD of reproducing photographs in copperplate, lithographic, or printing presses has been realised by Captain Louis Collardon, of Cordoba, Buenos Ayres. The relief surface for the photograph is a specially-prepared surface of gypsum, which is composed of 1 to 6 per cent. chalk and 50 per cent. water to each 100 parts gypsum, the latter, together with the chalk, being finely powdered and well worked with the water to obtain a homogeneous mass, which is then pressed into plates of suitable size, having a polished surface when dry. The pigment paper is prepared as follows:—

Common black pigment paper is placed in a bath composed of 4 per cent. bichromate of potash to 100 per cent. water for from one to five minutes, as required, and then dried in a temperature of 60 degrees to 70 degrees C. The paper is then exposed to the daylight for from ten minutes to two hours, according to the strength of the light, and then placed in cold water for about an hour, and then in a bath composed of about 6 per cent. pyrogallie acid to 100 per cent. alcohol for about ten minutes, when it is placed in a frame or on a plate and dried. As soon as completely dry it is covered with powdered oxide of zinc or oxide of bismuth, which is rubbed in with the palm of the hand, thus pressing it into the deep parts, and leaving the upper parts of the lines of the figures free, the surplus powder being removed. The pigment paper thus prepared is placed in front of the camera, and a negative produced in the usual way. The negative is removed from the glass and placed between the negative of the photograph to be reproduced, and a pigment paper, which has been prepared with a strong solution of gelatine containing only a small quantity of pigment, and then copied as usual, thereby producing a positive on the pigment paper with the same irregular surface as that on the negative, which is necessary to print from. The printing block is prepared as follows:—

The gypsum plate is placed under water, and upon it the positive, also under water, then the plate with the positive is removed from the water, and the positive pressed against the plate by an indiarubber roller or squeezer to remove any air that may be between, the positive closely adhering to the plate. It is then pressed tightly in a press, and then placed in a bath composed of water and 10 per cent. sulphocyanide of ammonium, which will dissolve those parts which are not or only partially developed. When removed from this bath and washed in cold water, it is placed in a bath composed of 5 per cent. chrome alum in water for about five minutes, then removed and washed, and immersed in a bath of concentrated alcohol and dried, and then impressed into a plastic mass composed of bone dust, albumen, blood, and silicate of soda, the proportions depending on the hardness required. Any other plastic substance may be used, such as celluloid, cyanoid, &c., by means of a hydraulic press or other suitable means, steam being introduced during the operation. When cold it is removed from the press.

—Invention.

Our Editorial Table.

HINTON'S PATENT PORTABLE WASHING AND DRAINING RACKS.

We have received from Messrs. Hinton & Co., 38, Bedford-street, Strand, a specimen of these racks, the nature of which will be readily understood from the following cuts and description:—

They have been specially designed for the convenience of roving photographers, both amateur and professional—especially the former—most of whom have doubtless often felt the want of such a contrivance. The one now being noticed adds very little to the weight of a travelling kit, and is quite indispensable for preventing injury to such negatives as must necessarily be developed during a tour.

With one of these little contrivances it will no longer be necessary to resort to the usual risky performances of washing negatives in a hand-basin, and drying them on the window-ledge, or similar makeshifts. It will be seen from our illustrations that the racks are capable of holding a dozen negatives, but they can be made, if required, to hold a greater number. The sides are made of the lightest zinc, bent so as to form corrugations or grooves for the negatives, and are connected together by two wire bands, hinged on them in such a way that they can be quickly folded up when required.

The operation of washing may be performed by placing the rack, full of negatives, in an ordinary pail, or other convenient vessel, filled with water. Wherever possible it is well to place the whole under a tap and allow the water to run slowly during the time devoted to washing.

Folding handles are provided for the purpose of suspending the

rack for drying the negatives; it can, however, be used as a standing rack, or it can be safely hung, by one handle, to a nail in the wall.

FOLDED.

OPENED.

There are no loose pieces, and no adjustment whatever of parts is required to prepare it for use; indeed, it is always ready.

From the trials we have made, they answer their intended purpose most admirably.

No. 12,940.—“Improvements in Photographic Shutters.” F. W. BRANSON.—*Dated September 24, 1887.*

PATENTS COMPLETED.

A NEW OR IMPROVED INSTANTANEOUS SHUTTER FOR PHOTOGRAPHIC CAMERAS.

No. 12,755. JOHN LEISK, 169, Commercial-street, Lerwick, Sutherland.—*October 6, 1886.*

My invention relates to a new or improved construction and arrangement of instantaneous acting shutter to be applied to photographic cameras, and has for its object to give separate exposures to the foreground and sky in a landscape on the same negative plate, the foreground exposure being long enough to give full details of moving objects, while the sky exposure would be short enough to print clouds very distinctly or shade the sky darker towards the zenith, as in nature. All in contradistinction to giving the same exposure both for the foreground and sky with the shutters heretofore used in photographic cameras.

And the nature and novelty of my invention consist in constructing the shutter of two separate discs of wood, metal, or other material. The one, a stationary disc, is formed with an eccentric circular aperture corresponding in size with the largest working aperture of the lens used, with which it is set in a concentric line; while the other, which is a rotating disc, is formed with an eccentric segmental winged aperture or segmental circular opening with two curved open projections, one on either side, to give three different stages of exposure during an oscillation of the disc on its eccentric centre coinciding with that of the fixed disc.

Thus the upper segment of the aperture in this moving disc coincides with the upper segment of the round aperture in the stationary disc and aperture of lens. Then from the eccentric centre of the oscillating disc, which may be a radius or more vertically down from the circular aperture in the fixed disc, a circle is drawn through the centre of this aperture for the outer circumference of the winged part of the aperture on either side in the oscillating disc, and another circle is drawn from the lower diameter of the aperture for the inner circumference of these winged apertures.

A centre is taken in the circumference of the outer wings with a radius equal to the radius of the central aperture, and the ends of the segmental winged apertures are drawn, forming the said segmental winged aperture, coinciding with the circumference of the central aperture.

My improved shutter, constructed as described, can be applied either to the front or back of the lens of a photographic camera.

In applying it to the former, I secure a block or tube, with a projecting piece on its lower side, round the hood or front of the lens, to which I attach the stationary disc of the shutter with its eccentric round aperture in line with the working aperture of the lens. The oscillating disc part of the shutter is mounted on its centre in front of the stationary disc, on an arbour or spindle which passes through the latter and through the projecting block. A coiled spring is by one arrangement fitted round this spindle, preferably within the oscillating disc keyed to the spindle; the outer end of the spring being attached to the oscillating disc, and this spring is wound up by turning by hand the milled head of the spindle; and a ratchet wheel is mounted on the spindle at its inner end, controlled by a movable detent for tightening up the spring and

regulating the speed of the rotating shutter disc. A metal rim is preferably mounted round the outer surface of the stationary disc, and projects slightly beyond the edge surface of the oscillating disc to cover and prevent any light entering the lens between these discs, and this stationary disc may carry a trigger and stop for making the exposure.

When a photograph of a landscape is to be taken by the camera, the action of the instantaneous shutter is as follows:—The coiled spring is wound up on its spindle until the required tension according to the rapidity required is obtained (or if the spring be wound up it may be let down by loosening the detent). The revolving disc is then turned round by hand by means of a stud on front of it till the centre of the winged aperture corresponds with that of the lens, and is there retained by the said trigger for focussing. That accomplished, it is turned further round so as to close the lens, and is there held by the trigger. To make the exposure the trigger is withdrawn and the movable disc makes an oscillation or rotation, during which the inner open winged part of the latter coincides with and passes the lower part of the apertures of the stationary disc and of the lens, and thus a negative of the landscape is taken in which three different phases of exposure are obtained, the foreground exposure being about three times that of the sky, so that the former is fully exposed and takes in all moving objects, while the sky is not over exposed and prints clouds very distinctly, and should no clouds be visible it shades the sky darker towards the zenith as in nature. Other equivalent arrangements of springs or weights than that of the spiral spring described, might be adopted for rotating the moving winged disc at any desired speed.

The claim is:—A photographic lens shutter having an aperture of such form as to uncover the upper and lower halves of the lens aperture for different periods of time, so as to give different periods of exposure to the foreground and sky of the picture, substantially as specified.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.
The usual weekly meeting was held on Thursday, the 22nd instant, Mr. A. Pringle presided.

A piece of very thin transparent tissue was shown by Mr. A. L. HENDERSON, who stated that it was intended to be used in the manufacture of sensitive films, and had been patented. He had subjected it to the action of boiling water; it smelt very strongly of castor oil; he found also that it dissolved readily in alcohol and ether. Apart from photographic purposes, it had already been taken up by one or two firms for capping bottles.

A detective camera was exhibited by Mr. J. T. Collins. Its outward form was a small case carried by a strap handle; at the top a hinged lid opened to admit of the dark slide being inserted into the back of the camera enclosed; the shutter is released by a catch at the side, and an arrangement for increasing or lengthening the focus of the camera is also provided for at the side, a five-and-a-half-inch focus rectilinear lens being employed.

Mr. J. B. B. Wellington also exhibited a detective camera; although from a different maker, many points of comparison in the two exhibits were identical.

The CHAIRMAN asked for any of the members' experience with sulphocyanide toning. It had been stated that a strong bath destroyed the gelatine film.

This was confirmed by one or two members present.

A question being asked as to whether this bath should be kept previous to using, the CHAIRMAN said the plan he adopted was to make up a bath with the sulphocyanide and phosphate or other salts, put a few strips of the paper in it, and leave it for a day or two; the gold was then added.

Mr. W. E. DEBENHAM asked what advantage was found in the addition of phosphate of soda.

The CHAIRMAN replied that it was the outcome of experiment, and that the phosphate gave a tone more like what he aimed at.

Mr. DEBENHAM remarked that gelatino-chloride prints kept for some time and then fixed would have the appearance of being toned.

The CHAIRMAN had not found gelatino-chloride prints keep well—a red, foggy appearance set up with keeping.

At the request of several members, Mr. HENDERSON gave his formula for a toning bath that he had employed for improving some developed prints of a very disagreeable colour:—

Gold	2 grains.
Acetate	20 "
Water	10 ounces.

Neutralise with chalk and filter.

Acetic acid

2 or 3 minutes.

Mr. A. L. ATKINSON drew attention to a very bad case of frilling, which he passed round. He had used methylated spirit, but with little effect.

Mr. H. Harland was elected a member of the Association.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

At the meeting held on Tuesday, September 20, 1887, at Myddelton Hall, Islington, N., Mr. A. Mackie, Vice-President, in the chair, a number of prints were exhibited from negatives taken by members at recent outdoor meetings or during holiday tours, and, in accordance with a promise made at the last meeting, Mr. A. Liddle had sent some specimens of "pinhole" photography, together with the apparatus used, which was of American manufacture, and sold under the name of "The Ready Photographer."

Mr. JOHN OAKLEY asked if any of the members had any experience of iodine as an eliminator of hypo in prints. He explained that during his holiday tour he had met a photographer who recommended its use. The method of its application was:—A small quantity of an alcoholic solution of iodine was to be added to the washing water, the result of this was that the back of the prints turned blue; the washing was to be continued until the colour was removed, when it might be assumed the hypo was eliminated.

The CHAIRMAN said that he had never heard of iodine being used in this connexion, but the use of iodide of starch as a test for the presence of hypo was well known.

Mr. F. W. Cox asked the best means of stripping the films from negatives on ordinary gelatine plates.

Mr. E. CLIFTON soaked his waste negatives in diluted sulphuric acid. He found in most instances the film came off entire.

A member said that it had been suggested to him that the plate should be first treated with a solution of chrome alum to harden the film, and then with a solution of fluoric acid, which would effectually effect a separation.

A question was asked whether it was possible to copy a Daguerreotype, and, if so, whether any special arrangement was required for lighting.

Mr. CLIFTON said that the only difficulty was in avoiding the reflection from objects in front of the picture appearing in the copy. The method he adopted was to illuminate the Daguerreotype by a side light only and to cover the camera with a black cloth with a hole in it for the lens. Except for the difficulty in dealing with the reflection the matter was quite an easy one, and the results were very satisfactory. The iridescent stain which appeared on some Daguerreotypes might be removed by treating with a solution of cyanide of potassium.

Mr. J. H. BIRD asked the best method of copying a paper print so as to avoid the grain showing in the copy.

Mr. CLIFTON advocated that the print to be copied be illuminated with a perfectly diffused light. He had obtained very good results by constructing a tunnel of tissue-paper at the end of which he placed the print to be copied.

The CHAIRMAN said that doctors differed as to the best method of lighting in copying paper prints. Many experienced workers advocated the use of a side light only, and that at an acute angle. In making a series of negatives for lantern transparencies from unmounted 10x8 prints he had soaked the prints in water, placed them in optical contact with glass plates, and copied them through the glass. In the transparencies from these negatives the grain of the paper of the original print could hardly be detected.

The next meeting will be held on Tuesday, October 4. Visitors are invited.

WALTHAMSTOW PHOTOGRAPHIC CLUB.

The first meeting of this Club after the summer recess was held at the Literary Institute on the 26th instant,—Mr. Gilbert Houghton in the chair.

From the large number of pictures that were handed round it was evident that this Club includes several enthusiastic and energetic members.

The Chairman had a large show of silver prints, both of landscape and figure studies, while platinum type was well represented in Mr. G. Naldrett's collection of views, taken principally in Sussex.

Mr. T. N. Waller had on view a series of bromide prints, showing a care in selection of point of view and careful manipulation of technical detail above the average.

Messrs. C. Worsfold and Betts also handed round prints.

A changing box, the invention of Mr. F. Houghton, exhibited and explained by him, calls for more than passing notice. Combining several novel features with a considerable amount of ingenuity in its construction, should render it a really useful and efficient accessory to the photographic tourist.

Discussions relative to little difficulties met with in working various processes occupied the remainder of the evening, a vote of thanks to the Chairman closing the proceedings.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of the above was held at the Technical Schools, Bridge-street, on Thursday, the 22nd instant,—Mr. J. J. Britton in the chair. Sixty-four members present.

The minutes of the last meeting were read and confirmed.

The following gentlemen were elected members of the Society:—Messrs. H. Copnall, G. Greening, H. Hollins, H. R. Leech, R. Mason, E. Shilton, G. F. Vernour, and Messrs. G. C. Lloyd, H. F. Woods, and W. Walkinshaw, were nominated for election.

Exhibits of photographs were shown by Mr. Harold Baker (very fine vignettéd cabinets and views); framed bromide prints, by Mr. Denuison; views of Norway, by Mr. Thomas Taylor; drying racks and phantom shutter, by Mr. W. Tylar; and a number of negatives taken on a new plate which combines the force of the old plates with the speed of the most rapid plate, by Mr. A. Pumphrey.

Question relating to the use of combined toning and fixing bath was answered by Messrs. Middleton, Pumphrey, and Tylar respectively.

Mr. MIDDLETON: Chief objection, sulphur; use a little common salt in the bath.

Mr. PUMPHREY: Not used by professionals; costs more; can take straight from printing frames and put into bath.

Mr. TYLAR: Used with success; prints toned five or six years ago still good.

Mr. E. H. JACQUES then gave his paper on *Film Negatives* [see page 615], which was a success in every way from beginning to end, and was very highly commented upon by the members present.

Mr. PUMPHREY thought the films would be liable to take up silver whilst printing.

Mr. J. H. PICKARD said coating the indiarubber with collodion before transferring the wet negative would obviate this.

In answer to an inquiry, Mr. JACQUES said bromide prints can be got from films very readily.

In consequence of the lateness of the hour, the discussion on the Ilford plate was postponed till October 6.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The first ordinary meeting of the present session was held on Thursday, September 15, 1887, at their Rooms, 36, George-street,—The President, Mr. Arthur Coventry, in the chair.

The minutes of the previous meeting were read and passed.

The PRESIDENT said he had the very great pleasure to introduce Mr. J. Traill Taylor, who had come from London that day to lecture to them on photographic lenses.

Mr. TAYLOR said that the subject he had selected for his discourse was *The Characteristics of Modern Photographic Lenses*. The portrait combination first claimed consideration. It was, as they all knew, a doublet, the component parts of the front lens (which is plano-convex, or nearly so) being cemented, so as to annihilate the reflections which would arise from its inner surfaces, and thus impair brilliancy, while the back lens cannot thus be treated in consequence of its inner curves being of dissimilar radii. This lens possesses in a greater degree than any other the property of large angular aperture, that is, a large diameter compared with its focus, and this property it is that gives it a greater rapidity in working than others. Its covering power is limited, but it amply suffices for the purpose for which it is intended. The separation of the back components is all important, for, owing to the non-concentricity of the inner curves, an amount of negative spherical aberration is introduced sufficient to counteract the positive aberration of the front lens and also to flatten the field. When the separation between front and back lenses is great the field is flatter than when the mount is short, but this is usually secured at the expense of astigmatism, which he explained to mean the inability of the lens to transmit an oblique ray correctly. A star or circular spot will be oblong, a cross will have its vertical bar at a different focus from its horizontal limb. To test a portrait lens for astigmatism, focus a white paper cross on a black ground or *vice versa*; both limbs will be equally sharp at the centre of the ground-glass; rotate the camera so as to bring it to the side, and if astigmatism be present the phenomenon described will be apparent—one limb may be altogether invisible when the other is at its best focus. If the lens mount were shortened, or other means adopted to lessen the distance apart of front and back lenses, then would this defect be ameliorated, but the field would be rounded, no great disadvantage in a sitting figure. Many portrait lenses, especially those of foreign make, while otherwise good, do not work sharply to visual focus. While the most satisfactory way to discover this is by actual trial in a camera, opticians adopt a simpler method. Take the lens into a darkened room, and having placed a lighted candle twelve or twenty feet away, point the lens towards it telescopic fashion, and examine the image of the flame by a powerful magnifying glass. After it is focussed withdraw the lens so as to place the image out of focus, when it will be seen surrounded by green; now bring the lens nearer and place the image out of focus again, and the image will be bordered with claret. This indicates correct achromatism for photography; the visual and chemical foci will coincide. When this is not the case the lens, although perhaps giving a good image on the ground-glass, will not work to focus. The remedy for this defect is fourfold:—Having ascertained the distance between the visual and chemical foci, (a), let the lens be racked in or out to this extent; (b), let the focussing screen be set a little in or out in its frame; (c), let an exceedingly weak lens be fixed in the cap or inserted like a Waterhouse stop in the mount while focussing and be withdrawn while exposing the picture, the strength of such lens being an equivalent to the difference of the chemical and visual foci; (d), or, lastly, send the front combination to a glass grinder with instructions to regrind the contact surfaces in a tool having a longer radius of curvature; for it is usually the front lens which is the defaulter in this respect, and its fault usually lies in the direction of over correction. He had known several large and otherwise fine lenses cured of their defect by either of the expedients mentioned. When a portrait lens gives a round field it may sometimes be cured by bringing the two elements of the back combination closer together, thus increasing the negative aberration of that lens. He knew of a case in which a three-and-a-half-inch whole-plate combination that performed very badly was cured by reducing the width of the separating ring of the back lens by more than one half and bringing the front lens nearer by the extent of an inch. Photographers ought to learn how to rectify their lenses when only defective to a slight extent, for it is a well-ascertained fact that lens makers rigidly abstain from repairing or altering the productions of rival makers, named or unnamed, hence the curing of lens defects devolved in a great measure upon photographers themselves. If a portrait lens is to be employed out of doors it is well either to avoid using a diaphragm or to see that little or no sky is introduced in the picture, and that the lens is even shaded from it. This arises from the fact that portrait lenses more than others cause a circular flare spot when employed for outdoor or landscape purposes when used with a stop. The cause of a flare spot he would presently treat of, but meantime would state that if a stop must be made use of it will be judicious to place it close up to the front lens. This does not apply to studio work or copying. The front lens of a portrait combination when used alone possesses some advantages over all others for large heads. To this end the back lens is unscrewed from the mount and placed away, and the front lens inserted in its

stead, flat side towards the sitter. Pose the sitter and examine the image; note that the definition is much too soft for good effect; but insert a diaphragm about two-thirds the diameter of the lens and observe the improvement that has taken place. It has now a fine crayon-like sharpness which many will not care to go beyond, especially if the head be large. But by reducing the aperture still further, say to one-half the diameter of the lens or less, then may the greatest necessary sharpness be obtained. Many of the large direct portraits for which the Americans are justly celebrated are taken in this way. For groups on a plate three or four sizes larger than the lens in its original complete form would cover this departure is invaluable. But the stop when in its Waterhouse position is too near to the lens when thus used singly; a far flatter field is secured by inserting it at the outer end of the tube. He dwelt on this because he foresaw that the single lens was likely to be more extensively employed in studio work than it has ever yet been. But, they would say, by the adaptation he had described he merely converted the portrait lens or a portion of it into a landscape one. Quite true, and where would they find a landscape lens to surpass it? For flatness of field, equality of definition, brilliancy of image, nothing could surpass a good single achromatic, and with a given aperture it works rather quicker than a combination of lenses. The only purpose for which it is inadequate is architecture and copying, but if one was hard pressed and had no other lens at command, an architectural subject might be taken with no appreciable degree of distortion by the expedient of employing a small stop pushed close up to the lens.

(To be continued.)

Correspondence.

Correspondents should never write on both sides of the paper.

ROYAL CORNWALL POLYTECHNIC SOCIETY.

To the EDITORS.

GENTLEMEN,—Having been asked by several exhibitors at the Royal Cornwall Polytechnic Exhibition to account for certain discrepancies which appear in the Judges' reports as published in your own and in another journal, I have to explain that the official reports sent to both yours and the other paper were absolutely alike, having been written in manifold.

That which appeared in THE BRITISH JOURNAL OF PHOTOGRAPHY of September 16 is quite correct, and as issued by the Judges; the other has undoubtedly been tampered with since it left their hands.

I write this as representing the Judges, to whom several complaints have been made respecting this matter.—I am, yours, &c.,

WM. BROOKS.

To the EDITORS.

GENTLEMEN,—In reply to your correspondent, Mr. W. Crooke, I beg to state that his pictures were judged as direct pictures and not as enlargements. It was a slight error in the report.—I am, yours, &c.,

September 27, 1887.

ONE OF THE JUDGES.

THE MERCHANDISE MARKS ACT.

To the EDITORS.

GENTLEMEN,—In your answer to "Optician," *re* the Merchandise Marks Act, I agree with you that the words "warranted and sold by" would be allowed, also "made for," or simply "sold by;" but I think that the use of the words "warranted by" would render himself liable, as it is a misleading term. Even the word "warranted" is bad, as we may ask what is "warranted?" If I buy a race glass and it is "warranted," what is warranted?—that it is a race glass! In the selling of Swiss watches the sellers in many instances engrave the words "examined by" So-and-so, or "sold by" So-and-so, but some sellers leave out the words "sold by" or "examined by," and only engrave their own name, and purchasers are under the idea that they had bought one of So-and-so's own make. The Act uses the words "calculated to deceive," and upon that only I think the words "warranted" or "warranted by" would place the seller of any goods so marked in a very false position. Apologising for troubling you —I am, yours, &c.,

J. W.

Clerkenwell, September 24, 1887.

THE AREA SYSTEM OF GEORGE SMITH.

To the EDITORS.

GENTLEMEN,—In common, doubtless, with many others who are in the habit of using many lenses for work of various kinds, I have experienced the inconvenience of carrying a battery of stops and stop cases into the field. I have, amongst others, four lenses the stops of which are interchangeable in respect to their fitting the lens tubes, these stops being at present marked with numbers on the uniform system, each set with reference to its own lens. The lenses themselves vary from 5½ to 12½ inches focus. I must confess that after many endeavours I have failed to select or make a set of stops that I can use for all these lenses without the necessity of consulting an elaborate table, or making a long calculation, when I wished to arrive at the relative intensity of a stop when used for a lens other than that for which it was originally intended.

On reading the very interesting and impressive article in your last issue by Mr. George Smith, entitled, *A Defence of the Area System*, it became evident to me that all the usual systems of marking stops are radically wrong, and that the area system is the only one in which are combined scientific accuracy and the simplicity necessary for everyday work. Being thus converted, I fondly imagined that all my troubles with respect to stops were at an end, and that all I had to do was, by an easy calculation, to work out the area numbers of my lenses and of my stops, and all the rest "would come out of itself almost like magic." My next step was to look up and peruse Mr. Smith's previous articles on the subject, after which I was still more convinced of the simplicity of the system and its adaptability for all practical purposes.

I have, however, so far, not been so successful in applying the system as I hoped, but I have no doubt that the fault is with me and not with the system. In the hope that Mr. Smith, or some other kind reader, will check my calculations and point out where I am in error, I venture to trouble you with an example of my difficulties.

One of my lenses, a wide-angle doublet, has an equivalent focus of $7\frac{3}{4}$ inches, as nearly as possible. This lens I determined to mark according to the area system, and therefore, as a preliminary, I worked out its area number according to the rule given by Mr. Smith in his article in this year's ALMANAC. The rule is—To obtain the area number, multiply the focal length in inches by 4, square, and then divide by 10, thus:— $(7\frac{3}{4} \times 4)^2 = 96$. That is to say, that the area number of a lens of

10

$7\frac{3}{4}$ -inch focus is 96. However, to carry out the area system in its entirety, it is necessary to mark on each separate combination its own area number. I therefore ascertained that the foci of the two lenses were 10 and 30 inches respectively. In case of error, as a check, I applied Mr. Traill Taylor's rule for obtaining the focal length of a combination:—

$$\frac{10 \times 30}{10 + 30 - 1} = \frac{300}{39} = 7\frac{1}{3} \text{ inches,}$$

the separation of the lenses being one inch. This result satisfied me that any calculation based on these figures would lead to a very trifling error only, and was sufficiently nearly being exact for all practical purposes.

Again applying the rule for obtaining the area number to each separate lens, we have—

$$\frac{(10 \times 4)^2}{10} = 160 \text{ and } \frac{(30 \times 4)^2}{10} = 1440.$$

Therefore the area numbers are 160 and 1440 respectively. These calculations are so easy that it would be almost impossible to blunder over them, but it is in the next step I get into difficulties. Mr. Smith's rule to find the area number of a combination is explicit enough, and yet my result *won't* come right. "The area number for a combination will be the two separate area numbers added together and divided by 8."

$$\frac{160 + 1440}{8} = 200$$

I have passed a sleepless night in a vain attempt to make the difference between 96 and 200 amount to only 10 per cent., the maximum error which, according to Mr. Smith, can occur. Nothing shall convince me that Mr. Smith can possibly be wrong, or that the system is not really accurate, although it appears to admit of such strange discrepancies. I shall always look upon the system as one which has particular advantages, and especially for amateurs and beginners; but as I have to earn my living by photography I shall, until I receive more light on the subject, be reluctantly compelled to plod along with that unpractical and unscientific uniform system.—I am, yours, &c., S. SIMON.

SAFETY LIMELIGHT.

To the Editors.

GENTLEMEN,—In answer to your correspondent, W. Hallett, in your number of September 23, he will find that he cannot use the blow-through jet for the Ethoxo light, as it is certain to light back and blow off the tubes. Although Broughton's ether saturator can be used safely, there is always an element of danger where there is a quantity of ether in the liquid form, and I think this style of apparatus should not be chosen by an amateur. I have used for two years the American style, "Ives's patent," made from the description given in the ALMANAC by Dr. Nicol, and found it perfectly safe in the hands of a complete ignoramus. Before using it, I tried every way to burst one, but failed in all the attempts I made. He will find that pumice tubes carefully prepared will stop back lighting, but as he purposes using gas from cylinders under high pressure, the arrangements recommended by Mr. Hardwich, viz., short tubes filled with slate-pencil dust, absolutely safe. Full particulars of size of these and method of filling will be found in the back numbers of the JOURNAL. I may tell him, however, that during last winter a single lantern was used with a simple mixed jet without safety tubes, and that during the whole time, some twenty exhibitions, nothing went wrong. Even if it had lighted back, as the saturator he was using (the one already mentioned) had so little room for gas in it the only effect would have been to blow off a tube. The operator had never used a lantern before. If you put Mr. Hallett in communication with me, I could give him all information.—I am, yours, &c., FRED. BARBER.

23, Chipping House-road, Sheffield, September 24, 1887.

PAINTERS v. PHOTOGRAPHERS.

To the Editors.

GENTLEMEN,—The recent correspondence in your columns under the heading of *Fifty Sitzings for a Portrait* has much interested me, for having had nearly twenty years' experience as a portrait painter and exhibitor, after my studentship at the Royal Academy, I am fully convinced as to the value of photography to a painter able to draw a model without its assistance, and think that no artist should be without this true friend, critic, and general assistant.

My excuse for encroaching upon your space is that the advice given me some years back by Sir John Millais with regard to one of the uses of photography in portrait painting may be of service to some of your readers. It was to have your first sketch in charcoal photographed to cabinet size, and reduced thus you would see at once any error in the proportion; in fact, so infallible had Sir John found this guide that he often corrected his sketch before the next sitting, and then later on the portrait would be photographed again.

Knowing the value of having one's subject picture photographed before completion, having seen many men repaint their work at the last moment before sending to exhibition in consequence of the discomfiting revelations of the camera, I took Sir John's hint (then Mr. Millais), and seeing that he generally painted with his canvas close to and parallel with his sitter, first viewing both from a distance, I had both my sitter and canvas photographed on the same plate, and found the result *very instructive*, and came to the conclusion that five minutes with the camera was worth more than all the criticism of a host of morning callers. I think it wise to first secure the basis of a good portrait, viz., likeness, and then to proceed to make Brown, Jones, and Robinson more as they should be, and not *quite* as they are, then to start with Brown, Jones, and Robinson in an artistic flight of fancy on the canvas as you imagine they ought to be, and endeavour to work in a little resemblance at the finish.

Art owes a great deal to photography; it put second-rate portrait painters on their metal, and alarmed many with its truthful drawing and modelling compared with their own mediocrity; but it has outlived most of its detractors, and of the many painters I know most of them possess a camera, make good use of it, and speak up for the "handmaid," knowing that their hand-made work has its own individual value, every inch being hall marked by their own touch. It is the second and third rate strugglers who, having called in the aid of photography, find it more than a match, and either become abject slaves or rail against it in disgust begotten of their own incapacity.

I will not presume to touch upon photography as an art, or the highest aims of portraiture—the subtle blending of the real with the ideal, but hasten back to work, to share with all true workers in the art world—their medium photographic chemicals or turps and oil—that great incentive, the striving to attain something better than our best.—I am, yours, &c.,

Kensington, September 27, 1887.

LIFE STUDENT.

Exchange Column.

* * No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Would exchange enlarging lantern for good portable half-plate camera, lens, &c.—Address, H. HATTON, Dewsbury.

Wanted, 10x8 rapid lens by good maker in exchange for whole-plate rapid Paragon by S. Mift, equal to new.—Address, E. SHAW HARPER, Box 28, Southampton.

Will exchange a whole-plate camera and view lens for a complete set of lantern slides (lecture); also a Burr lens, cabinet, half-plate view lens, and sliding-body camera, for a Ross' half-plate Universal lens.—Address, HERRIOTT, Photographer, Berwick-on-Tweed.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a NOM DE PLUME as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

PHOTOGRAPHS REGISTERED:—

W. H. Batten, 4, Oxford-grove, Ilfracombe.—Photograph of Miss M. Flynn and Miss B. Ash, both drowned by yacht accident at Ilfracombe, August 28.

A. Rogers, Mount Pleasant House, Baccup.—Two photographs of A. Derhurst, Esq., alias Mad Ab.

J. McLeod, 8, Wilson-street, Newark.—Two photographs of Duke and Duchess of Newcastle, and one group of ditto.

Thomas Ball, 7, Comberton-hill, Kidderminster.—Photograph of Baxter Church, Kidderminster.

Mowll & Morrison, Hardman-street, Liverpool.—Four Photographs of Bishop of Sodor and Man.

J. C. Swales, Toll Gavel, Beverley, Yorkshire.—Four photographs of cliff climber collecting eggs of sea birds on Flambro' Cliffs. One photograph of groups of sea birds on Flambro' Cliffs, Yorkshire.

- A. Knighton, 88, High-street, Ketterington.—Four photographs of the town of Kettering (bird's-eye views).
- A. B. (Stowmarket).—We prefer the No. 3 cabinet.
- LANTERN.—The oxyhydrogen light is best for your purpose.
- GREENHORSE.—The correct exposure can only be ascertained by trial.
- H. B. A.—Most, if not all, the exhibitions held are announced in our columns.
- R. W.—Precipitate the silver as a chloride by adding common salt and add to the other residues.
- J. C.—Negatives were broken when received, but enough remained to enable us to see the quality.
- A. B.—G. F. Williams, 36, St. Martin's-lane, can supply the thin covering glasses for lantern slides.
- C.—You have certainly got density enough and to spare. In such a case as this it may be well to try a bath of bichloride of mercury.
- C. A. S.—Better take the lantern with you. If it is taken as one of your tools of trade or has been for some time in use no duty will be charged.
- F. NIXON.—We know nothing of the firm named. We are in no way responsible for the advertisements which appear in our columns or those of the ALMANAC.
- D. M. S. (Glasgow).—Obtain plain unaluminised paper and float it on a ten-grain solution of chloride of sodium, sensitising on a sixty or seventy-grain silver bath for one minute, over print considerably, tone in a lime bath, fix in the hyposulphite of soda in the ordinary way.
- F. W. B.—1. In practice one method will be found about as good as the other. —2. If the furnace be deep enough a No. 10 or even No. 12 skittle pot may be used. Small coal would be about the worst fuel that could be used. Employ the best furnace coke.—3. Better employ the method as described in its entirety.
- W. S. ANDERSON.—1. The micro apparatus is not now an article of commerce. Any optician would, of course, make it to your order, or you might obtain a second-hand one by advertising.—2. The gelatine cannot be successfully removed by dissolving it off, but it may be by scraping it away.—3. The slide enclosed is by the Woodburytype process.
- J. COURTIER says: "Having a good supply of old silver by me in the shape of watch cases, &c., I am desirous of making some pure nitrate solution free from the blue colour; please give me the exact formula for same."—First dissolve the metal in dilute nitric acid—acid, two parts; water, one part; then place some strips of copper or zinc in the solution; this will precipitate the silver in the metallic form. The precipitate is then well washed and redissolved and afterwards crystallised.
- B. C. C. inquires: "Will you please tell me the cause of halation in a negative, and means of prevention? It has occurred in one or two landscapes of mine, exposed with the sun behind the camera."—In reply: Halation is commonly caused by the light passing through the sensitive film to the back of the glass plate, from which a portion of it is reflected forward upon the film, thus blurring the image. To prevent this, paint the back of the plate with a mixture of Spanish brown (or any other convenient dark pigment), water, and enough gum arabic to impart firmness, with a few drops of glycerine to enable it to be readily removed by a wet sponge previous to development.
- TOM asks: "How do some photographers manage such beautiful straight lines to their architectural subjects? I find a great difficulty. While using care, Dallmeyer's rapid, and swing back well out from the bottom, still 'I am not happy' with my results. The camera is propped up on a five-foot tripod, but to obtain the whole building you must slightly tilt, even after lifting the raising front. How do they do it? Is it by using a stand higher than mine or fire away from some elevation, as a first-floor window?"—The rule for the remedying of the evil complained of is very simple: see that the back of the camera is in an accurately vertical position before exposing. If the whole of the subject cannot be included use a lens of shorter focus. In these are comprised the whole secret of straight lines, by which we understand non-converging lines. If the lines are curved it is a certain indication that the lens distorts.
- R. STEWART writes: "Could you help me to obtain a formula for printing on to wood? I have tried every way I can think of and have once been nearly successful, but I cannot find a good substance to coat my wood with first. I have tried all kinds of enamel but can get none to hold strong enough to bear being made wet. If you could help me or put me in the way of obtaining a formula I should be very grateful to you. I can get prints on with a film, but I want to get it without a film on the wood such as collodion or gelatine. I have seen woodblocks with the silver image on a white ground, which I believe is some kind of enamel. To make a photograph on to wood in that way is what I wish to obtain the formula for. I have never seen anything in the JOURNAL of the kind, so I thought perhaps there was something secret about it."—Will any one working the process practically furnish our correspondent with the desired information?
- J. R. GORZ, alluding to a notice that appeared in our number of last week, respecting a compendium of catalogues issued as a separate work, writes: "I find in it an illustration of my 'Volute' shutter described in your JOURNAL some time since, and again exhibited this year (in an improved form) at the Exhibition of the Photographic Society of Great Britain, but mentioned as the property or invention of the Stereoscopic Company, and I am surprised to find that I am entirely ignored as the inventor. I have not parted with any proprietary rights in selling some of these instruments to the Stereoscopic Company, and can therefore not understand by what means they come to claim this shutter as their own, substituting for its original name, the 'Volute' (which is actually on the block by which it is illustrated), the simulation 'Evolute.' Now far their claims to this instrument are made good by prefixing an 'E' to the original name, and using it without my knowledge or sanction, I must let your readers judge."—This is a matter which the Stereoscopic Company will doubtless be able to explain,

CORRECTION.—In the names on the key to the Convention group for "Bunn" read "Brown."

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting, October 5, 1887, will be on *Developers and Developing*. Saturday outing at Broxbourne. Train from Liverpool Street, near two o'clock. During the Exhibition of the Photographic Society the members of the Photographic Club will be pleased to see any gentleman, taking an interest in photography, at their Wednesday evening meetings.

PHOTOGRAPHY IN COURT.—At the Barret County Court the following case was heard before J. J. Cooper Wyld, Deputy Judge:—Ferrari, photographer, v. Dawson, landlord of the Hartshorns Inn, Barret. Claim, 30s. for a coloured enlargement of a photograph and frame containing the same. Plaintiff deposed that defendant brought him a small photograph, and he agreed to make a coloured enlargement for 80s. He had done the work, but defendant refused to pay the money; he produced the picture in respect to which the claim arose. Defendant: That (pointing to the picture) is not my mother. Plaintiff, in reply to his Honour, said he had returned to the defendant the photograph which he copied, but he produced a copy of that photograph. His Honour, examining the copy and the enlargement, said he considered the portrait a good one—the likeness was undoubted. Defendant produced another photograph, saying "This is my mother; that is not." (Laughter.) His Honour, looking at the second photograph, said he could not alter his opinion. Defendant: When that thing was brought home my wife did not know it. His Honour: Is your mother living? Defendant: No. His Honour: Then you can't produce her to the court. (Laughter.) So far as I can judge the portrait is a good copy of the photograph. Defendant said he would like to call a witness, and accordingly called a lodger named Lovey, who stated that he knew the deceased lady, and the portrait produced by the plaintiff was nothing like her. His Honour: There will be judgment for the plaintiff. How can you pay. Defendant: A shilling a month. His Honour: Nonsense. What are you? Defendant: A publican. His Honour: You must pay in fourteen days. I must say the portrait is an extremely good copy of the photograph—perhaps it is a little younger, but there is a certain amount of artistic merit about it, and at 30s. it is very cheap. Plaintiff, on leaving the witness box, handed the portrait to defendant, who refused to take it, and he then set it down in the court. Mr. Jenour (high bailiff): Don't leave it there; it will get broken. You (the plaintiff) had better keep it. Plaintiff: It is not my property. His Honour: You are entitled to keep it till you get your money safe in your pocket. Defendant: I won't have the thing. His Honour: The defendant must pay the money; he will please himself whether he takes the portrait when he pays the money.

THE LATE MR. J. G. TUNNY.—Our obituary of to-day records the death of a well-known citizen, Mr. James G. Tunny, which took place at his residence in Salisbury-place on Saturday morning after a protracted illness. Known for many years as a photographic artist, he early took a prominent position in his profession, and upwards of thirty years ago was the first to produce portraits on paper in place of the then prevalent mode of the Daguerreotype on the silvered plates. This new system he brought to great perfection in his little studio in South Clerk-street, which was then the resort of many in the highest scientific and artistic circles in the city. Mr. Tunny began life in an altogether different calling, but being gifted with tastes which led him to the study of chemistry, he carried his knowledge into practice in connexion with the art with which his name has been closely connected for so many years. In those times the leading Daguerreotypists of the city were Popowitz, Ross and Thompson, Orange and Ivan Zabot. Mr. Tunny soon forced his way to the front, and by 1851 was prosperous beyond his fondest hopes. Scarcely had Le Gray suggested the employment of collodion than Mr. Tunny, perceiving its advantages at a glance, began persistently and indefatigably to strive to overcome the many practical difficulties attending the manufacture of a stable pyroxyline and the production and maintenance of a sufficient sensitising bath. Indeed Mr. Tunny explored every new field which the rapid march of photography opened to its followers, and he communicated the results of all his efforts to the Photographic Society of Scotland, of which Sir David Brewster was the first president, and to all the photographic journals of the period. He was among the first to turn his attention to the production of burnt-in photographic enamels, and at the present time his firm is the only one in Scotland engaged in the practice of this branch. In the working of other methods, such as platinotype and collotype, Mr. Tunny was alike successful. He took great interest in the affairs of the city, and devoted a good portion of his time to what he considered the public interests. He was a Liberal of an advanced type, but for a long time past he has been laid aside from taking any part in these matters. In private life he was much esteemed by a large circle of friends for his genial and kindly disposition, and having by his own energetic exertions raised himself from an humble position in life, he was ever ready to extend a helping hand to friends who had not been so prosperous as himself in the battle of life.—*The Scottish Leader*.

No. 1431. VOL. XXXIV.—OCTOBER 7, 1887.

THE PHOTOGRAPHIC EXHIBITION.

WHEN the members of the Photographic Society of Great Britain and their friends entered the Exhibition room on the occasion of the *soirée* on Saturday evening last, they at once saw that the Exhibition this year is quite up to the mark, and that retrogression could not be thought of in connexion with it. The visitors were very numerous, and the crowding was such as to bear out the aspirations of many that the fine Gallery might have been much greater with advantage. They were received by the leading officials, including Mr. Glaisher, the President, and Mr. Cocking, the Director of the Exhibition, to the strenuous in-season and out-of-season exertions of which last-named gentleman much more is owing for the general success of the whole than an outsider can anticipate. Numerous friends of by-past times were there, and it was a great pleasure to us to resume acquaintance with them, some of them coming a considerable distance to be present on the occasion.

The Exhibition of 1887 may very well be designated one of large direct work, as the first impression we have upon entering the Gallery is the general tendency to produce large direct pictures. Now this reveals two facts, one being the advance made in the handling of gelatine dry plates consequent upon the acquired mastery over the difficulties which of necessity appertained to the introduction of an entirely new mode of producing negatives, and the other fact the advance of artistic ambition in the realisation of some preconceived idea of pose, light and shade, and general effect, which it seems to be evident is now sought to be accomplished by the production of large negatives, over which the photographer can exercise so much personal control, and which, as a consequence, reveal most undoubtedly the capacity of photography for showing individuality of treatment.

Another result which this year's Exhibition shows is the supremacy of platinotype, with its matt surface, or, properly speaking, its absence of albuminous glaze, which gives that atmospheric quality and which adds such a charm to landscapes. Of this we see numerous examples on the walls, and also that as now various tints of colour can be produced, we recognise its adaptability for giving sentiment by the suggestiveness of colour. In this connexion we may observe that the progress made in platinotype printing has singularly brought to the front one matter connected with gelatine negatives about which opinions have been numerous—we allude to the statement which has been discussed before, that distances (especially when grey tints prevailed) were not so easy to obtain with gelatine as with collodion. Probably, as far as the negative was concerned, this may partially be correct, but the printing by platinotype appears to have altered that

condition of things; the sensitiveness of platinum seems to have brought out from the gelatine negative those very delicate tints in distances which will induce photographers to devote more attention than hitherto to landscapes where these conditions form the principal attraction of the view.

In the application of photography to engraving, we are struck with the rapid progress which this branch of our art-science makes towards proficiency. We see on the walls of the Exhibition several very fine examples of, in the first place, the very good rendering of paintings by negatives, and the utilisation of these for the production of metal plates capable of being charged with printers' ink, and then giving off a print which gives so much of the individuality of the painter, without involving anything of the same kind from the manipulator, the plate being almost wholly executed by chemical means. Some of the specimens shown are most unique in their results.

We had anticipated finding many exhibits arising from the impetus given in the early part of the year to orthochromatic photography, especially in its application to natural landscape work, but, strange to say, there is not one example in the Exhibition. There are, however, on the walls several copies of paintings, but they are entirely the production of the same exhibitors who showed some examples last year, and which prove the extreme value of the process used.

There are some exceedingly interesting photographs—collotype prints—of some of the aboriginal people on the earth, which are most wonderful to contemplate, as here we have photography truthfully giving facts and suggesting ideas almost the very antipodes of advanced civilisation, and here our art-science becomes a valuable coadjutor to those studies which are outside the domain of both art and science.

The possibilities of pictorial work being done by photography are exemplified, perhaps, in a very marked way this year—although it will not follow that the attempts have in all cases been successful. At the same time, it is most gratifying to record that the desire is very evident to produce, by photographic means, either a higher phase of portrait work, or to embody the more ambitious aspirations in beauty, grace, and sentiment.

And here crops up the oft-repeated question, How much is due to the model in photographing figure subjects? Well, at once it will be conceded that the camera cannot produce beauty from ugliness, and therefore, so far, the model must be accorded some share of any success; and it also may be observed that it is a great pity, when photographs are being prepared for public exhibition, that considerably more attention is not given to the selection of better models (both for portraits and studies), where beauty of form, expression of character, and general

picturesqueness, invest their presentments with, we may say, local attractions, and then the artistic treatment should enhance and intensify those attributes by studied pose, well balanced light and shade, and carefully chosen colour of the resulting print.

As must inevitably be the case in all photographic as well as in other exhibitions, there will be seen many productions of a very mediocre character, where nothing but the simple and diagrammatic has been attempted from the art point of view, and also some very imperfect technical results from the science point of view.

We rejoice to observe that much attention seems to have been most carefully given to the framing of the exhibits, where the pictorial matter has been effectively aided by the rich *entourage* which has been adopted. Still there are many subjects which would have been doubly enhanced if darker tints had been employed, instead of light and absolutely white mounts.

We are pleased to notice that so many of our veteran photographers still keep up their annual contributions, and it is very gratifying also to observe that fresh candidates for honours are coming forward, to whom we may look for more advanced works, which assuredly will tend to their own prestige and to that of photography.

Medals have been awarded to H. P. Robinson, G. P. Cartland, W. H. Hyslop, Harry Tolley, T. A. Green, H. Collis Pettitt, John F. Roberts, W. J. Byrne & Co., F. Müller, Andrew Pringle, Boussod, Valadon, & Co., Dr. P. H. Emerson, Amman & Swan, J. B. B. Wellington, F. E. Evans, and F. M. Sutcliffe.

The first of a series of critical notices of the various exhibits, both pictures and apparatus, will appear in our next.

AFTER the Convention meeting at Glasgow some of the local members met to consider the best means of showing their appreciation of the willing labour undertaken and so well discharged by their local Secretary, Mr. J. Davie. It was then resolved to give him a testimonial in some tangible form, so that the members might convey to him that they were quite alive to the many onerous duties that had fallen to his share in the working out of the meeting to a successful issue. The call upon the local members as a body was responded to with such hearty goodwill, that the executive committee formed for the purpose met on September 23 in Cranston's Waverley Hotel, and on the occasion presented Mr. J. Davie with a purse of sovereigns.

MECHANICAL processes are, without doubt, making steady progress in England, and some excellent specimens of photographic engraving—*intaglio* plates—are shown in the Exhibition now open. But there are very few examples by the other mechanical processes. Collotype, Woodburytype, relief-block printing, photo-lithography, &c., are, we know, now being worked extensively by several firms, yet the present Exhibition is conspicuous by the absence of examples of their productions. This is somewhat a matter of surprise. Many foreign visitors to the Exhibition, we fear, will arrive at the conclusion that English photographers are still behind the age in mechanical printing processes. Perhaps, after all, many of those who do not show work of this class consider that exhibiting at a photographic exhibition would not be to their commercial advantage. However, as some of these processes become more popular amongst photographers themselves, we may hope for a large show on future occasions.

"THEY manage things better in France," says an old adage; but, if we may judge from a letter that appeared in a daily contemporary one day last week, this can scarcely be said with reference to photographing from the pier at Calais, where it appears to be more rigidly prohibited than at Dover Pier. In France, photographing or sketching in the neighbourhood of fortifications is forbidden by law; at Dover it is simply a matter of *l. s. d.* There any one who chooses to pay

the pier authorities their ten shilling impost can photograph to their hearts' content for an entire day. On Calais Pier photographing is not permitted at any price.

Now that pink-tinted albumenised paper is so very commonly employed, would it not be well to search for more permanent pigments, or dyes, than those which are so generally used? So fugitive indeed are some of them when exposed to light that even a few hours is sufficient to produce a well marked change. We recently saw some specimens which had only been two or three days in a show-case, and nearly the whole of the roseate tint had disappeared through the action of the strong light. The matter would not be of very much importance provided the colour was merely discharged and it left the paper of its pristine whiteness; but this, in all instances, does not appear to be the case. In the examples to which we refer—and we have seen many others like them—an unpleasant, faint, yellowish-brown tint remains, almost suggestive of incipient fading in the image itself. Pink-tinted papers are now being employed for collotype, particularly on the Continent, and it is to be hoped that in this case permanent pigments are used, otherwise it may tend to bring an undoubted permanent process into disrepute.

It may not be generally known to photographers that in the South Kensington establishment are some most interesting examples of very early photography, and the apparatus which was used in the early days. Amongst them are several Daguerreotypes taken by Daguerre himself. There is also a camera picture, in bitumen, by Niepce, taken sixty years ago. The early apparatus is very interesting. Many who may now be considered old at photography have heard, no doubt, of Archer's fluid lens but yet have never seen one, but they can do so in this collection, as well as the first portrait lens made by Andrew Ross, Sutton's panoramic lens, &c. A large proportion of those who have but recently entered the ranks of photography have never seen a complete set of Daguerreotype apparatus. They should pay a visit to the Museum, as they will find much that would interest them as well as afford them some instruction. They would also see examples of photography produced thirty or forty years ago, which would, no doubt, take them by surprise.

In looking through a couple of bound volumes of the now extinct *Photographic World*, published by Bannerman & Wilson, of Philadelphia, about fifteen years ago, we could but be struck by the lamentable condition of the illustrations. With two or three exceptions the prints were all badly faded, although they were for the most part the productions of different photographers. The exceptions were two or three examples of Woodburytypes and photo-lithography. The pictures being bound up in the books have not, of course, been exposed to the influences which are usually supposed to work the destruction of silver prints, namely, moisture and noxious vapours, or the action of light. Evidently American photographs cannot be classed as being a whit more permanent than are those which are made here.

LANTERN SLIDES ON GELATINE PLATES.

III.

WE now come to the exposure and development, the latter an operation which requires care in two separate directions, namely, in producing a pleasing and suitable colour and in preserving the purity and brightness of the lights of the picture.

The colour or tone of the image will depend upon two circumstances, the developer employed and the length of exposure, the one being arranged to suit the other. With regard to the exposure itself I do not propose to say much, as nothing is likely to be so misleading as inaccurate information on this point. I have been myself so woefully disappointed in the performance of plates which, according to their makers, were warranted to produce unheard of varieties of tone with fabulously short exposures, that I shall attempt not to offend in the same way, and will merely say that the proper exposure must be learnt by practice.

One thing, however, I would point out to those who have never

previously made lantern slides with the camera, that is, that they are likely to be disappointed at first in the comparatively long exposures they are compelled to give even with rapid plates, in order to get satisfactory results as regards gradation and tone. It is easy enough to obtain fully, or even over exposed positives with very short exposures, but they will be useless for the purposes of the lantern, though probably answering well for enlarging from or for the stereoscope, as Mr. Chadwick points out. Therefore, I would warn the beginner in this class of work to fight shy of rapid exposures, but rather to commence at the other extreme, by "systematically over exposing," as somebody recently described it.

As regards the light employed, daylight, if available—that is to say, if the amateur's time permit him to work during the daytime—will perhaps prove the most generally satisfactory. Between now and the spring, it is true, the variations in value of our daylight will be many, frequent, and erratic, but on the whole, for convenience of even illumination, I do not think any form of artificial light can approach it; the only element of calculation in its employment is its strength, and as it is used direct and not reflected from terrestrial objects as in a landscape, the actinometer may be employed with perfect safety. All that is needful is to provide an arrangement by means of which the negative and copying camera may be directed at a suitable angle towards a clear sky, or, with a sheet of ground-glass interposed, towards the sun itself, when it deigns to shine. On the whole, however, I prefer diffused light.

In this connexion I may mention a "wrinkle" derived from the JOURNAL some twenty years or more ago, applied then to printing in winter. A correspondent, whose name I forget, pointed out that when snow lies on the ground, ordinary albumenised paper will frequently print quicker if the frames are inclined at an angle downwards to the snow than if turned upwards to the dull leaden winter sky. Setting altogether on one side the question of comparative rapidity, we could scarcely select a better and more even reflector for copying purposes, than a wide expanse of tolerably unsullied snow; therefore, I recommend when the opportunity occurs of a snowfall, that advantage be taken of the cheap reflector thus provided by the reversal of the ordinary direction of the camera.

In case artificial light is a necessity, now that magnesium is so cheap I think nothing else can compete with it for either economy or convenience. Economy is served by the absence of all necessity for elaborate arrangements of reflectors or condensers to distribute the light equally, and this also constitutes its convenience. Nothing more is required than to place a sheet of ground-glass in front of the negative and to burn the magnesium at a moderate distance from this diffusing screen, the distance varying in proportion to the size of the negative it is desired to evenly illuminate.

Whatever form of development may be adopted, strict care must be observed throughout, as in the preparation of the emulsion to prevent the deposition or formation in the film of insoluble lime compounds. Indeed, it is of even greater importance at this stage, for while opalescence of a plain gelatine solution or of liquid emulsion may be partially or nearly wholly removed by the addition of a minute trace of nitric acid with the only ill effect of slightly decreasing the sensitiveness, the same treatment is inapplicable to the film after development, since the strength of acid needful to dissolve the lime would also dissolve the gelatine, or cause it to frill to such an extent as to render the result useless. The means must, therefore, be preventive rather than curative.

For this purpose it is necessary to employ distilled or boiled rain water for development as well as washing, or, if these be not available, ordinary water must be freed from its lime salts as completely as possible by boiling with a small quantity of carbonate of potash or soda, and allowing it to cool and settle clear. The milkiness produced on the addition of the carbonate will show how necessary the treatment is. It is scarcely necessary to take any heed of the alkali left in the water after the lime has separated, but if the operator be ultra-sensitive on the point of accuracy he may neutralise it with hydrochloric acid before mixing his developer or soaking his plate; but I do not think he is likely to be greatly upset in his calculation if he disregard it altogether.

After development, whether pyro or iron be employed, it is desirable, but especially so in the latter case, to transfer the plate,

without previous washing, into a dish of very dilute hydrochloric acid; this will neutralise the alkalinity of the film in the one case, and protect it from the subsequent formation of insoluble lime compounds, while in the case of iron the acid prevents the formation of oxalate of lime, which is far more injurious in degree to the clearness of the film. Two or three successive washes in dilute acid—one drachm to a pint of water—may be used in this latter instance before proceeding to use plain water. The acid must be thoroughly removed before the plate is fixed, or opalescence from another cause—the deposition of sulphur—will result, and this will be impossible of removal.

It will be remarked that I recommend the use of plain dilute acid, and not acid and alum. My reason for this is that alum has an erratic tendency itself to cause opalescence, especially if the washing be carelessly performed and with ordinary water. If any signs of frilling make their appearance—a very rare occurrence nowadays—the evil should be met by the free use of common salt, or, if necessary, alcohol, rather than alum. After fixing the anti-lime precautions may be relaxed, as the danger is then past.

With regard to the formula, we have the choice between alkaline pyro, ferrous oxalate, and ferrous citro-oxalate, but I strongly prefer the first on account of the greater command of colour it gives. Ferrous oxalate may be made to give beautifully clear and colourless lights, and is *perhaps* the simplest developer to use if grey or cool black tones will satisfy, but it is extremely difficult to obtain anything like warm tones by its use. When it is used the solutions should be mixed in the proportion of five or six of potassic oxalate to one of ferrous sulphate, and used at once, and only once.

For warmer tones, though not always agreeable ones, nor under any certainty of control, the citro-ferrous oxalate developer may be used, the exposure of the plate being varied in proportion to the degree of warmth desired and the developer correspondingly restrained. The formula given in the ALMANAC (1887, page 316) answers as well as any modification I have tried.

But for range and beauty of colour we are forced to fall back upon pyro, which is capable of giving all the tones obtainable with either form of iron developer, and others which the iron entirely fails in imitating. For black or grey tones little variation need be made from the ordinary pyro and ammonia mixture—of course using sulphite—if anything the proportion of bromide may be increased with advantage to the clearness and freedom from colour of the lights. In any case, with the formulæ I gave for the emulsion in my last article, the colour will be of a warmer tint, whether grey or black, than when ferrous oxalate is employed. If decidedly brown tones be desired, they may be obtained with the bromo-iodide formula, giving a full, but not abnormally long exposure, omitting the sulphite from the developer and using the solution of full strength, and strongly restrained with bromide to keep the lights clean.

For the warm purple-black or purple-brown tones—which are so greatly admired by most competent judges—the developing solution must be considerably modified by the addition of some quasi-neutral substance, which, while taking no active part in the development proper, exercises a modifying action upon the colour of the image. A number of such substances were mentioned by Mr. William Brooks in connexion with collodion emulsion plates some years ago, and the same materials are available for gelatine with like results. The chief of these are acetate, phosphate, and tungstate of soda, which give purple-brown, purple-black, and brown tones respectively. They are used in the proportion of from five to thirty grains to each ounce of developer, being conveniently kept in solution with the pyro, thus:—

Pyrogallie acid	1 ounce.
Bisulphite of soda	2 ounces.
Acetate of soda	2 to 4 "
Water, to make	11 "

Each drachm of this solution contains as nearly as possible five grains of pyro, with a corresponding allowance of bisulphite and acetate of soda.

Browner tones are given if the sulphite of soda is omitted and the pyro kept in concentrated solution with acetic acid as the preservative, allowance being made in mixing the developer for the neutralisation of the acid and the formation of the acetate necessary to produce the

tone. Very little, if any, difference is produced whatever may be the base employed, provided the neutralisation is so performed as to leave a similar excess of alkali in each case, so that ammonia, soda, or potash may be used as preferred. I am not, however, in a position to say how long such a solution of pyro retains its original properties, having only used it when comparatively fresh.

With regard to the alkali employed, I have a strong preference for carbonate of potash as giving clearness and brightness in the film. Formerly I preferred carbonate of ammonia for the better colour it gives *easily*, but it is an uncertain and unstable salt, and not always to be trusted. The carbonates may be used without restraining bromide, and if the exposure be accurately hit for the particular solution nice warm tones are the result; but if the tone be not right, neither is the colour, so that on the whole I prefer to use the bromide and to expose a little longer than is really necessary.

Very fine tones are obtained with a formula published some time ago by Mr. Brooks in which bromide is dispensed with, and the necessary restraint applied by means of bicarbonate of potash, the loose atom of acid acting as a gentle restrainer. I have not Mr. Brooks's formula at hand, but if from ten to fifteen grains each of carbonate and bicarbonate of soda be used in each ounce of developer, the proportions will be within bounds for the results required. The bicarbonate must be increased with the exposure and warmth of tone desired. One important point in the preparation of this developer must be observed, namely, that it is imperative that the bicarbonate be dissolved in *cold* water. If hot water be used to hasten solution, a portion of the carbonic acid is given off and the acid carbonate converted to neutral carbonate.

It is impossible in these columns to fully treat the subject of variations in exposure and development and their effect in modifying the colour of the image, but I have tried to say sufficient to indicate in which direction the operator should move. I have also endeavoured to show how plates may be specially prepared from gelatine, which for lantern slides shall give results comparatively free from the usual faults of modern rapid dry plates.

W. B. BOLTON.

PHOSPHORESCENCE AND PHOTOGRAPHY.

In the year 1874, I think it was, I engaged myself in numerous experiments in connexion with phosphorescence and photography. I had noticed that the luminous sulphides, particularly the one emitting blue or purple rays, all made impressions on wet collodion plates, which impressions easily admitted of development. The idea readily occurs to one that substances other than the sulphides, and substances which do not emit rays visible to the eye, may nevertheless radiate energy capable of effecting photographic action. The term "phosphorescence" seems scarcely applicable to radiation which is not visible. "Radescence" would seem to be a preferable term. I have found, however, when experimenting with a solar spectrum fourteen feet in length, that different eyes fix its terminations red or indigo in very different places, that what is visible to some is frequently invisible to others; and to me it appears probable that what are termed the "ultra red" and "ultra violet" rays are distinctly visible to some members of the animal "creation." The fishes which have eyes and are said to be "quite blind," and which are found in the silent waters of the great Kentucky cave, miles from the faintest light of day, very likely, in my opinion, do see and enjoy a possibly rapturous existence in a radescence of their surroundings—a radescence invisible to us. Cats are said to see in the dark—upon what evidence I am unaware; but as "eyes were made for seeing," I apprehend that all animals possessing them can see in their natural environment. No one doubts that bats and nocturnal birds can see, yet they are mostly abroad when it is "dark." Cockroaches and various "noxious insects" have eyes, and as they are particular not to be much about until the gloom to us is blackness, I apprehend they are surrounded by what is visibility to them. However, farewell to argument on mere terms. "Radescence," I apprehend, is right, though "phosphorescence" may not be wrong. "Radescence" then be it.

I proceeded in 1875 to make experiments, with the view of ascertaining if there were not bodies emitting radiant energy powerfully photographic in its character, but invisible to my own, and, perhaps,

to any other human eyes. I forget at this moment, and have not by me the means of reference what has been done in this way before. This, however, will not be a matter of much consequence, as my own experiments have not been based on those of others, and the results obtained are certainly of an interesting kind. "Phosphorescence," though generally regarded as an exceptional phenomenon, is, on the contrary, one of the most common, and it is usually regarded as exceptional in consequence of the circumstance that its duration (as visible to the human eye) is in most instances extremely brief (often only the fraction of a second), and that its intensity is extremely feeble. By experimenting in a proper way both these facts have long since been ascertained. Now, as the study of "phosphorescence" commenced naturally (and properly) with the substances exhibiting the phenomenon most conspicuously, my own studies on "invisible" radescence have again naturally and properly begun with those substances which exhibit this phenomenon in the most conspicuous way; that is to say, where I speak negatively of the phenomenon in connexion with a certain body, I do not mean that it does not exist or is not exhibited, but that its exhibition was not detected by the intentionally rude means employed. I have elected to use "standard photographic paper" as prepared by the formulæ of Roscoe in preference to the processes of development, that I might the more readily distinguish the *marked* cases of "invisible" radescence capable of producing photographic action. I will place on record a portion of the results which I obtained, in the order in which I find them in my note-book; and I may here give expression to my regret, firstly, that volume the second of my notes has disappeared during my journeyings abroad, and, secondly, that my work should have been interrupted, as it so often has been, in consequence not only of considerations of a merely pecuniary kind, but in consequence of the very low commercial morality of the present age, which so often—I think I may say so generally—prevents a scientific man reaping where he has sown and gathering where he has garnered. But more of this another time.

August 11, 1875, Experiment 1.—Exposed a sheet of common writing-paper (white) to sunlight for one hour. Placed on it, in a decidedly dark photographer's dark room, a piece of paper cut like a fern leaf. This piece of paper had been for four-and-twenty hours in that dark room (from which *all* light was excluded each time I left) with the object of permitting it to radiate any energy it might possess. Placed on this a piece of sensitised silver paper (Roscoe's standard), and enclosed the whole in a book. Examined under the yellow window after four-and-twenty hours. *Result:* A photograph of the cut-out leaf; not a mere trace, but a bold impression. *Inference:* That photographic action may be induced on chloride of silver paper by contact with certain substances after they have been exposed to light, although they do not then emit rays visible to the eye, and that common white writing-paper is one of these substances.

Experiment 2.—Exposed a sheet of common white writing-paper in a printing frame and under a negative of considerable density for one hour's time to bright sunshine. Removed it in dark room and placed exposed side of writing-paper in contact with standard sensitive paper, and enclosed in book. *Result:* In four-and-twenty hours a distinctly perceptible trace of the image on the negative. *Inference:* That the power of acting on the sensitised paper was caused by the action of the light on the white paper which had been in contact with it.

Experiment 3.—Soaked a piece of common writing-paper in a strong solution of uranium nitrate. Dried and exposed to daylight for some hours. Placed on a piece of standard silver paper crosswise (Fig. 1). Enclosed in book and in a few hours examined. *Result:* A decided brown on Ag paper where in contact with Ur paper, showing wire lines of the writing-paper. The silver paper where uncovered by the uranium paper remained quite white. In twenty-four hours again examined. Very singular result. The brown had vanished from the silvered side of the silvered paper and appeared on the side behind. Contact side quite white and margined by the pale blue tint produced in the first stages of photographic action, and different altogether from the deep brown upon the other side, which resembled the colour produced on photographic paper by long keeping. *Inference:* That paper soaked in a solution of nitrate of uranium is one of those other substances indicated in the inference to Experiment 1, and also that

the photographic image is capable of destruction after being produced, and of reproduction through the thickness of the paper by the con-

Fig. 1.

tinued action in the case of a uranium salt of the material which produced it.

Experiment 4.—Soaked paper in uranium nitrate solution as before, and exposed to sunshine for some hours. Placed a piece at the

Fig. 2.

bottom of a tin box four inches deep. At the top of box placed transversely a piece of writing-paper previously long kept in the dark, and longitudinally face downwards, and above it a piece of sensitised paper (Fig. 2). Left in the dark for four-and-twenty hours. *Result*: Intense photographic action where not shielded by the writing-paper. Intensity of tint, 9 of Roscoe's unit. *Inference*: That the exposed uranium nitrate paper emitted radiant energy capable of producing photographic action on argentic chloride. D. WINSTANLEY.

(To be continued.)

WRITING AND DRAWING ON GLASS.

III.

Black Ink.—In the previous article (see page 568) a film of sugar was recommended as the best coating to apply on glass as a means of enabling writing with pen or lead pencil to be executed thereon. We may now consider the question of the best ink to use. We have already examined common writing ink, and have found it defective in various points, and it becomes necessary to find a fluid better adapted to the special purpose we have in view. We want an ink that shall take freely to the glass, which will not blot or spread, which will produce lines of sufficient depth of colour, and which is adapted for the finest work.

In order that the ink may take or adhere to the glass, we require a fluid of the same nature as the substratum—thus on a surface soluble in turpentine we should use a substance also soluble in that fluid, as in writing with diluted Canada balsam, mixed with lampblack, upon a film of gold size. As we have selected a surface of sugar to work upon, we cannot have a better ink than one consisting of sugar dissolved in water, and, in order to render the writing visible, we must add some pigment to the syrup. Ordinary moist water colours, as used by artists, answer very well indeed; a penny cake of lampblack dissolves quickly in warm water, and if we add a little crystallised sugar we possess an ink that will answer our purpose perfectly. If the ink spreads on the glass more sugar should be added; if it does

not flow freely more water is needed; if the lines are not black enough more lampblack is required. The syrup should be thick enough to prevent the pigment settling quickly, but if the bottle containing it is shaken before use no trouble will be incurred on this account. After the writing or sketch is completed, the work may be protected from damage by a coating of plain collodion on the glass, or shellac varnish can be used without fear of disturbing the design.

Red Ink.—A good crimson ink suitable for glass writing can be made in the same way, substituting crimson lake or carmine for the lampblack. If we use the colour as we find it in the pan, it will not be perfectly transparent, and in the case of a lantern slide the lines would appear on the screen more of a black colour than red; but a simple treatment will cure this fault. We will take a pan of Winsor & Newton's moist water colour, either crimson lake or carmine, and dissolve the contents in about an ounce of hot water; when cold, ammonia is added drop by drop until the brick-red colour turns apparently to a black. This effect is caused by the pigment changing from translucency to transparency. We will now add sugar and water till a suitable consistence is arrived at, which may be ascertained by trying it as ink in a pen on a prepared glass. This crimson ink should be kept in a corked bottle, as if exposed to the atmosphere the transparency is gradually lost, owing to the escape of the ammonia. If the ink should become of its former brick-red aspect, a little ammonia dropped into the bottle and shaken up will set matters right again. Lines written with this ink will be found perfectly transparent and of a brilliant colour; the design may be protected by mastic varnish, or shellac varnish, or plain collodion. As the carmine, treated in the manner described, forms a perfect solution, it is unnecessary to shake the bottle before use.

Blue Ink.—A blue fluid, suitable for writing on glass, can be made in a similar way by using Prussian blue prepared as moist water colour. This pigment being very strong in colouring power, a small portion only of the contents of a pan will be needed, unless a large quantity of ink is wanted. The addition of sugar and water, as directed for black ink, will be all that is necessary. The fluid will then give transparent blue lines, and the writing so produced is not liable to fade. As the pigment settles in course of time, it is necessary to shake the bottle before using the ink. Varnish or plain collodion can be applied over the design as a protective film without fear of any disturbance taking place.

Yellow and Green Inks.—Various other colours can be had with the aid of different pigments. For a transparent yellow ink, we may use gamboge, Italian pink, or Indian yellow, mixed with syrup. These, however, being comparatively weak in colouring power, will not produce dark lines; if a dark yellow is wanted, a trace of lampblack may be added with advantage. By mixing the blue and yellow fluids we obtain a bright green colour; the yellow and crimson mixed yield orange or scarlet ink; the blue and crimson inks mixed together yield a violet or purple liquid. A dark blue may be had by using indigo, or by mixing Prussian blue with lampblack. In fact nearly any colour can be obtained by the various combinations; but it will be found that the black, the red, and the blue, are the best inks for use on glass.

Aniline Inks, &c.—If we make use of the dyes known as coal-tar colours, we can produce a great variety of fluids suitable for writing on glass. The mode of preparing these is not different to that adopted for the ordinary water colours, and the results are very similar in tone, brilliance, and ease of working. We can, however, produce better results with the dyes in the case of the yellow, orange, and scarlet inks, as the corresponding tints in water colours are of a gummy nature, and do not flow very well from a pen. The chief disadvantage of the dyes for our purpose is that the writings done with them do not admit of being varnished with shellac varnish or with collodion, without a spreading action taking place, through the dye being partly redissolved by the spirit. The proper varnish to employ in this case is a turpentine varnish, such as mastic, copal, or diluted Canada balsam. There are some dyes, however, which are insoluble in spirit, and if we could use for these a shellac varnish made with absolute alcohol, we might obtain good results. The ordinary varnishes contain a trace of water, which is sufficient to cause the lines to spread, unless a considerable proportion of sugar has been added to

the ink. As the dyes form perfect solutions, it is not necessary to shake up these fluids before use.

Aniline Blue dissolves easily in cold water, and if sugar is added it makes an excellent blue ink, of a more purple tone than Prussian blue.

Picric Acid, treated in the same way, yields a pale greenish yellow.

Eosine, dissolved in water, with sugar added, makes a capital scarlet ink, which can be made fairly intense by using a strong solution. Eosine is to be had in various shades and qualities—those which dissolve in cold water are the best, as the spirit-soluble dyes are less manageable. There is also a powder of a similar nature to eosine, but of a yellowish orange colour in solution; the sample in my possession dissolves easily in cold water, and makes a better yellow ink than picric acid, as it gives a more intense colour.

Aniline Black is made also of various qualities—one that dissolves in cold water is the best for our purpose; it will be found very intense, and will compare well with lampblack in this respect. It has the advantage over the latter of not requiring to be shaken up before use when prepared as ink, and if it was not so liable to spread during the varnishing it would be the best black ink we could use. The tint being generally a dark purple, it will probably be an improvement to add a little eosine or aniline orange to take off the coldness of the colour.

A small quantity of the ink may be made thus: A large tinned-iron spoon is filled with cold water, some of the powdered dye is then intimately mixed with it, and finally dissolved by holding the spoon over a gas jet, so as to boil the water. A little brown sugar is then added, and the fluid is again heated, and boiled down to a proper consistence for ink. The liquid should be tested by writing with it on prepared glass, and when a correct adjustment of the water, dye, and sugar is made, the black syrup can be poured off into a two-ounce bottle. When cold it is ready for use.

If these inks are in good condition for writing on glass, they will be scarcely suitable for paper, being too thick, and having too much colour for the latter; it will be the best plan to have special inks for each purpose. The foregoing directions for ink making are intended exclusively for glass work, and I believe, from my own experience, that they will be found quite satisfactory for the end in view.

I have not mentioned inks specially intended for the brush, simply because the conditions are the same as with the pen. If the ink and substratum are such that perfect lines can be made with the pen, it will be found that equally fine work can be done with a good brown sable; the latter has greater capabilities, but they can only be fully appreciated by those experienced in its use.

ALBERT WM. SCOTT.

SIMPLE PROCESS OF ENGRAVING GLASS AND METALS.

THERE are very many applications for an inexpensive and effectual method of etching or engraving glass in various forms, plain and plated metals, enamelled surfaces, pottery, &c. Of all existing processes for accomplishing this work, the sand blast is undoubtedly capable of the most universal application. In point of effectiveness and in general usefulness it may never be surpassed, or even equalled; yet a substitute for it, even though incapable of as extended application, will find uses in the arts, and will, doubtless, be appreciated by amateurs.

The requisites for carrying out the process in its simplest form are:—A pound of coarse emery, a pound of lead shot, a wooden box ten or twelve inches long (a cigar box will answer for the experiment), some pieces of glass or metal, and some paper patterns or stencils. The box is provided with a clip at the back and a sliding clamp at the front for holding the plate to be engraved, and it may with advantage be furnished with a clamping device of the same sort at the upper end. The lid of the box must be provided with a packing strip of thick cloth or felt to prevent the loss of emery.

The glass or metal to be engraved is cleaned thoroughly, and to secure the best effects it should be polished. A paper stencil of the desired form is fastened to the glass or metal plate by means of mucilage of good quality. The pattern should be made of thick writing paper, and care should be taken to see that every part of the paper is thoroughly attached to the plate. Any gum around the edges of the paper should be removed by means of a moist sponge. The exposed parts of the plate must be perfectly clean and free from streaks, otherwise there will be undesirable markings on the finished work.

When metal plates are to be engraved, they should be well polished before applying the stencil, to secure good contrasts. For coarse stencils and rough work, the shot should be large and the emery coarse, but for fine work moderately fine shot and finer emery are required.

After the plates to be engraved are placed in the box, the shot and the emery are poured in, the box is closed and the lid fastened, when the box is shaken violently endwise, causing the shot and emery to strike the plates at opposite ends of the box in alternation. The shot, in the operation of driving the particles of emery against the plates, become charged with particles of emery. The emery becomes so embedded in the shot as to be permanent, and a number of shot thus armed, together with loose emery, soon abrade the surface of the metal or glass wherever it is unprotected by the paper, and produce a fine matted surface, which contrasts strongly with the polished parts of the surface protected by the paper. After roughening the unprotected parts of the plate, the paper stencil is soaked off and the plate is dried, and in case it is metal it is lacquered.

Symmetrical stencils, which answer a very good purpose, may be made by cutting paper folded in various ways. Lace may be employed as a stencil, and where only slight etching or engraving is required the pattern may be produced in varnish.

To adapt this method to engraving articles having curved or irregular surfaces, the box is left open at the lower end and provided with a flexible sleeve of soft rubber. The articles to be engraved are held against the sleeve by leather straps. Designs of various kinds may in this way be permanently delineated upon the glass and metal ware, and upon small panes of glass for ornamental windows, for lamp shades, &c. Mirrors may be provided around their edges with leaves and flowers, and metal panels may be prepared for various kinds of ornamental metal work.

NOTES ON TRIMMING PRINTS.

TRIMMING photographs is one of those little matters that do not challenge attention in anything like the same degree as other processes connected with photography. True, most people like to see a nice smooth edge to their prints, as it gives a neat and finished appearance to them. But the importance of it is perhaps greater than that generally accorded, affecting as it undoubtedly does the artistic appearance and value of the work. Artistic, by-the-by, is the only term that can be applied, as no difference is made in any other particular than appearance; but in this respect there is the power either to make or mar. In rather dark subjects especially, the slightest irregularity of the edges is at once apparent and becomes a veritable eyesore and detriment to the general effect. If a picture that ought to be rectangular is a trifle wider at one end than the other, it gives a lopsided look that is very annoying. The clean, straight edge formed by trimming may be said to be the very antithesis of the pictorial lines of the subject trimmed. Uncompromising in symmetry, it is therefore the greatest contrast of picturesque irregularity, acting as a foil to the picture, emphasising straight lines by a near means of comparison, and also increasing the picturesque effect by a severe contrast. I do not think a greater mistake can be made from an artistic point of view than the endeavour to make as large a photograph out of the negative as possible; "*quantitas non qualitas*" is a bad motto, and many really good pictures are damaged by this anxiety to have as much as possible (regardless of the ill effect) of the subject as can be made out of the negative. I would advise that all the worthless parts of the print, judging from an artistic point of view, should be ruthlessly trimmed off, as it is better to sacrifice part than spoil the whole.

To assist one's judgment in this respect, two cardboard masks with square openings the size of the negative will be found very useful. The print may be laid down on some flat surface and the two masks, one on the other, placed over it; by shifting them about it will be easily seen how much and what part of the margin of the print can be cut off with advantage. A pencil mark is then made and the prints trimmed to it. It will astonish many to find the amount of subject that a photograph looks better without. Foregrounds are great offenders in this respect; an unbroken patch of grass or a bare road have little beauty, photographically speaking, although we frequently see a lavish display of both in many otherwise creditable pictures. The free use of the knife on them is an unmistakable advantage.

Other shapes than those bordered by right lines will frequently add to the effectiveness of the subject. Oval, dome, and circular may often be substituted for the parallelogram; the circular is, however, scarcely so pleasing as the oval, and is only suitable for subjects

with little or no sky—those generally denominated upright pictures. Shapes of various kinds and sizes should be easily available to afford an opportunity of trying them on the prints. Preconceived ideas as to the best shapes are not always found best after trying a variety of masks. The form and amount of subject being decided upon, then comes the application of the knife or scissors. It is a very good plan when no large numbers are required, to attach a piece of hard, thick, and smooth cardboard to the face of an ordinary drawing board as a surface to cut upon. The advantages are that the knife retains its edge, the print is easily adjusted, a T square being guided by the edges of the board, and after the first incision the print becomes attached to the cardboard sufficiently firm to prevent it shifting during the remaining trimming, and this without making any objectionable burr on the edges. If a circular or oval shape has to be cut, by first securing the outer edges of the paper to the card by trimming them well, by retaining the paper in its place, facilitate cutting the oval, &c., during that operation, a point of considerable value to those unaccustomed to trim prints with other than straight edges.

A sheet of glass is perhaps as favourite a support for print trimming as any, and if the wheel cutter is used, almost necessary. The principal objection is, it so rapidly dulls the knife, and great care has to be taken to keep the prints in their proper places, on account of the smooth surface. However, the edges of the prints are cut nice and clean, which perhaps makes up for the extra trouble. In cutting, the knife well sloped should be drawn towards the operator; if held too upright there is a chance at the outset of tearing the print instead of cutting it, especially if the ruler or guide is not pressed very firmly on to the print—a point of the greatest importance during the whole of the process. If the print is at all loose between the guide and the cutting surface the cut will be irregular or notched, necessitating further trimming, possibly to the prejudice of the print if the size has been accurately marked in the first instance. Sometimes as little as the eighth of an inch taken off a picture will considerably damage the result, especially in a small print, either by destroying the balance or by removing some small object that the interest of the subject was centered in. For instance, suppose a boy flying a kite; the kite might be cut off, but many things will suggest themselves that being removed or mutilated would wholly or in part destroy the interest of the subject.

A fault we sometimes see is that prints are trimmed out of square, so that buildings have the effect of toppling over to one side or the other.

In cases where architectural objects are portrayed, the first cut should be made parallel with the upright lines of the buildings and this line used as a base for the remaining sides, then there will be no fear of getting out of square as there would be if the first side trimmed was either the sky or foreground, either of which would not supply the check the upright lines of buildings do. The foregoing remarks apply especially to landscape and architectural photography. In trimming portraits the same artistic considerations hold good; in addition, there is the effect of the proportion that it is desirable to convey. A figure is apparently increased in size if a very small space is left between the head and the top margin of the picture; the greater the space between the two the less the figure will appear, irrespective of the accessories used therewith. There should always be a somewhat larger space left in front of the figure than at the back, or the result will be a cramped effect, unpleasant and inartistic, as if the figure was passing out of the picture. In an oval or vignette head and bust, the head being uncovered, the central point of the picture between top and bottom should be generally the chin, but as a very little alteration makes a great deal of difference in effect, no absolute rule can be laid down as to the exact position of the head, this must be left to the artistic perception of the trimmer or mounter, according as the picture is to be placed in a cut-out or on a plain mount. In the latter case the trimming of the margin of the portrait will have to be *most carefully judged*, so that the right *pose* is given. A mask laid over the picture, and pencil marks made to indicate the proper direction of the marginal cuts, is almost a necessity. If the precautions in trimming prints to which I have alluded were invariably carried out we might have fewer large pictures but more artistic ones.

EDWARD DUNMORE.

ADVANCES IN PHOTO-ZINCOGRAPHY.

THE Survey of India Department have published some Notes which cannot fail to interest photo-lithographers. From these we extract the following:—

In the Photographic Office, Calcutta, a new method of preparing the photo-zincographic transfer paper with arrowroot has quite lately

been introduced, which has the advantages of being very much cheaper than the method of coating with gelatine usually adopted, and of giving results quite as good, if not even better, than by the old process.

Bank post paper is coated in the usual way with two coats of the following mixture:—

Arrowroot	140 parts.
Bichromate of potash	70 "
Water	3500 "

After exposure to light, the prints are coated with transfer ink in the press as usual, the transfer ink used being composed of—

Hard retransfer ink (plate to stone)	100 parts.
Lithographic chalk ink	100 "
Palm oil	7 "

After inking in, the prints are washed off with hot water—hotter than is required for gelatine transfers. The arrowroot transfer prints are found to go down well on the zinc without sticking and give clear, sharp transfers. The economy of the process may be judged from the fact that 2½ pounds of arrowroot cost only 5 annas, and coat 70 sheets of paper 34 × 26, while the same quantity of gelatine costs about Rs. 8, and only coats 40 sheets of paper.

A new varnish for negatives has also been introduced, which, likewise, is very economical and efficient. The formula was given in THE BRITISH JOURNAL OF PHOTOGRAPHY for April 22, 1887, as very suitable for gelatine dry plate negatives, but it has been found also to answer very well for collodion. It is as follows:—

Bleached lac	32 parts.
Borax	8 "
Carbonate of soda	2 "
Glycerine	1 to 2 "
Water	320 "

Dissolve the borax and carbonate of soda in 160 parts of hot water and throw in the lac broken into small pieces. Place the containing vessel upon a clear fire or over a gas stove, and stir till the lac is dissolved. When dissolved, allow to cool partially, and filter through filter paper, after which the glycerine is added and the bulk made up to 320 parts. After a few days a sediment separates out, and the solution should again be filtered; it will then come off quite clear and bright. Bleached lac not being obtainable, test pale shellac has been used, and it has been found that the dark colour it gives does no harm.

Collodion negatives are varnished with this varnish while still wet, after the development and intensifying are finished. Gelatine negatives may be immersed in the varnish for about a minute, or it may be flowed over them, and allowed to soak in. In either case a hard, brilliant surface results, which resists the action of water well and shows no tackiness, as the resinous varnishes sometimes do. This varnish is much cheaper than the resinous varnishes hitherto in use, the cost per litre being only 4½ annas, while benzole crystal varnish, the kind most suitable for use in the damp climate of Calcutta, costs about Rs. 8 per litre, and is not such a good protection.

Since the above was written it has been found that the borax varnish is scarcely strong enough for very tender collodion films that have been highly intensified with bichloride of mercury, followed by hyposulphite of soda and ammonia. The addition of more shellac will probably be an improvement.

TEN-PER-CENT. SOLUTIONS.

In the analysis of developing formulae, which will be found in another portion of this issue, the quantities of pyro, bromide, or other salts, have been given in grains and decimals of grains. This notation has been adopted with the idea of facilitating the making up of the actual developer in the case of those members who use so-called ten-per-cent. solutions. Now, although a ten-per-cent. solution seems on the face a very simple expression, it is not so easy to construct in practice, and, as a perusal of the back numbers of the photographic journals will show, is frequently very erroneously described. The difficulty of making up a ten-per-cent. solution arises from two causes—first, from the horrible muddle in which our weights and measures have got into, and, secondly, from the fact that, in dealing with a solution of a dry salt, we are speaking of two terms, solids and fluids. We wish to get a certain weight of solid by measuring out a certain quantity of fluid. A ten-per-cent. solution of a dry salt is really an impossibility. Percentages can only apply to quantities of the same term, and it is incorrect to say that a solution of ten minims of water by bulk containing one grain of pyro by weight is a ten-per-cent. solution,

any more than one could say that ten pears were ten per cent. of a basket of one hundred apples. One ounce of pyro dissolved in ten ounces of water is without doubt a ten-per-cent. solution *by weight* only; but since the whole idea and utility of making a solution is to obtain an easy method of measuring out our chemicals in a graduated glass, instead of having to go through the bother of weighing them, it is manifestly absurd to construct such a solution. Still, as long as we keep to ounces such a solution is perfectly practical, for undoubtedly one ounce of it will contain one-tenth of an ounce of pyro, and one-tenth of an ounce of the solution will contain one-hundredth of an ounce of pyro; but here the absurdity and complication of our measures come in. An ounce of water, a given bulk, weighs exactly, at a certain temperature and barometrical pressure, 437.5 grains; but, as a relic of the dark ages, we have handed down to us an ounce identical in bulk and weight, but divided into 480 parts or minims. You see the difficulty and confusion. As we said above, one-tenth of an ounce of our ten-per-cent. solution by weight contains one-one-hundredth of a grain of pyro, but one-tenth of an ounce of solution measured is forty-eight minims, and this quantity does not contain 4.8 grains pyro, as it should if it is to be a ten-per-cent. solution, but 4.375 grains, for the ounce of pyro contained 4.375 grains. We could, of course, get over the difficulty if we were to take the old apothecary's ounce of 480 grains to make up our solution; but, practically, this would give a good deal of trouble. An ounce bottle or tin of pyro contains 437.5 grains, and we should, therefore, have to open a fresh bottle and weigh out 42.5 grains to make up the difference. Fortunately, however, we can evade these difficulties. Let us see what we really mean and want when we make up a ten-per-cent. solution. We want a solution of which every minim contains one-tenth grain of pyro. This is not truly a ten-per-cent. solution, but rather a solution of one in ten, one grain of pyro in ten minims of water. And I think it would be advisable to call them by this name in preference to the misleading one of percentage. Such a solution is made up in the following way:—Take the avoirdupois ounce of pyro; take, then, the whole bottle or tin, and empty it into a graduated measure; then pour into the beaker 9 ounces and 1 drachm of water, or, if you wish to be very exact, 9 ounces and 55 minims. We have now a true one-in-ten mixture, containing 437.5 grains of pyro, dissolved in 4375 minims of water (4375 drachms = 9 ounces 55 minims), and, therefore, one grain of pyro in ten minims of solution.

I have no doubt that this is what is always meant where a ten-per-cent. solution is spoken of, although, strictly speaking, it is quite incorrect to say one grain of pyro is ten per cent. of a solution of ten minims. If we had adopted the metrical system in England, the difficulty would never have happened, for in this system all the different measures are based on each other. A litre of water weighs one kilo, and one side of its cube gives a unit of long measure.

In those cases, however, where we are dealing exclusively with fluids, all the above difficulties vanish, even with our English measures. In the case of a ten-per-cent. solution of ammonia, for instance, one ounce of NH_3 and nine of H_2O make up a true and correct ten-per-cent. solution, for here we are dealing entirely with one term—namely, bulk, and one ounce of solution will contain one-tenth of an ounce, or forty-eight minims of ammonia; a drachm will contain one-tenth drachm, or six minims, of ammonia. We don't need to trouble ourselves here about grains at all. The first ounce of ammonia is measured, not weighed, and we neither know, nor want to know, how many grains it weighs.

Whilst on this subject, it may not be amiss to say a few words anent dropping-bottles. This is, without doubt, the most convenient form of using the ammonia solution. There is no need to take out a stopper and flood the dark room with ammonia fumes every time you wish to add a drop or two to the developer. A turn of the stopper and the bottle is ready for use. I find the most convenient form of solution to keep ammonia in is as follows:—I fill my dropping-bottle with water, and then let it run out, drop by drop, into a graduated measure, counting the drops. I can then see what number of minims the drops of my bottle are equivalent to. Usually I find about four drops equal to six minims. I therefore make up my ammonia solution in these proportions—that is, 4 of ammonia \times 2 of water; then every drop of my bottle contains one minim of pure ammonia, and I have no calculation whatever to make; if the formula gives three minims of NH_3 , I pour out three drops from my bottle. I prefer this to keeping the ammonia in a ten-per-cent. solution, as in this case with large plates you require a considerable quantity to be measured out, and this requires two hands; whereas, with the dropping-bottle, one suffices. This is a very small matter, after all, but grains and minims are by no means large, and their use or misuse considerably affects results.

—Camera Club.

SUGGESTIONS FOR COLOURED PHOTOGRAPHS.

RECENTLY there was some talk of the production of colour photographs; but, as predicted by the *Bulletin*, the pretenders proved on dissection to be no more than ordinary prints coloured from the reverse side. It is surprising that so crude a thing should hope to deceive even the most unknowing. It occurred to me, when first reading these paragraphs, that some one had put in practice a process similar to the one with which I had previously made a few encouraging experiments.

The difficulty with coloured photographs so far is that the tones and shadows of all the colours represented are formed by the browns or blacks of the print. For example, suppose in treating the picture of a lady it were required to colour the dress blue, when this was done the lighter parts would appear blue but the shadows brown-black, an effect of which nature has never been convicted. A painter would render the shadows principally by increasing the intensity of the blue. A blue print would render the dress more truthfully, but the other parts would necessarily be of the same colour. Now, if we could change the colour of the print locally, so that one part might be red, another blue, and so on, each with its proper gradations, we would have the power to produce more satisfactory pictures of coloured objects. There are several printing processes that are capable of producing pictures of any tone or colour desired, notably the "powder" and carbon processes.

I prepared sheets of paper as directed for the powder process and exposed them under a transparency. Instead of developing the faintly visible image with ivory black in the usual way, I applied dry colours (powders) carefully to different parts as seemed desirable and thus developed a coloured photograph. Being no artist, and using a poor assortment of colours not well adapted to the work, my results were encouraging though not very satisfactory in an artistic way. Still I am convinced that this process, when properly developed, in the hands of an artist would produce results superior to anything yet accomplished in colour photography. I have had no opportunity to continue my experiments in this direction. Something might be done with liquid colours on a film of bichromated gelatine exposed under a positive, which would absorb the colour in proportion as it had not been acted on by light. Again, the carbon process might be followed, the pigment being omitted and the image developed on waxed glass where it might be coloured to suit the fancy before being transferred to its final support. It might be an advantage to charge the film with tin salt or like mordant to produce insoluble precipitates of the required colours.

D. L. HUNTSMAN.

—Anthony's Bulletin.

RECOLLECTIONS OF EARLY DAYS IN PHOTOGRAPHY.

III.

THE Daguerreotype died hard, and many who had got their livelihood from it struggled on, but gradually were reduced to poverty. One morning, a clever Daguerreotype photographer, who came to purchase a few plates, complained of the falling away of customers, at the same time exclaiming that he was dying of starvation. I asked him why he did not adopt the collodion process, and he answered me that he had no means of purchasing the requisite glass slides, &c. I offered to teach him and give him credit for all that was needed. He very gratefully accepted my offer, and in a few weeks paid me. About three months afterwards he received his clients in a flaming *robe de chambre*, and treated them as recipients of his favours, the rush for portraits on collodion glass having been so great and profitable to him.

People from all conditions of life at once styled themselves "photographic artists;" poor dwarfed cobblers and tradespeople of all denominations left their pursuits to become artists in photography. They pitched their tents on houses, between chimneys even, and sometimes often above the chimneys! Others converted their parlours or little courtyards into studios, and some descended into coal-holes to manipulate there. These are things that I have seen, and during that rush if I had opened studios on every street of London and occupied myself only in riding from one to the other to supply their wants and to receive their cash, and even had the people I employed robbed me of fifty per cent., in a very short time the profits resulting would have made me a millionaire. The range of prices from quarter to half-size pictures was so great that it seemed like a fabulous mine of gold opened up to hundreds, but few laid up their profits for the future. Men who followed fairs and were adepts in cutting profiles on black paper soon became skilful in posing the sitters, and I have known some of these people to be prudent enough not to spend all they earned, but become purchasers of real estate and afterwards develop into respectable artists.

Some died leaving wealth, but very few remained at their posts in the advance of science. Mr. Grubb at that time made the finest lens for landscape photography, and thus assured the future success of the greatest discovery of the nineteenth century.

Dr. Hill Norris, of Birmingham, first introduced dry sensitised collodion glass plates, which obtained a short success. The printing on plain paper was helped on by albumenising the paper. This paper for some time was made by the French manufacturers, and owing to their abundant supply of eggs they should have been the sole manufacturers of this article, but the Germans, who were obliged to purchase their paper in France and paid an import duty, succeeded in combating the Frenchmen, and took their position in supplying the photographic dealers throughout the world on equal, or even better terms.

After Dr. Hill Norris produced sensitised collodion glass plates, Bolton, of Liverpool, succeeded in giving a better one, and others followed in the same way; but Colonel Stuart Wortley, a clever amateur photographer, produced a sensitised collodion plate that was even better. My close business transactions, as agent for the sale of sensitised collodion glass plates, allowed me to observe that whatever merit may be due to Colonel Stuart Wortley, the success of his plates was largely due to his wife, a lady descended from a noble family who was a maid of honour to the Queen.

The process for producing Talbotypes required so much neatness in manipulation, that if the suggestion made by M. Le Gray, and so ably perfected by Mr. Archer, to employ a sensitised collodion had not been made, the Talbot process would only have gone side by side with the Daguerreotype, and would have not entirely superseded it as it did.

Talbot pictures were made on a waxed sensitised paper. The first pictures of this class which were shown by Mr. Talbot were small—not larger than 4×6. Waxing paper was accomplished as follows:—Into a strong silver-plated tray sufficient white wax was put that, when melted, would be a deep, clear solution. The tray was placed over a small charcoal fire, and the paper laid on the wax. Great care was taken that there were no air bubbles left upon the paper, and a sheet was removed from the wax, and, while hot, held over it to allow all the surplus solution to drip off. When cool, the paper was put away to be sensitised. That being accomplished, after it had become quite dry it was placed in a dark slide, and pieces of twine were adjusted to keep the paper smooth and flat. All the operations that were accomplished after the paper was sensitised were, of course, done in a room lighted with red or yellow glass.

When the paper was exposed correctly, it was full of detail. It was developed with gallic acid and fixed with hyposulphite of soda. The pictures were usually of a reddish-brown colour, and were seldom a perfect brown or black.

The cleverest preparer of wax-sensitised paper was a man named Sanford, who was also a clever photographer, and at one time the largest producer of albumenised paper.

Among those who made immense fortunes in the great field of photography at this time were two that especially attracted attention: one, a descendant of a very humble family, died Lord Mayor of London; the other, one of a firm of glass-blowers and dealers in barometers, thermometers, and other scientific instruments. These two men's sudden rise to fortune was related to me by Mr. James Glaisher, the eminent meteorologist and since President of the London Photographic Society. During the Exhibition of 1851, Mr. Glaisher was sauntering about, looking at the scientific and other instruments in the show, when he picked up a small glass case containing specimens of blown-glass tubing for barometers, &c. He said to himself: "These were made by workmen whom I have long wished to find," and he immediately sought the address—Negretti & Zambra, Hatton Garden, London. From the interview which followed, orders were sent to them from the Greenwich Observatory, and more extensive ones from the Government. When the Great Exhibition was closed, the building was purchased by a company, which made of it the great Crystal Palace, on grounds at Sydenham, near London. The trustees gave permission to erect a studio in the building, to manipulate in the production of photographic pictures. Permission was given to the under-secretary or principal bookkeeper of the Society of Arts, and, some years after, he granted the permit to Negretti & Zambra.

Daguerreotype photography only had been carried on in the Palace up to this time, but soon after Talbot gave the right to use his patent by the public, and when Archer's collodion process was made known, the making of regular photographs in the Crystal Palace became immensely profitable to these fortunate men. They sold thousands of dozens of card stereoscopic pictures—and all were pictures of the

Palace, grounds, fountains, statuary, &c., within its circuit—at twelve shillings per dozen.

As I have said, there was another man who amassed a large fortune from the pursuit of photography. He early saw that photography would yield large profits to any one who followed it closely, and he opened half of a shop near Hanover-square with the determination to make it pay. This man's name was Nottage. He placed over the door "Stereoscopic Co.," and exposed for sale stereoscopic and other photographic pictures. His success was due largely to the aid which clever photographic artists gave him at home and abroad. Among these I may mention the names of Wilson, of Glasgow; England, of London; and Ferrier, of Paris. Nottage took a large corner house in Cheap-side, London, erected on the top floor a studio for portraiture, and employed the best manipulators in photography. When the Exhibition of 1862 was opened, Nottage was purchasing largely from Mr. England, and he suggested to that photographer to offer a large sum of money to the managers of the Exhibition for sole permission to take photographs of the buildings and on the grounds, and also to erect stalls for the sale of photographs. He obtained the permission and he shared the speculation with Nottage. From the day it was opened until the last day the sales from photographs of the Exhibition amounted each day to 800*l.*, and at one time to 1400*l.*

About the year 1865 the *carte-de-visite* was first introduced by a photographer, and these little photographs at once became popular with the public, and threatened to supersede the stereoscopic pictures in public favour. The success of the photographer in producing the *carte-de-visite* picture was not followed up by many whose situation would have enabled them to obtain custom. The stereoscopic and *carte-de-visite* was the key that opened the door of palaces of emperors and princes to the plebeians, for these pictures gave correct likenesses of the inhabitants of their magnificent residences. The *carte-de-visite* picture was a very great saving of money to royalty, and they were distributed more freely. Autographs generally accompanied the *carte-de-visite*, and sometimes it was sent as a present with a diamond ring or gold pencil-case instead of a coloured miniature on the lid of a gold snuff-box surrounded with diamonds and other precious gems, as had formerly been the custom.

The enlargement of pictures from small negatives was no longer a secret in the hands of a few. I did my utmost to help photographers with a machine to easily accomplish the production of enlarged pictures. About the year 1865, the discovery was made that magnesium was not so rare as was hitherto supposed. It had formerly only been seen in the cabinets of scientific collectors of rare metals, &c., but now magnesium was sold by a firm in Manchester in the form of very small wires about seventy to eighty yards to an ounce, and this wire, when set fire, burned with a splendid white flame which was suitable for making photographs. I purchased with much difficulty one-quarter of an ounce for twenty-one shillings. I was much excited over this discovery, and thought from the light so nearly resembling sunlight that it would greatly benefit the photographers of London, where so many dark days prevailed in the winter, and thought it would also help photographers to work at night. I thought it might also be used for the magic lantern, but the manufacturer of the metal could not produce it free from alloy with other matter. I had this light adapted to the machine for enlarging small pictures, which it did in many instances, before rock oil was better understood. For some years I made the sale of magnesium the speciality of the house with which I was connected, and I have no doubt I was the best customer of the manufacturer of that metal. I may mention that one customer of mine, a Mr. Parker, an antiquarian and the celebrated author of the *Remains in Rome*, from his friendship with the Cardinal Antonelli obtained permission for a photographer whom he kept to photograph the interiors of the catacombs in Rome, and with the aid of magnesium some excellent pictures were made.

At a meeting of the London Photographic Society, soon before the retirement of Baron Pollock, the honoured and revered judge who was President of the Society, there were shown to the members some large pictures on paper which were unlike anything that had hitherto been seen. They consisted of landscapes, and were prints that had been discovered in the studio of Watt, the great engineer and partner of the manufacturer Bolton, of Birmingham. It was said that the studio had been closed for many years after the death of Watt, and had only just been opened by a descendant who found with these prints a camera obscura. The President and others thought that these prints were produced by photographic means, but the colour was a deep brown, one that could not have been acquired by age. They were not lithographs, and it could not be decided upon by the learned members just what they were. If the descendants of Watt have in their possession anything found in the old studio, the present advanced knowledge of chemistry and other scientific studies might enable us to solve this apparent mystery.

J. SOLOMON.

OPINION OF THE LONDON DAILY PRESS ON THE PHOTOGRAPHIC EXHIBITION.

[The Times.]

PHOTOGRAPHY is nearing its jubilee. Like telegraphy, its origin and growth have been almost contemporaneous with Her Majesty's reign, for if any year could be assigned for its invention it would certainly be the year 1839, in which Daguerre and Fox Talbot published their respective discoveries.

No discreditable result of forty-eight years' work is to be seen in the Exhibition of the Photographic Society, which opens this morning at the rooms of the Royal Society of Painters in Water Colours in Pall Mall. The number of pictures shown is a little smaller than last year; but this is itself a distinct advantage, whether it be due to greater strictness on the part of the Hanging Committee, or to the competition of the numerous similar exhibitions which have been held this year in different parts of the country. Certainly in no other respect is there any falling off. In the quality of the work exhibited the present collection need not fear comparison with any of its predecessors. It is true that it contains no striking triumph of the interesting art of photography, nor has it any special examples which can be pointed out as marking progress made during this particular year, but it certainly illustrates, as completely as could be desired, the present condition of the art, and shows the point which the most skilful photographers have now reached. One specially attractive feature of last year's Exhibition is again noticeable. Three or four years ago the most usual objection urged against any collection of photographs was its monotonous appearance. Photographic printing had but a limited range in colour. Only purplish blacks and various tones of brown were available. Even when prints produced by the "carbon" process were shown they were generally of the same tints, and it was understood that the public taste had been so educated to the "photographic" colours that no other hues were permissible in a photograph.

This notion is now quite obsolete. A glance round the walls of the Gallery shows as wide a range of colour as need be wished for monochrome pictures. Probably the old process of printing on albumenised paper rendered sensitive by a salt of silver is still used by a majority of the exhibitors; it is only by a small majority, and its most important rival, the platinotype process, runs it very hard. As regards the best pictures, judged by the awards of the medals, the two processes are precisely on a level, for platinum and silver each carry off six medals. Considering that the adoption of the newer method involves the abandonment of one long tested and thoroughly familiar to all photographers, this fact shows pretty plainly that the cleverest photographers find platinum a better medium than silver. The use of the latest of printing processes, that in which silver is still employed, while the albumen is replaced by gelatine, seems to be for the most part confined to enlargements. Many admirable examples of these are exhibited, the limit of size being reached by two enormous figures, each some eight feet high, which suggest future applications of photography to the art of bill posting. It is, however, but fair to add that the results obtained by direct printing on the gelatino-bromide paper are so like platinotype that it is often difficult, sometimes impossible, even for an expert to distinguish between them, and the catalogue does not always give the process.

The Judges have up to the present awarded seventeen medals, and the awards for apparatus, &c., have yet to be announced. Of these, three have gone to landscape, two to portraiture, four have been given for figure and other studies, one for pictures of yachts, two for photo-micrographs, two for photogravure, two for photographs of theatrical performances, and one for photographic lantern slides.

The landscapes generally are certainly not above the average; perhaps they are even a little below it. Mr. Tolley's view of a bit of cliff and shore, with its single solitary figure, is perhaps the best, but Messrs. Pettitt's and Green's views of the Lake District are both very good. The atmospheric effect in two of the latter gentleman's views is very finely rendered. There are other landscapes nearly as good as the medalled pictures, but certainly none better.

Without much question the finest portrait in the Exhibition is the head of Mr. Perigal shown by Mr. Mendelssohn, who, as one of the Judges, could not receive a medal. Mr. Byrne's prize medal portrait, a life-size head, is fine, but two other portraits in the same frame certainly make the spectator doubtful of the advantage of taking these big heads life-size. The other medal for a portrait goes to Mr. Müller for a pleasing half-length figure of a lady.

The series of studies for which a medal has been given to Mr. Sutcliffe includes some of the best work in the Gallery. They are small landscapes with figures; in two of them singularly beautiful cloud effects are given. Mr. Robinson is well known as one of the most skilful of those photographers who devote themselves to the composition of pictures by photography, either by introducing specially dressed models into a suitable scene, and thus arranging a picture which is photographed as a whole, or by taking separate negatives which in the process of printing are skilfully combined into a single picture. His picture this year of a couple of country girls following a path over a moor, with sheep grazing in the background, is very pleasing at first sight, but a closer inspection raises questions of perspective and lighting in different parts of the picture which detract from its artistic value. Mr. Emerson's *Poacher*, a

study of a single figure, shows a certain artistic sentiment, but is not very attractive. Mr. Wellington's frame of various small pictures has been fortunate in catching the eye of the Judges among so many others of a similar character and excellence.

The medal awarded to Mr. Hyslop for his yachts is thoroughly well bestowed. So much excellence has been attained in this line of work that it is difficult to see where there would be room for improvement, but Mr. Hyslop has succeeded in giving an appearance of life and motion to his yachts that has perhaps never previously been shown. This is due to the fact that the vessels are taken broadside on, when they are passing before the camera with the greatest apparent motion. As a rule, objects in rapid motion are taken when crossing the line of sight at a slight angle, and their motion in the field of view is consequently less. Mr. Hyslop's yachts were, it is understood, taken from a steamer running alongside them, and consequently the difference of motion between the camera itself and the object photographed was probably not very great. The same exhibitor shows some views of the yacht "Thistle," which are not quite so good, but are interesting just now.

Mr. Roberts's theatrical scenes, taken by gaslight, receive a medal on account of the technical difficulties attending such work, and a similar reason must be assumed to justify the medal for Mr. Cartland's picture of the performing elephants at Olympia.

Among the pictures which have not been noticed by the Judges are some which might well have deserved such a distinction. The most interesting series of photographs in the Exhibition is the collection of views in New Guinea by Mr. Lindt. These must be the first of the sort that have reached this country, and they afford an excellent example of one of the most important applications of photography, the production of trustworthy evidence of exploration in unknown lands. For these reasons a medal might well have been bestowed upon them. Mr. Gale (who takes the medal for lantern slides) has some exquisite little figure studies. Mr. Donkin shows some more of his well-known Alpine views (as he is one of the Judges they are out of competition), and Captain Abney supplements these with some fine Swiss pictures from points below the snow line.

Mr. Cobb, whose instantaneous views of London streets are in all the shop windows, has a rival in Mr. England, who exhibits a delightful series of tiny pictures taken from a tricycle with a small camera.

Mr. Wyles and Mr. Mallin show pictures of flying gulls, remarkable as illustrations of the powers of modern dry plates. Messrs. Benque & Co. show some admirable portraits printed in platinotype, while remarkable photographs of lightning have been contributed by E. S. Sheppard and J. Guardia. These, like all previous photographs of the same sort, show nothing of the conventional zigzag flash, but give either waved lines like those produced by the spark between the terminals of a powerful electrical machine, or a series of such lines branching out from the principal lines. Also worth notice are the pictures sent by Seymour Conway, R. G. Wilkinson, L. Sawyer, W. Wainwright, Messrs. West (yachts), G. Davison, T. Hall (some fine heads of dogs, but a little too much "retouched"), the School of Military Engineering, and G. Renwick.

Messrs. Bousso, Valadon, & Co. (the successors to Messrs. Goupil) show some singularly fine examples of photogravure, the largest of which takes a medal, though in point of technical excellence it will by many be thought to be surpassed by a frame of smaller reproductions exhibited by the same firm. Messrs. Annan & Swan also show some good photogravures, for one of which a medal is awarded. These examples show the progress which has been made in the art of reproducing pictures in the form of engravings by mechanical processes. It is true that the plates are very far from being produced without handwork—how much is hand and how much photography cannot be said—but it is quite certain that the process leaves much less to the hand now than it did a few years back, while giving results that are better than of old. The work has been greatly assisted by use of so-called orthochromatic plates—plates, that is, which render colours in a scale of light and shade more natural to us, more consonant with what the eye sees, than the scale on which they are reproduced on the photographic plate. The best results which had up to that time been produced were shown in last year's Exhibition. Similar examples are now exhibited, but nothing very much better. The application of the same process to landscape photography, from which much was hoped, does not appear to have produced results of any great importance.

Only two series of photo-micrographs are shown, by A. Pringle and F. E. Evans. Both of these take a medal, though there seems little in the pictures of the latter gentleman beyond the usual average of such productions. Mr. Pringle's photographs of microscopic organisms belong to a much more difficult class of work.

In addition to the pictures on the walls, the Exhibition includes a collection of photographic apparatus, and this to many photographers is the most interesting part of it. One striking point about this collection is the wonderful complexity of the mechanism which the modern inventor thinks needful, or at all events desirable, for the not very elaborate process of taking a photograph. It would be interesting to know, if it were possible to ascertain, how many of these elaborate devices have been used in the production of the pictures by which they are surrounded. Cameras with every conceivable adjustment, shutters said to be capable to making exposures of any duration from some infinitesimal fraction of

a second upwards, stands which collapse into a few inches and extend to many feet—examples of these and more than these are shown till one admires at once the ingenuity of the maker and the skill required by the user. Among the cameras, the most novel—if it be now novel—is the “detective,” a camera made to look like anything but a camera, with which the unsuspected photographer may pursue his way, undisturbed by the interested street-boy or the suspicious policeman. Several types of these are shown, many of considerable ingenuity and excellent workmanship. They may be considered to culminate in the waistcoat or bosom camera, which instrument is to be concealed within the folds of the wearer's waistcoat or shirt front, the minute lens projecting through a spare buttonhole. Some small but excellent photographs are shown which were said to have been taken in this remarkable little apparatus.

Among the more important of recent photographic instruments is the device by which a series of pictures can be taken on a long roll of sensitive paper, the successively exposed pieces being afterwards cut off and developed in the ordinary manner. The roller slide in its completed form is now just two years old. Several improvements in it are shown by different makers. The Eastman Company show also a good series of “film” negatives taken in one of these slides. To produce these, the thin gelatine film, which is mounted on paper originally, and is in that state exposed and developed, is eventually stripped from the supporting paper, and, after being backed up by a transparent gelatine skin to strengthen it, is used for printing. These films are coming largely into use for outdoor work, but for portraits in the studio, where the weight of the apparatus is not a primary consideration, they are not likely to be used.

[The Standard.]

The Annual Exhibition of the Photographic Society, which has just been opened, enables us to appreciate, at a glance, the vast progress which has been made in an art still in little more than its youth. The visitor who wanders through the rooms in Pall Mall, hung with specimens of every artistic, scientific, or commercial application of sun-picturing, and strewn with apparatus of the most ingenious description, has some difficulty in realising that he is witnessing the triumphs of an invention which began within the memory of men now only middle-aged, and attained nothing like its present perfection until times so recent that we can all recall them. Photography, using the word in its most comprehensive sense, is, indeed, within a couple of years of its Jubilee. Only lately France was celebrating the glories of Daguerre, and erecting a statue to him in his native place. But had Daguerre lived he would to-day have been no more than a century old, and he was so well advanced in life before he hit upon his great discovery that fifty years have not yet elapsed since he and Isidore Niepce parted with their great secret for the very slender pensions paid, in order that their country might present the world with a discovery which, next to printing, has of all the graphic arts influenced it most. Daguerre's ghostly shadows were, however, if wonderful in their way, somewhat expensive, and by no means the most artistic triumphs of the sun. Daguerre died in 1851. But years before, modest and little known, our countryman, Fox Talbot, was hard at work on an experiment which has had more to do with the popularisation of photography than all the improvements in it which have been effected within the last thirty years. Long before he heard of Daguerre's triumph, he had been endeavouring to fix that fleeting image of the camera which had so often eluded the grasp of eager experimenters. But his medium was paper instead of glass. That he succeeded we know. His method may have been cumbersome and costly, and the French, in their excusable jealousy, have declared that it was impracticable. Yet, though inventions out of number have revolutionised Talbot's process, he, and he alone, hit upon the plan which is now so familiar to us. Five years, indeed, before Daguerre's method was a *secret de Polichinelle*, this unobtrusive man had solved for himself the problem of fixing the photographic image on paper. But there was yet another unknown discoverer who anticipated them all. While half the Academy of Sciences were struggling with the difficulty, a poorly-clad, half-famished-looking lad left a plate at the shop of Chevalier, the optician, on the Quai de l'Horloge, which proved that he had succeeded where all others had failed. He promised to return next day and show how the victory had been obtained. But from that hour to this he was never seen. Probably he fell sick, and was buried in a pauper's grave, and the world will never now know the name of the first Professor of Photography, or the details of its earliest romance.

In the Exhibition in Pall Mall there are no signs of crudeness to our eyes. Yet crude, no doubt, and ludicrously imperfect, will to-day's performances seem to the photographers of a decade hence. But we, who lack the power of prying into futurity, may well regard these proofs of the industry and ingenuity of the last thirty or forty years with a pride unchastened by the dread of its being premature. Not only are the pictures fairly deserving of the misused title of “artistic,” but even the mechanical processes by which they have been produced show an advance on what we used to witness, demonstrating the technical skill which is at the service of the art. The old process of printing on albumenised paper, rendered sensitive by a salt of silver, still holds its

own as one of the neatest of methods whereby negatives can be multiplied into positives. But the platinotype runs it closely, and now the direct printing on gelatino-bromide paper is likely to become a rival to the best of the old plans. When the local photographer first made his appearance, his ambition was to imitate the painter's conventionalities. His sitters were lay figures—stiff as tobaccoists' signs. They sat or stood by a marble pillar, with a window curtain in the rear, and had either their forefingers in a “property” volume, or, after the ancient fashion of the painted portrait, pointed menacingly to a pile of correspondence on the table. Nothing like this appears in Pall Mall. Even the “photographic face”—the wooden smirk or the frozen glare—seems to be a thing of the past; instantaneous plates rendering a sitting no longer the torture it used to be in a day of three-minute exposures. There are portraits of people as natural as in life, and *tableaux vivants* which form pictures in the strictest meaning of the term. The landscapes are in many instances even better than the figure groups, for the difficulty of getting the lights and shadows has often been admirably overcome. As for the works of utility, the views of remarkable buildings, and of other objects, the chief merit of which is absolute accuracy, photography has long ousted the pencil from the place which it once enjoyed as the only means of reproducing them on paper. This triumph is in no small respect due to amateurs. They, having more license than the professional photographer, and being less in dread of the pecuniary risks run by the innovator, have in a remarkable degree contributed to the advancement of the art. Some of the best work in this year's Exhibition is theirs. Dry plates are so easily carried that photography forms the favourite amusement of hundreds of tourists and residents in the country; with a result which might well abate some of that kindly contempt which the professional photographer, like the professional painter, is in the habit of extending to the “amateur.”

There are, of course, limits which photography will never pass. A photograph is at best only a transcript of Nature in her passing moods. It is not, and can never be, even in the shape of a “composite” photograph, anything corresponding to what the painter endeavours to transfer to his canvas. But allowing for these deductions, it is scarcely possible to exaggerate the uses of the sun as a limner. A traveller is no longer compelled, like Bruece, to laboriously acquire an art for which he has possibly little aptitude, in order to return with a portfolio of drawings from the region which he visits. He carries a camera, and in fewer minutes than his predecessors took days secures views which put to silence the sceptic, and make his readers almost as wise as himself. In a few years the old painted travel-pictures will have disappeared from the books, though they die hard. Mr. Cope Whitehouse, in the current number of a geographical magazine, has illustrated the persistence of erroneous views by a curious study of Fingal's Cave as it appears in the works of the most distinguished geographers and geologists. Nine out of every ten engravings of it are traditional and erroneous, dating as they do before the days of Talbot; while the illustrations in Livingstone's early volumes of travels bear the distinct impress of being for the most part the results of a London draughtsman's imagination. But science no longer depends for the figures of minute objects on the engraver. Micro-photography has displaced him. The ethnographer has now an ample series of photographs on which to work. By aid of Mr. Dalton's superimposed pictures he can even obtain an average racial or family type. The geologist has found that, as the camera has no theory to support, its sections and its contours are more trustworthy than those which unconsciously take a bias from the prepossessions of the artist. Even the zoologist and botanist find photography serviceable. There are glacier views such as the finest of Agassiz's plates cannot equal, and so large that there can be little question that photography before long will be pressed into the service of the bill-poster. In fact, we all now run hourly danger of being photographed in spite of ourselves. There are “detective cameras,” which render it possible for your *vis-à-vis* at a dinner-party to secure your likeness by means of a tiny instrument, furnished with a lens which looks like a shirt-stud. And there are others which enable the polite gentleman who lifts his hat to a lady to walk away with her portrait at the same moment. The criminal who dreads having his “pictier took” in prison, and does his best by contorting his features to render it unrecognisable, can be photographed in the street and in the dock without his being aware of the fact. At one time the knavish contractor in Peru or China could draw on the London office for work which had never been performed. But now with his accounts he is expected to send a photograph of the condition of his bridge or his dock, so that the Directors may know that they are not paying for what has still to be done. The scholar copies a rare manuscript or engraving by photography, and reproduces it by one of the many photo-engraving processes with a speed and a cheapness utterly unattainable a few years ago. The day will doubtless come when the oft-announced discovery of photography in colours will actually be made. Then the art lover may for a few pounds own half the masterpieces of the Pitti Palace, reproduced with an accuracy which no copyist can approach, and with a celerity which can only be attained by an art which pictures a flash of lightning, a spray of foam from the crest of a wave, a horse in full gallop, or a railway train rushing along at such speed that it is impossible to recognise the faces of passengers at the open windows.

METROPOLITAN INDUSTRIES.

THE ATELIERS OF MESSRS. ENGLAND BROTHERS.

No name is better known in London circles in connexion with photography than that of Mr. William England, who has practised in succession every branch and process of photography from the Daguerreotype onwards, and has done so with a high degree of success, both technically and financially. It is claimed for Mr. England that he was the first who made views of America, especially of the Niagara portion of it, by photography, from which the inference may be deduced that he has been in harness for a long period.

A few days ago we paid a visit to this veteran photographer at his residence, St. James's-square, Notting Hill. The whole of the rear premises is devoted to working purposes.

Since a previous visit, paid over twenty years ago, the *ateliers* have grown considerably in extent, owing to the scope of the business having increased; for whereas formerly it was mainly confined to the production of silver prints, this has, within a recent period, been supplemented by the introduction of letterpress and lithographic printing, the manufacture of photographic mounts in *carte*, cabinet, and every other size made use of in the profession, not to speak of the manufacture of gelatine dry plates, of the performance of which we have had occasion to write favourably only a few months ago.

As Mr. England has for some little time been resting on his oars, the whole of these businesses is now carried on by his sons, under the firm of England Brothers, and it is mainly of the newer departments introduced by them that we are now going to speak.

The various workshops and laboratories are in the rear of the residential premises. The first that we visited was the plate-making department. This has been specially fitted up in the most commodious manner, with all the recent appliances and improvements for this class of work. This department is under the charge of the younger son, Mr. J. Désiré England, who, in addition to being an experienced chemist and photographer, seems to make it a labour of love. We have already had occasion to speak concerning the good qualities of the England plate, hence no observations concerning them are now necessary. At the time of our visit, a collection of pretty little instantaneous views, taken by Mr. England, sen., on a tricycle, were being printed and got ready for the Photographic Society's Exhibition, on the walls of which they are now to be seen. Their inspection will give a stimulus to every photographer having cycling proclivities by whom they are examined. In the plate-making rooms the form of electric lamp introduced by Mr. England some time ago, and shown at the London Societies, is exclusively employed, and we were informed that it is found to be a great advance on any system of lighting previously adopted by them.

Some of the premises are devoted to letterpress and lithographic printing. This, especially the latter, is carried on primarily in connexion with the production of photographic mounts, in which a large business appears to be done. In the letterpress department all kinds of printing is carried on, including books, magazines, and photographic catalogues, one elegant illuminated specimen of the last of these now lies before us, sparkling with gold and coloured inks. So far as we saw, the lithographic department is mainly confined to the printing on mounts already referred to. It is doubtless the case that all kinds of mounts are here made, but at the time of our inspection operations were being confined principally to those with gilt bevelled edges. These we saw produced from the initial stage of being cut from the boards (which are got in five or six tons at a time), to the trimming, bevelling, gilding, and burnishing of the edges, and afterwards to the printing of the names and addresses on them in gold.

The production of lantern slides is a well-known feature of Mr. England's factory. It is safe to say that the exquisite beauty of some of these, more especially his statuary, has never been surpassed. They are produced by the wet collodion process, which Mr. England, in common with many others, holds to be one in which, when worked with knowledge and judgment, lies for transparency work the balance of advantages.

RECENT PATENTS.

APPLICATIONS FOR PATENTS.

No. 13,332.—"An Improved Photometer for Measuring Intensity of Light in the Photographic Camera." J. DECOUDUN.—*Dated October 1, 1887.*

PATENTS COMPLETED.

IMPROVEMENTS IN APPARATUS FOR WASHING PHOTOGRAPHIC PRINTS.

No. 14,099. ALEXANDER KELLAR, Dumfries Engine Works, Bute Docks, Cardiff.—*November 2, 1886.*

My invention relates to the construction of an improved apparatus for washing

photographic prints, and consists in a perforated cylinder capable of rotation within an outer vessel.

The cylinder has formed in it suitable openings at which the prints can be introduced.

I form floats upon the periphery of the cylinder, upon which a jet or jets of water play, causing the cylinder to revolve, and, therefore, carry the prints through the water delivered into the outer vessel.

The latter is fitted with suitable openings for the escape of the water.

The dynamic force of the jets above mentioned may be replaced or supplemented by any convenient type of mechanical motor.

Claims:—1. The combination of water tank, perforated washing cylinder revolvable therein by means of a jet of water admitted into the tank and discharging upon a water wheel combined with said washing cylinder, and an exhaust from said tank; substantially as described with reference to the accompanying figures. 2. The combination of water tank, perforated washing cylinder revolvable therein by a jet of water discharged on to a water wheel combined with said washing cylinder, a perforated central cylinder within said washing cylinder and communicating with the exhaust through a perforated bearing, substantially as described with reference to the accompanying figures. 3. In a revolving apparatus for washing photographic prints, the combination of a revolving perforated washing cylinder, a perforated axial cylinder extending from one end of the washing cylinder to the other, and an exhaust consisting of a tube embracing a perforated bearing and working watertight within a bush fixed in the end of the water tank, a centre pin supported by said bush and engaging in said perforated bearing, and an external tubular continuation of the said tube and bush adjustable for the purpose of regulating the level of the water in the tank, substantially as described with reference to the accompanying figures.

IMPROVEMENTS IN THE PRODUCTION OF COLOURED PHOTOGRAPHIC PICTURES.

No. 14,120. EDWARD WILLIAM PARKES, 3, Salters' Hall-court, London.—*November 2, 1886.*

ACCORDING to this invention, after having taken a negative in the ordinary way and produced a positive either by the carbon or other similar process, I fix the same with the reverse side of print on glass, opal, porcelain, egg-shell glass, or other similar material as a support, which has been previously waxed or French chalked and collodionised. I prefer opal, egg-shell glass, or porcelain, inasmuch as the photographic printer can the more readily discern the quality and various shades and tones of the print required, ensuring more general similarity of light and shade when a number of copies is required, and the painter or colourist can the more easily trace the lines and depth of colour required without the assistance of a paper support, desk, or other accessory, thereby securing more accuracy of detail in colours. Again, the egg-shell glass and finely-grained opal or porcelain impart to the photograph a very artistic and highly-finished appearance, saving the labour and expense of rolling, as usually adopted with photographs on paper or similar substances. The print is then developed on such support, after which it is allowed to dry, and the pellicle receives the required colours in flat tints (either oil or water colours), these colours being first suitably prepared, i.e., if oil colours (which I have found preferable) are used, I add a substance to bind the colours, that is, to prevent the colours from running into one another, and the medium I have found answer best in practice is three parts best terebene, one part pure mastic, a few drops of oil of turpentine thinned with ordinary spirit of turpentine. At times I add amber and best copal varnish in proportion of one to twelve, or jappanned gold size diluted with oil of turpentine. In the case of water colours being used, I employ sufficient ox-gall or similar medium for a like purpose.

I have found oil colours more suitable to my process, as I can lay the colours more flatly and evenly, and infuse the colour into the film by means of the fleshy part of the fingers, or by using a stippling brush pad, or similar contrivance, the brush having a tendency to cause unevenness and irregularity in the substance of the colour and destruction of the film which must necessarily destroy the value of the photograph. I then pour over the film and colour, slightly warming them, a solution composed of and proportioned as follows:—One part of borax dissolved in twelve parts of boiling water, to which I add an equal quantity of varnish made of white lac or similar substance and methylated spirits in the proportion of one to three. This operation fixes the colours and removes all greasiness of oil colours and bubbles, pimples, and peeling off the film, which otherwise occurs when the transfer is effected without this precaution. If jappanned gold size with oil of turpentine has been used in the earlier part of the process the use of the fixing solution may be dispensed with, unless the colours employed are of a vegetable character, when it should still be applied. A permanent support of paper sized and starched, or the ordinary transfer paper is then affixed to the pellicle by damping the paper in cold and warm water alternately, sufficient to cause the pellicle to adhere to the said last-mentioned support.

The pellicle and paper forming the support for the pellicle are allowed to dry thoroughly and then stripped from the glass and mounted on cardboard, opal, glass, porcelain, or other similar suitable strong and permanent support, the result forming a permanent and highly finished photograph in colours.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I would remark in conclusion that I am aware of several attempts having been made to produce coloured photographs by painting on the back of a carbon or other pellicle, and by afterwards stripping the coloured pellicle from the supporting glass, but all such attempts have proved practically unsuccessful, but what I claim as my invention, and desire to secure by Letters Patent is: The improved method, substantially as hereinbefore described, for the production of coloured photographic prints on a carbon or other equivalent film.

IMPROVED PHOTOGRAPHIC MOUNTING CARDS.

No. 5772. LEWIS WOLFE, 30, York-road, Battersea, S.W.—*April 20, 1887.*

My invention has for its object the saving of time and trouble required for preparing and using a mucilage each time it is desired to mount a few photographs. I cause ordinary photographic card mounts to be made adhesive by coating

them with a solution of glue, dextrine, or other suitable material; the adhesive coating may be applied either with a brush or by means of one of the well-known machines in use for coating surfaces with thickened fluids; the cards are dried and are then ready to be used at any time.

To mount a photograph, take a print from its final washing, remove the superfluous water from it with blotting-paper, place it in position upon the coated side of the mount, and press the two into contact in the ordinary way.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—A card suitable for mounting a photograph, coated with an adhesive material in such a manner that when it has become dry it is capable of being used at any time in the manner as substantially described.

" 14	Ireland	Royal College of Science, Dublin.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting was held on Thursday, September 29, at the Royal Institution,—in the absence of the President, Mr. J. H. Day took the chair.

The minutes of the last meeting were read and confirmed.

The SECRETARY acknowledged an invitation to the *soirée* of the Photographic Society of Great Britain, also some tickets for their Autumn Exhibition, which were at the service of any members intending to be in London during the time it was open. He also distributed prospectuses of the *Photographers' Indispensable Handbook*, by Messrs. Welford and Sturmev.

It was announced that the Sub-Committee for arranging an exhibition and *soirée* had succeeded in securing the use of a room at the Walker Art Gallery for two weeks in March next.

Mr. Day exhibited an engagement on opal of a group taken by him during the Ingleton excursion. The opal, executed by Messrs. Morgan & Kidd, was much admired.

Mr. W. B. IRVIN read a paper entitled *A Holiday among the Turks* [this will appear in a future number], illustrated by a number of whole-plate prints on Eastman bromide paper.

A unanimous vote of thanks was passed to Mr. Irvin, and, in reply to a question, he stated that he used a Ross rapid symmetrical lens usually (except the instantaneous exposures), $\frac{1}{4}$ stop, exposures generally five or six seconds, and Ilford plates.

Mr. E. TWIGGE showed some specimens of work on Obernetter's emulsion paper, exhibiting considerable variety of tone.

It was asked whether Obernetter's paper gave the best result with hard or soft negatives, and whether there was any difference between it and silver paper in the character of negative required to produce the best result.

Mr. TWIGGE stated that in his experience a rather soft negative gave the best print; such a one as would print well with albumen paper would succeed with emulsion paper.

Mr. TOMKINSON showed an album of views taken in Norway whilst with the Str. St. Sunniva, promising a paper on the subject at some future date, and Mr. C. M. Robertson exhibited a series of whole-plate enlargements on Eastman bromide paper from quarter-plate negatives.

MANCHESTER PHOTOGRAPHIC SOCIETY.*

Mr. TAYLOR then fittingly introduced the subject of distortion. That phase of it to which he confined himself was the projecting of straight lines as curves, the antithesis of orthographic or rectilinear projection. It is a condition in this class of projection that a ray shall emerge from the lens in a parallel direction from that at which it entered. To fulfil this condition it is necessary that it pass through the optical centre of the lens or combination of lenses employed. But the form of the lens often precludes the possibility of this, as the lecturer proceeded to demonstrate. Returning, he said the nature of the distortion is influenced by the position of the stop; when inside of the lens (that is, between it and the ground-glass) it causes pincushion distortion; outside, barrel distortion. The knowledge of this enables one to copy the most terribly distorted picture in such a way as to yield a result which is absolutely rectilinear. He wound up this part of his subject by saying that it was not material to the issue what particular form of copying lens was employed, so long as the diaphragm is in the position best adapted for giving a flat field and in the optical centre. As both these conditions cannot exist coscientaneously in the single lens, copying and architectural lenses must be compound.

RAPID DOUBLET.

Were he asked in what lens lay the advantage when contrasted with others, he would reply—In that of Steinheil. In 1866 Steinheil invented the Aplanat which, under other names in which the term "rapid" usually formed a prefix, was now more extensively employed than any lens extant. It has much

* Concluded from page 622.

to recommend it: it works with an aperture a sixth or even less of its focus, covers a fairly large field with a wide diaphragm, and with a small one a wide field, and is absolutely orthographic or rectilinear. It is commonly constructed of two kinds of flint glass, as density of material is a condition of the excellence of this class of lens. With light optical flint and crown glass excellent central or axial definition may be obtained with a large aperture, but density of material is essential to definition over anything like an extended field. Mr. Taylor then explained why it was requisite that the glass should be dense, and demonstrated it by drawings with the black board. From this, he said, you will perceive that the aperture of this lens is limited by the density of the glass employed. The greater this density the larger may be the aperture, while still retaining those qualities for which this lens is famous, viz., good transmission of oblique rays. But, unfortunately, glass of this enhanced degree of density is liable to decomposition and discolouration with more or less rapidity. He advised those who possessed lenses, for which a claim for very great rapidity is justly made, to be careful to keep them under cover from the action of light when not in use, as the glass of which they are formed contains so much lead or analogous density-conferring bodies as may ensure serious discolouration and consequent slowness of action before many years have elapsed. A lens having what may be considered a rather small aperture may work more quickly than one having an actual aperture larger in relation to its focus. He here repeated what he had said in another country and under different auspices concerning another, and too common a defect inherent in some of these lenses; that is, their tendency to give a ghost or flare-spot in the centre of the plate.

FLARE IN LENSES.

Lenses prepared by the best and most fastidious manufacturers occasionally show this defect, and in two lenses ranking in precisely the same category, one may have it, and the other be quite free from the defect. This often arises, singular as it may seem, from the very perfection to which lens-testing has been carried in the better class of manufacturing establishments. A watch dial placed at a certain distance forms the test for definition, and when the central or axial definition of the lens has been found to be correct, then is the eyepiece (one of great power) by which the image is tested removed in a line strictly rectangular to the axis until the image of the dial transmitted obliquely is found in line. It is here where the skill of the examiner is displayed. He has to adjust the lenses so as to strike the golden mean between flatness of field and astigmatism. It is a peculiarity of all combinations of lenses that if the field be made too flat, this quality is secured at the expense of astigmatism, or the inability of the lens to transmit an oblique ray under circumstances giving absolute sharpness. For example: If the object to be delineated near the margin of the plate be a white cross upon a dark ground, it will be found that when the vertical lines are focussed to sharpness, the horizontal lines will be out of focus, while by racking the lens in or out, to ensure the sharpness of the horizontal line, the vertical one goes so far out of focus as in many cases to vanish altogether, the full aperture of the lens being employed. It would be out of place here to indicate the methods employed by opticians to effect the necessary compromise between good marginal definition and flatness of field, but for our present purpose I may say that the distance at which the one lens is separated from the other is an important factor in such adjustment. But in aiming at securing that compromise in which lies such perfection as they consider attainable, opticians sometimes ignore an evil that, under certain circumstances, results from adopting the standard that they do. With the most perfectly corrected lens it often happens that when employed for out-of-door work, and used with a small diaphragm, there will be a distressing spot of luminousness on the centre of the plate. This is not peculiar alone to the cemented rapid lens, but was a well-recognised characteristic of the now unused globe lens. It is a peculiarity of almost every existing portrait combination, and sometimes, also, of single landscape lenses. When lenses are used in the studio, for portraiture or groups, it is never seen, but when a bright sky forms a portion of the included subject then it is apparent, but mainly so only when there is a small stop, for the smaller the diaphragm the more pronounced will be the flare or ghost-spot. There is no lens made, even the simplest magnifying glass, that has not two foci, one of them the principle focus caused by the refraction of the transmitted rays, the other being much closer to the lens, and caused by an internal reflection to which a portion of the light has been subjected. This it is which operates in the case of a ghost produced by a single landscape lens, and it is remedied by displacing the diaphragm from its position to the extent of from a quarter to a half inch, the ghost in such a case being an image of the stop, which is in one conjugate of the abnormal transmission, the sensitive plate being in the other. Disturb the relation of the first, and the second vanishes. This explanation does not meet the case where a combination is concerned.

HOW TO DISCOVER THE FLARE SPOT.

Premising that the ghost is only discernible when operating outside with a moderately bright sky, or when taking the interior of a church or similar building, he would repeat what he had recommended as being the best means by which to discover whether a lens possesses this propensity. Screw it on a camera and bring it into a room lit by a gas flame. Go to a distance of several feet and examine the flame on the ground-glass. The image will be sharp, bright, and inverted. Now move the camera slightly, so as to cause the inverted image to be a little to one side of the centre of the focussing screen, and in nine cases out of ten there will be seen a ghostly image at the opposite side of the centre. This secondary image is non-inverted, and upon rotating the camera it moves in the opposite direction to the primary image. The nature of this secondary image or ghost, and the cause of its formation, may be examined in the following way:—Move the camera so that the ghost shall be near the margin, and then, placing the eye in the line of that image and the lens, withdraw the ground-glass, when the posterior surface of the lens will be found to be quite luminous. That the false image is, in this case, caused by a reflection from the back surface of the anterior lens is demonstrable by unscrewing the cell containing it until it almost drops out of the tube, and then, keeping an eye upon both the primary and secondary images on the ground glass, move or slightly wriggle the front cell, which, by its being nearly unscrewed, may now be easily done, when it will be seen that when the primary or legitimate image of the flame remains motionless, the

ghostly image caused by the reflection from the front lens dances about all over the plate. But observe, further, there is a certain distance between the front and back lenses at which this secondary image is sharp and bright, and in proportion as either the front or the back lens cells is screwed in or out so does the image become more attenuated and expanded, till at last it ceases to be seen altogether, while all this time the real image is not seen to suffer in any way. This tendency of the ghostly image to pass out of focus with such extreme rapidity upon separating the lenses by a few turns of the screw or by making them come nearer each other provides the means by which this evil may be cured. A rapid doublet may be excellent for portraits, groups, copying, and every other purpose, and yet break down when employed with a small stop in landscape work.

IMPROVED MOUNTS.

The most generally perfect and useful mount for lenses of this rapid class would be that in which the privilege was afforded the user of making an adjustment to suit work of any nature by the separation of the lenses to a very limited extent, so as to be used under the most perfect conditions for the special work in hand. With a lens of about eleven inches focus a sliding adjustment of half an inch has been adopted with beneficial results. He then alluded in terms of high approval to a system adopted by Darlot, of Paris, in connexion with the adjustability of diaphragms. In one combination which he had from him in 1866 the stops, instead of occupying a definitely fixed position, were inserted in a second sliding tube inside the main mount, thus affording the means of effecting a separation of it from either the front or the back, according to the purpose for which it was being employed. You could have in copying either pin-cushion or barrel distortion, or an entire freedom from distortion at will, a feature of great value when a variety of lenses are to be used in one mount. It is obvious that with such a power at command a photographer can lay the ghost or flare spot with the greatest ease. Mr. Taylor had been repeatedly asked if one element of the rapid doublet could not be used alone for either covering a large plate or making a larger image of a distant object. He said certainly it could; but bearing in mind, first, that as the focus is now doubled the exposure must with any given stop be quadrupled; and, secondly, that the distance between the stop and the lens must be increased. Instead of inserting it in the slit in the tube bring it forward to the end and the marginal definition will be at its best. After speaking of the point from which the equivalent focus of a lens must be measured, and which was near to, but not quite at, the optical centre of a combination, and explaining why it was termed the *equivalent* focus, Mr. Taylor then treated in succession the methods of testing lenses for mechanical and optical defects, explained the principles involved in what he considered the misnomer of depth of focus, and spoke of lenses for special purposes, amongst others, that for detective cameras.

DETECTIVE LENSES.

While any of the generic "rapid" lenses would serve admirably for detective work in an open country or where there was good light, yet would they be found inefficient for a certain class of detective work for which he had a great liking, viz., the obtaining of instantaneous views of scenes in the dark, dingy courts and closes, in which squalor and its accompaniments were so frequently found, in London, at any rate. These scenes necessitated the employment of a portrait lens of considerable angular aperture. But it was unfortunate that portrait lenses when corrected for flatness of field gave marginal definition so low as not to bear subsequent enlarging, while if the oblique pencils were well corrected they gave a round field. In his experience there was only one way available by which the difficulty could be overcome, which was to employ a very ingenious invention of Piazzi Smyth, the Scotch Astronomer Royal, who some years ago made the discovery that by intercepting the rays by means of a plano-concave lens just before they reached the sensitive plate the oblique rays would be prolonged so as to reach the plane of a flat plate without suffering from astigmatism. (The speaker here submitted a diagram showing the position of Smyth's interceptor and the way in which the rays were influenced by it.) By no other means of which he was aware could a picture uniformly sharp to the margin be obtained by means of a portrait lens when worked with its full aperture; and Piazzi Smyth must be recognised as one who had made a useful departure from the beaten path of photographic optics.

THE LENS OF THE FUTURE.

Concerning the lens of the future, Mr. Taylor said it must possess at least one feature: with a fairly large stop it must cover a plate under such circumstances that there will be no appreciable difference between the centre and the margin of a plate as regards definition. No lens now in commerce would do so. One lens only has hitherto existed of which it could be said that the focal delineation of an oblique ray absolutely equalled that of the central one, and that was Sutton's panoramic lens, which was a sphere in every respect, the centre of the flint glass spherical shell being filled with water. But it was defective to this extent, that it necessitated the image being received not on a flat plate but on a hemispherical bowl. The lens of the future must propel a sharp image to the extreme end of a flat plate. Was such a thing possible? Two or three years ago he would have said no, and by employing the ordinary optical glass of commerce he would still say no. But he had recently seen and examined closely a lens produced by a firm of the greatest eminence, a lens in which this apparent impossibility had been most perfectly overcome; the focus of the oblique ray was absolutely equal to that of the central one, so far as it could be determined by a very powerful magnifier. They might accept his assurance as to this, for he had examined the lens under crucial circumstances. But as great difficulties still lay in the way of the commercial introduction of this lens, he would recommend those of his audience who were about to purchase lenses not to take any cognisance of the one referred to, but to secure the best at present in the market while still indulging the hope that the good time coming in which this lens could be commercially introduced would make its advent sooner than he himself could venture to anticipate.

During the course of the lecture Mr. Taylor made frequent use of the black-board to illustrate by diagrams his remarks, and concluded by stating that he

hoped if there was any portion of his lecture not thoroughly understood by any of the members they would allow him to give further explanation, and that he should be very pleased to reply to questions put by those present.

Many members availed themselves of this offer, amongst whom were Messrs. H. Smith, Robinson, McKellen, and the Hon. Secretary; and, in reply to Mr. Schofield, the lecturer gave some valuable information on lantern optics.

Mr. J. POLLITT proposed a vote of thanks to Mr. Taylor, and expressed the pleasure it had been to listen to so high an authority on photographic optics.

Mr. ABEL HEYWOOD, JUN., in seconding the vote of thanks, said, of all things in photography the study of lenses was to many about the *driest*, but the lecture they had just heard had been so extremely lucid that he felt sure everybody in the room must have been interested in the highest degree; and, from the explanations and replies to the questions that followed the lecture, he was sure much profit had been the result.

Mr. TAYLOR responded to the vote of thanks, and spoke in very graceful terms of the Manchester Photographic Society, "one of the oldest, ablest, and most energetic societies in the world."

Mr. Smith exhibited several stereoscopic pictures printed on silver paper which he had mounted in optical contact with glass and rendered transparent by various means. They looked almost as good as transparencies backed by ground-glass.

Mr. Blakely exhibited a number of very beautiful stereoscopic pictures taken during the summer.

Mr. Pollitt showed a negative of the interior of a church and the east window, the peculiarity in the negative was a second image of the window in another portion of the plate. Various opinions were expressed for the cause, the general impression being that the second image was the result of reflection from one of the lenses in use (viz., a doublet).

The Hon. Secretary exhibited a Kershaw shutter made for a pair of stereoscopic lenses.

A letter was then read from the City Waterworks Department cautioning photographers against the waste of water.

The Hon. Secretary distributed a number of circulars from the Photographic Society of Ireland relating to their forthcoming Exhibition. He also exhibited a very simple and apparently efficient print washer made by W. B. Osborn, of Birmingham.

Mr. W. I. CHADWICK said he had not yet tried it, but would do so and report at the next meeting.

Mr. W. WATTS gave notice in writing of a change or addition to the rules which he intended to propose at the annual meeting, to the effect that any member of this Society who should be on the Council of any other photographic society in Manchester should not be eligible for office in this Society.

Some little discussion followed, when the Chairman adjourned the meeting to October 13.

Correspondence.

THE AREA SYSTEM OF GEORGE SMITH.

To the Editors.

GENTLEMEN,—The courteous letter of Mr. Simon deserves a reply, and I will therefore respond.

I must, however, first explain the *rationale* of the whole affair. Although I have been actively engaged in photography for very many years, there was a very considerable interregnum during which it fell to my lot to have only to do with other folk's negatives. I had long formed the opinion that a very large proportion of them might have been vastly improved by a more artistic treatment in the camera, but it is but comparatively recently that I fully realised how simple this was.

The outcome of it was a camera with a long range of focus, and the desideratum—a set of lenses to suit it. I applied in vain to some of the most eminent opticians in this country and abroad, but they unanimously refused to entertain the idea, on the plea that it was contrary to their interests. I therefore had to set about it myself.

The result of my experience is, that for a lantern slide any lens of less focus than four inches produces a "picture" only on condition that the object it is intended to represent is not known. If it is known, the perspective is so strained that the view is not recognisable. On the other hand, a lens of about six inches focus is the most generally useful, while it is the only focus that will allow, and that not always, of a large stop. Further, that on frequent occasions much longer focus is useful—twelve inches or even more. Holding, moreover, the heretical opinion that exposure is everything, development being comparatively nothing, my object was, the greatest possible accuracy in exposure compatible with practical work. My camera has a range of thirteen inches, and could have fifteen (for a greater plate) if it were made square; but as this would increase the bulk I refrain from doing it at present, principally for the reason that vertical pictures on a quarter-plate are useless as lantern slides, while for portraits they are easily obtained by reversing the camera. I therefore use it, as a rule, horizontally, looking through the lens-hole to group my picture, racking out the camera till it is exactly framed by the rear end. This, by its position on the baseboard, approximately indicates the focus of the lens required to secure it. Theoretically, a large number of lenses are required; practically, five are ample, each used as a single lens at the rear end of the one mount; while if used as doublets, one is placed at either end, preferably, according to custom, the longer in front. They interchange by a bayonet joint with a quarter turn. I thus get nine foci; in other words, the church opposite my house, either the whole, with a house on either side, or only the

main door, with, of course, seven on intermediate scales, within the limit of a lantern slide. I find six stops, each double the area of the other, varying from about one-seventh to two-thirds of an inch, ample for all ordinary purposes with the nine lenses.

The set of lenses may vary according to fancy or the capacity of the camera, approximately, say, seven, eight and a half, ten, eleven and a half, and thirteen. The two longest form the longest possible rectilinear, the two shortest the shortest possible, and the five make four rectilinears of, approximately, six, five and a quarter, four and a half, and four inches focus, using in each case the longer in front and the next shorter behind.

The necessary adjunct to the lenses was a system of marking each separately with its intensity ratio, practically the area system.

If Mr. Simon will take the trouble to work out the area numbers of these lenses, and compare the foci of the several doublets obtained by the elaborate formula with the simple rule of thumb and very unscientific process of adding the area numbers together and dividing by eight, he will find that the difference is inappreciable, not nearly ten per cent. in any case, the area number being slightly the smaller.

Now, with regard to Mr. Simon's own experience. Having ascertained that the focus of his wide-angle doublet was seven and three-quarter inches, he correctly estimated its area number as ninety-six, and presuming that his lenses were of the extraordinary divergence he mentions, namely, ten and thirty inches respectively, he also quite correctly estimated their relative exposure values as 160 and 1440, one actually requiring nine times the exposure of the other. This convinces me that he is either an expert, and that he will realise the importance of the fact he has learnt by this measurement (though I fear he may not have the advantage of a range of focus to his camera to utilise the thirty-inch lens), or else that he is *somebody else*.

It is, of course, evident that the simple rule of thumb, of adding together the separate area number of any two lenses and dividing by eight, is not intended as a guide to solving the problem of the various focal lengths, which, admittedly, can be produced by simply changing the position of the two same lenses in the mount; but I venture to predict that if the area system should become as popular as I believe it deserves, no such combinations as a ten and thirty-inch will be employed, and that with more rational lenses the simple method I have advocated will be found sufficiently accurate to ensure its adoption. I have, therefore, no apology to offer for its unscientific character.—I am, yours, &c.,

GEORGE SMITH.

P.S.—Since the above was written I have inquired of Mr. J. Traill Taylor, who confirms my opinion that such a wide-angle lens as described by Mr. S(imple) Simon does not exist to his knowledge, and that if it does, it would be by no means a desirable acquisition. I, therefore, do not hesitate to challenge Mr. Simon's letter as a hoax.

MATTERS OF HISTORY.

To the Editors.

GENTLEMEN,—In page 602 of your valuable JOURNAL Mr. J. Solomon has unfortunately made a very awkward blunder in his recollections of M. Daguerre's early days of photography. Mr. Solomon says:—"Either about the same time, or shortly after the negotiation for the purchase of his secret, he went to England, and from the aid given him in London by a Frenchman named Claudet was enabled to obtain an English patent. The English patent was placed in the hands of an agent to sell, and although the French Government purchased the secret to give to the world, the English patent debarred the gift to the English nation."

The real fact is that M. Daguerre did not obtain a patent in England, although he patented his invention in other countries. After the invention was patented in France, M. Daguerre succumbed to the law when the nation took his patent from him for the use of the French people, the authorities compensating him for the loss of his rights. Mr. Claudet (a naturalised Frenchman residing in England, a glass dealer in Holborn, and who has been dead eight or nine years) observed that M. Daguerre had not patented his invention in England, then availed himself of the English law of patents, and obtained an English patent (No. 9193, 18th December, 1841), and practised in the Lowther Gallery, Lowther Arcade, London. Mr. Claudet was the first who applied chloride of iodine, which entered largely into the Daguerreotype process.

Then, later on, M. Daguerre came to England, and practised his invention in Regent-street, after which Mr. Claudet obtained an injunction from the Chancery Court, restraining M. Daguerre from using that which (although his own invention) was, under the circumstances, the sole property of Mr. Claudet; and not only the profits earned by M. Daguerre, but also all Mr. Claudet's costs of the suit, had to be paid to Mr. Claudet by M. Daguerre.

The statement "after Daguerre obtained his patent in England, he gave a written authority to Mr. Claudet to take pictures in London, without requiring any permission from the purchaser of the patent" is incorrect, inasmuch as M. Daguerre did not, and could not, give any authority, written or otherwise, to Mr. Claudet to use the patent in England, because Mr. Claudet had the *bona fide* property in the patent in England. Mr. Henry Beard obtained an improvement upon Mr. Claudet's patent, and it was said that he earned 100,000*l.* in England.

After the reading of the above, the writer of this cannot drop his pen without thinking of a few words, and carrying on the result of

M. Daguerre's invention. A young gentleman, who was articled to a chemist and did his daily work, employed his leisure hours in discoveries, and in secret mastering Daguerre, Tissandier, Thompson, Talbot, Beard, and Claudet. This young gentleman, in his own leisure hours, shortly before the termination of the apprenticeship, *gratuitously* and *openly* published his collodion process, afterwards called photography, and at the same time proposed the substitution of pyrogallie acid for the gallic acid previously employed in developing the image.

In the same year (1851) the present Photographic Society of London was instituted, with Lord Chief Baron Pollock, President; Sir W. J. Newton, Her Majesty's Portrait Painter, Vice-President; and Mr. Wm. Crookes, the Secretary (who is shortly to be knighted), were the elected officers.

Poor young Archer married, and shortly worked himself to death, leaving a widow and children, at which event some members of the Photographic Society subscribed 600*l.* for the bereaved family.

Wishing continuous success of the Society and of your BRITISH JOURNAL OF PHOTOGRAPHY—I am, yours, &c.,

WM. WEBB.

P.S.—Poor Archer deserves to have many of his statues in every city in the world.

[Our venerable friend, Mr. Webb, has slightly missed the point of Claudet's patent obtained in 1841. It was not for Daguerreotyping, as a process, but for certain alleged improvements connected therewith, such, for example, as the application of lenses of various size to a camera and the capability of using both large or small plates; in short, movable sliding fronts with lenses of short or long focus. A second item in the patent was the application of the vapour of mercury (the developing agent) within the camera, and which in his subsequent practice Mr. Claudet did not employ. The third claim was for a background of painted scenery; and the fourth, the application of artificial light, such as the limelight, in which the oxygen might or might not be charged with the vapour of sulphuric ether. These, it will be seen, do not touch the *process* of Daguerre, but are only improvements upon the practice of the process. Again—and we are really sorry to have to differ from Mr. Webb—when the Photographic Society was formed in 1851, it was *not* under the presidency of Lord Chief Baron Pollock, but of Sir Charles Eastlake, P.R.A. The Chief Baron was not elected President until 1856, and Mr. Crookes did not assume the office of Secretary until April, 1857.—Eds.]

PAINTERS v. PHOTOGRAPHERS.

To the Editors.

GENTLEMEN,—In the interest of the matter, kindly permit me a few lines in reply to "Free Lance's" epistle concerning my correspondence in last week's and earlier issues of THE BRITISH JOURNAL OF PHOTOGRAPHY.

"Free Lance's" tutor told him some stories about the battle of Waterloo. Well, my tutor related once a story about a gentleman losing his temper whenever contradicted in his assertions, and who, instead of proofs for same, gave strong words. "Free Lance" condemns my assertion that a portrait painter cannot have assistance by aid of photography as audacious and ludicrous, because there are painters who use photography as a help, although I proved such work to be nothing else than an imitation, and he himself pointed out a certain class of such productions as fraudulent, and related distinctly a case of this kind. But he gave no details of the circumstances which led him to his conclusion, and consequently, questioned about this particular case, I answer that I cannot form an opinion on such insufficient information. He blames me for this, and calls it impertinence. When "Free Lance" further thinks it a visible proof of the correctness of his first conclusion that in after years he was told "the faces went all black"—so can this, of course, only be an additional proof to himself, not to any one not fully acquainted with the secret circumstances which made him formerly sure of the committed fraud.

Concerning the blackening of paintings by keeping them in the dark, so are the meanings of experts divided, whether this result is the exclusion of light or atmospheric influences of the respectively closed rooms. Paintings excavated at Herculaneum were found conserved as fresh as if they had been painted yesterday, but changed rapidly after exposure to air and light.

Although I never mentioned a single word about the *technique* of oil paintings in all my notes, "Free Lance" denounces my "lack of practical acquaintance with the *technique* of oil painting as used by artists." He must have here again secret reasons, known only by himself, which led him to this conclusion. The remark about a varnish-maker starting business is too famous, as not to provoke the question why painters should be compelled to buy from a man who cannot supply the thing they want?

Finally, "Free Lance" says I am wrong in all what I said about second painting, &c., it being "little better than nonsense." If so, then a great many painters of my special acquaintance must be betrayed as I myself, notwithstanding long years of experience, and the fact that all my suggestions in my notes were, and are, only repetitions according to principles taken from the periphery of art academies of which we were, and some of us are still members, and then, in *nomine* *Patris et Minervæ*

sanctissima, I humbly acknowledge I am beaten and we all were shamefully deceived. With gratitude to your forbearance—I am, yours, &c.,
A PAINTER.

[This subject has now received due elucidation.—EDS.]

AMATEUR PHOTOGRAPHIC EXHIBITION.

To the Editors.

GENTLEMEN,—We shall be obliged if, through the medium of your columns, you will allow us to notify to those of your readers interested in our forthcoming Amateur Photographic Exhibition, that the sending in of exhibits has been extended for an additional fourteen days, and that the closing day is now fixed for October 20. Our reason for giving this extension of time is owing to the numerous letters that have reached us from amateur photographers stating that owing to absence from home they have been unable to develop and print their specimens. Allow us, at the same time, to remind those of your readers who are amateurs, that we have arranged with the Secretary of the Photographers' Benevolent Association to hand over to him intact all the entrance fees connected with this Exhibition.—We are, yours, &c.,

THE LONDON STEREOSCOPIC AND PHOTOGRAPHIC COMPANY, LIMITED.
54, Cheapside, E.C., October 3, 1887.

THE CORNWALL EXHIBITION REPORT.

To the Editors.

GENTLEMEN,—Mr. Brooks, as one of the Judges of the Royal Cornwall Polytechnic Society's late Exhibition, shows in your last issue that the report of the Judges has been tampered with in the columns of a contemporary, but he does not show to what extent or in what manner.

As one of those mentioned in the report, I may point out that there are not only suppressions of parts and alterations of words and phrases, but the editor has undertaken, without any explanation, the very grave responsibility of substituting his own words and opinions for those of the Judges, thus deliberately falsifying an official document.

An editor, I believe, may refuse to admit anything to his columns, but having accepted an official report for publication he is bound in honesty to print it in its integrity. Trivial omissions, perhaps, may be doubtfully justified (if explained) by want of space, but by what name are we to characterise the substituting of passages of his own of which the Judges knew nothing? To quote "J. B." in *Dombey and Son*, "one hardly knows what one comes to when one comes to that!"

A paragraph in which my picture was, perhaps, unduly praised in this report must have been extremely distasteful to the editor of the contemporary in question, for he entirely suppressed it and substituted one of his own which conveyed a different meaning to the original.

The moral of all this is: If we convict the editor of a journal, as is done in this case, of falsifying official documents, how are we to believe in the veracity or honesty of anything else written by the present editor of your once well-conducted and highly respected contemporary?—I am, yours, &c.,
H. P. ROBINSON.

Tunbridge Wells, October 3, 1887.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a NOM DE PLUME as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

PHOTOGRAPHS REGISTERED:—

W. Crawford, 18, Wentworth-place, Newcastle.—Photograph of paddle steamer "Ivanhoe" arriving off Corrie.

T. Ball, 7, Comberton-hill, Kidderminster.—Photograph of Arley Church interior.

L. F. C.—See table of enlargements in the ALMANAC.

Boxwood.—It is our intention to have some articles shortly on photographing on wood.

J. McLEOD.—You may present a claim, but it is doubtful if the railway company will admit it.

A. B.—Any formula will answer if you use the equivalent proportion of the potassium salt for any other that may be given.

C. BANYARD.—See report of the Manchester Photographic Society in the present number. The Pall Mall Exhibition is now open.

F. & C.—The address of such firms as you desire will doubtless be obtained by writing to any towns in the pottery district, such as Stafford.

R. W.—The slides are made too dense in the development to begin with. Make them less intense; they will then require less toning, and the stain will be avoided.

HENRY STURMEY.—As we understand Mr. Gotz, his grievance is not so much against you as against the firm who appropriated his invention, and made a colourable imitation of its title. The matter had better rest here.

P. B. W.—1. Bad paste is evidently the cause of the fading. Acidity must have been induced.—2. For the irritation on the skin after developing, try the application of vaseline. Thanks for the fine pictures taken at the Convention.

R. WILSON.—The specimen forwarded is not a photograph or a photo-mechanical print, it is simply a lithograph printed in a colour to imitate a photograph and then varnished. A large business is done in these pictures at watering-places during the season. Many people purchase them thinking that they are really photographs.

H. B. A.—1. Messrs. Boeth Brothers, Dublin, supply a very good mitring machine. Messrs. Marion will supply the other articles.—2. Yes, if the slide be altered to take the smaller size spools.—3. If ordinary print will not answer your requirements the table might be covered with American cloth and neatly nailed over the edges. This can be easily washed and kept clean.

S. E. TURNER writes: "I have an oil painting to copy which is very old and indistinct as well as very yellow, apparently from the varnish having changed colour. How had I better proceed?"—In the first place carefully wash off the dirt with clean water and a little soap and dry with a soft cloth, next rub the surface over with a soft rag charged with linseed oil, which will bring up the colours; then copy on an orthochromatic plate, using a yellow screen with the lens. In place of the oil glycerine is sometimes used; but this is not good for the painting.

F. A. C.—1. As you have been getting on so well with the formula you have been using we should not recommend you to make a change. In the formula you quote the proportion of pyrogallic acid seems unusually large. Different workers often have pet formulae which they imagine are superior to all others. After all, much depends upon the operator.—2. We are pleased the article *The Effect of Moisture in Printing* has proved so useful to you. Bear the fact in mind if you meet with similar toning difficulties in abnormally dry weather.—3. The acid to acidify the sulphite of soda is much a matter of opinion; on the whole, sulphurous is the best.—4. Most retouchers use from H to HHH pencils. You ought to experience no difficulty in obtaining these grades at any artists' colourman's.

J. HAMPTON asks: "Can you please tell me the following?—1. I have got a lens by Ross for pictures $8\frac{1}{2} \times 6\frac{1}{2}$, rapid symmetrical, it is said to have an equivalent focus of eleven inches. I have no copying camera at present, so I do not know how large a map I can copy with the lens. I have a map sixteen inches square, and I want to photograph it the same size (sixteen-inch); will the above lens do for that?—2. How long bellows must the copying camera have to pull out for the sixteen-inch map?"—1. The eleven-inch focus lens will certainly not do for copying the map. One with an equivalent focus of at least twenty inches—twenty-four would be better—will be required. However, the copy may be made smaller in the first instance and subsequently enlarged; but unless this is skilfully done a loss of sharpness will be entailed.—2. To copy an object the same size, the camera must be extended to double the equivalent focal length of the lens, whatever that may be.

J. COURTIER says: "I carried out your instructions as regards the old silver, and find that the acids dissolve the strip of copper I put in to throw down the silver, so that I still get a coloured solution, but it is green. Is it possible to get the silver nitrate white like the nitrate of commerce? Will you also kindly inform me the best mode of crystallising and evaporating to dryness, with the proper appliances? Is there a table of exposures showing the difference in time of exposure for different size stops and work? Also, where can I get a list of the standard stops with their diameters—in fact, a complete explanation of above?"—In reply: No doubt far more acid has been used than was necessary to dissolve the silver; however, sufficient copper must now be added to precipitate the silver; then, as we said before, the precipitated silver must be washed to get rid of the copper before it is re-dissolved. In this way colourless nitrate of silver may be obtained. To evaporate, place the solution in a Berlin evaporating dish on a sand bath over a Bunsen burner until crystals begin to form, then turn out the gas and allow it to cool. The crystals are now collected and dried. The mother liquor may then be evaporated to dryness, but from this perfect crystals will not be obtained. The tables will be found on pages 341-2-3-4 of our ALMANAC for the current year.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting, October 12, 1887, will be *Photography by Artificial Light*. Saturday outing at Hampstead. Meet at "Bull and Bush" at six o'clock.

CAMERA CLUB NOTICES.—Thursday, October 13, at eight p.m., Mr. Lyonel Clark: *The Selection of Lenses*. Thursday, October 20, eight p.m., Lantern evening. Mr. W. Brooks will show a series of lantern transparencies of interiors of Windsor Castle. Members are invited to bring slides. Thursday, October 27, eight p.m., Dr. G. Lindsay Johnson: *The Practical Testing of Photographic Lenses*. Members are invited to bring lenses to be tested.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1432. VOL. XXXIV.—OCTOBER 14, 1887.

INCANDESCENT GAS LIGHTING.

How to get the most light and the purest light from gas has long been a problem in the solution of which all are interested.

The incandescent system has for many years engaged much attention. Briefly speaking, this system consists in the employment of the heating powers of the gas, especially when mixed with common air, in bringing to a white heat certain bodies which, when thus rendered incandescent, emit a light more or less powerful.

In the early summer of 1868 we published a system of gas lighting introduced by a Frenchman, M. Bourbouze, in which a mixture of air and gas, the former under a pressure of seven inches, was propelled against a thimble or other shaped sheet of platinum gauze, which, being thus rendered incandescent, emitted a pure and powerful light. This was known as the Bourbouze lamp, or, more generally, as the platina gauze lamp. Although changes were rung upon its construction, and patents obtained for it since the time mentioned, yet has it never found general acceptance with the public, probably from the fact that the air had to be emitted under considerable pressure, necessitating the employment of machinery or some analogous means for its propulsion. In Mr. Lewis's lamp, described in these pages three or four years ago, the requisite degree of draught was obtained, when the light was employed on a domestic scale, by making use of a tall chimney, one from three to six feet in length, which proved inconvenient, although when thus burnt the light was a very excellent and steady one.

In order to ameliorate the inconvenience of this very tall chimney, we adapted to the stand of one of Mr. Lewis's burners a small fan driven by clockwork, which supplied the air to the jet under conditions approximating those obtained by the elongation of the chimney; and when the lamp thus modified was placed in a lantern some good enlargements were obtained with a not unduly protracted exposure.

The recent improvements in incandescent gas lighting effected by Dr. Auer, appear to overcome the various difficulties hitherto incident to this kind of illumination. The Welsbach light, so termed from the residence of its inventor, while in general principle similar to those mentioned, differs from them in this important degree that, instead of the thimble or mantle which caps the flame and is by it rendered incandescent, being of metallic gauze, it is formed of a species of muslin made of cotton, which, after being impregnated with the salts of certain refractory metals, zirconium for instance, is afterwards subjected to a high temperature for such a length of time as suffices for the entire destruction of the cotton fabric, the mantle thus becoming converted into zircon. The advantage of this over the metallic platinum mantle, is that

the requisite incandescence is obtained by the admission of air which is not under pressure other than that induced by the current of gas with which it is mixed, under conditions similar to those which obtain in Bunsen or atmospheric gas burners of the usual order. Hence its applicability for domestic lighting.

We have been fortunate enough to see the preparation of the Welsbach burners from beginning to end, and shall endeavour as briefly as possible to describe it. The factory, which is situated in Westminster, within a few minutes walk from St. James's Park Station, seems to be very complete, and we saw in every room a large staff of *employées*, mostly young women. In one room we saw seven or eight machines of a nature similar to those employed in stocking weaving. By these the mantles were being manufactured from cotton thread and turned out in long gauze-like tubes, which were afterwards cut into suitable lengths and transferred to another set of operatives, who, by means of gold needles, stitched one end of each to a loop of fine platinum wire, by which they are afterwards supported when *in situ* in the burner. In connexion with the needles employed we were told that iron or steel would prove fatal to the subsequent efficiency of the mantle, and that too great care could not be taken to prevent these or any of the baser metals from touching them.

In another room these mantles, now about the length of one's finger and of a somewhat greater diameter, were "impregnated" by immersion in a solution which we understood to be that of zirconium, after which they were transferred to a drying room, where they were hung over glass rods. This room was strongly heated. When dry they were taken to the shaping and centering room, where by dexterous manipulation each was made to rotate, and "patted" into its ultimate form by a small platinum spatula and brought into centralisation. There being a Bunsen flame playing on the inside of the mantles they already at this stage began to emit a strong light, and we observed that several of the operatives thus employed wore coloured spectacles to protect the eyes. After this operation the Bunsen flame had, we were told, to be allowed to play on the mantles for two or three hours in order to ensure the last traces of the cotton being destroyed. In order to do this there were seven tables, on each of which there were about fifty lamps all undergoing this finishing process; the light thus emitted was intense, but the heat was not so great as would have been anticipated owing to perfect ventilation. When this operation was completed, the lamps were then transferred to a packing box and were ready for market.

According to the constitution of the impregnating bath, so is the colour of the light. When zirconium alone is employed the light is of a pure white colour, which, we were told and we

know it from experience, ladies rather object to, as they imagine it imparts a somewhat pale, if not sickly, tint to their faces in contrast with the yellow colour of an ordinary gas light. To meet this difficulty the mantles are made in two classes, one giving a white light and the other of a yellower and warmer hue. This latter is done by the addition of a salt of cerium to that of the zirconium.

For photographic purposes it is the white light that must be preferred, for reasons too well known by every one who is acquainted with the diminished action of coloured lights upon sensitive plates. While not of such a penetrating nature as some other lights, the Welsbach answers well for enlarging photographs by the lantern, and it is in this especially that advantage arises from the employment of a white light.

Although we have not tried the experiment, we imagine that by the employment of a battery of six or seven such lights judiciously controlled by reflectors and screens, there would be no difficulty experienced in taking portraits by its agency.

The "life" of one of these mantles is estimated to be a thousand hours of burning, at the termination of which time it can, of course, be replaced by another.

"TEN PER CENT." OR "ONE IN TEN" SOLUTIONS?

AN article by Mr. Lyonel Clark on *Ten per cent. Solutions*, reprinted in our last issue, is so well calculated to raise fictitious troubles in connexion with a highly convenient system, that we cannot refrain from drawing attention to it rather for the purpose of preventing its leading others astray than from any new information to be derived from it. We take this step the more readily because it was in the editorial columns of this JOURNAL that "ten per cent. solutions" now so universally employed were first advocated, and there also the modes of accurate preparation of such solutions have been frequently discussed.

The distinction Mr. Clark attempts to draw between "ten per cent." and "one in ten" solutions is one entirely without a difference, and is little more than an *ad captandum* argument to draw the unwary off the scent. A ten per cent. solution is a one in ten, and *vice versa*, whatever arguments Mr. Clark may bring forward to prove the contrary. It is difficult to grasp his meaning when he says that a "ten per cent. solution of a dry salt is really an impossibility," unless he means the statement to apply to the fictitious difficulty he has raised for apparently the sole purpose of laying it, namely, the conjunction of grains and minims. Forsaking for the moment our own uncouth system of weights and measures, does Mr. Clark seriously mean to argue that one hundred cubic centimetres of solution containing one gramme of "dry salt" is not strictly and absolutely a one per cent. solution in the clearest sense of the term? The attempted analogy between "a solution of ten minims of water by bulk with one grain of pyro by weight," and ten pears in a basket of one hundred apples, is illogical; while to say that "one ounce of pyro dissolved in ten ounces of water is without doubt a ten per cent. solution *by weight only*" is indubitably incorrect.

It may be, and we hope it is the case, that Mr. Clark has badly expressed his meaning. It is "without doubt" that such a solution would be a ten per cent. one neither by weight nor by measure; by weight it would be a nine and one-eleventh per cent. mixture, each ounce containing one-eleventh of an ounce of pyro, while by measure it would be

somewhere between a nine and a ten per cent. It has been over and over again pointed out in these pages that in making percentage solutions, or solutions containing definite proportions of the ingredients and which are to be used by measure, the proper way is not to measure out the full volume of solvent and add to it the full weight of salt, but to dissolve the latter in a portion only of the former, and then to make up to the required bulk. Mr. Clark can scarcely be ignorant of this, though again he does not express himself accurately in giving his directions for making what he calls a "true one in ten mixture," for he tells the reader, after placing an ounce avoirdupois of pyro into a graduated measure, to "pour into the beaker . . . if you wish to be very exact, nine ounces and fifty-five minims" of water. It is clear that by following the directions the volume of solution would greatly exceed the 4375 minims required. Mr. Clark ought to have said "pour into the beaker *sufficient water* to make nine ounces and fifty-five minims of solution."

The discrepancy between the subdivisions of the solid and fluid ounces, and its bearing on this particular question, appears to have long since struck those who have previously advocated the employment of solutions, so many minims of which are intended to represent one grain of the solid contents, call them what we will, though the matter appears only now to have attracted Mr. Clark's attention. Mr. H. B. Berkeley long since, in introducing the sulpho-pyrogallol developer, directed about eight ounces, or eight and a quarter of water, to be used with one ounce of pyro—a quantity which, with the increase of volume caused by the pyro and sulphite, brought it practically to a ten per cent. solution. Several makers of plates also direct an ounce of pyro to be dissolved to make nine, ten, or eleven ounces of solution, as the case may be, the first being for all practical purposes a "one grain in ten minims" solution, and the last one in twelve.

The solution containing one ounce avoirdupois of pyro in a volume of ten fluid ounces is, despite Mr. Clark's statement to the contrary, strictly and accurately a ten per cent. solution both by weight and volume, but the error is his of attempting to use the wrong system of volumetric subdivision. If, for convenience sake, he must dissolve an avoirdupois ounce of pyro at a time—and we wonder how often, when accuracy is a point, the one-ounce bottles contain exactly 437.5 grains—he should act consistently and obtain a graduate such as we have frequently recommended, namely, one divided into "grain measures" instead of into minims, and the last trace of the difficulty will disappear. If, on the other hand, he must use minims he must weigh out his pyro in accordance with the requirements of a ten per cent. solution.

But supposing we ignore the fact that one minim by measure of water is less than a grain by weight, what practical difference will it make in developing? The photographic chemist scarcely finds it necessary in *any* of his operations to strive after the minute accuracy of the analyst; certainly not in development, where the elasticity of the plates affords a very wide latitude, and less still with regard to the item of pyro. With plates of good quality variations of one or two hundred per cent. may be made in the quantity of pyro employed without producing any particularly disastrous results, while even with the most delicately constituted films we question whether a difference of twenty-five per cent. in the strength of the pyro solution would produce any difference in the result on the closest scrutiny whatever length of exposure is given, provided it is the same in the cases compared. What, then, would be the error in

dissolving one ounce of pyro to make ten ounces of solution to be measured by minims? We shall find on calculation that each minim of the solution contains '0911 of a grain of pyro, or a drachm contains five and a half grains nearly; that is to say that in mixing two ounces of developer to contain presumably six grains of pyro, we rob it of half a grain, or less than nine per cent. If we found that such a variation of the strength of the developer produced any appreciable difference in our results we should change our brand of plates for one that required less careful treatment.

Passing from the percentage solutions of solids, which, in the earlier portion of his article he declares to be an impossibility, though he afterwards somewhat modifies his view, the writer goes on to state that when dealing with liquids the difficulties immediately vanish, even with our English measures, as we are "then dealing entirely with one term, namely, bulk." The difficulties vanish because one has not the same power of raising them, unless, indeed, he goes to the trouble of mixing liquids of different specific gravities by weight and using them by volume.

But the statement that "one ounce of NH_3 " (how does he measure, weigh, or handle that, by the way?) "and nine of H_2O make up a true and correct ten per cent. solution" is, again, quite inaccurate, and is based on the fallacy that dissimilar liquids mix with one another without change of volume. Presuming that by NH_3 he means the concentrated solution of ammonia, he will find that if he measures out accurately the respective quantities named and mixes them they will occupy *less* than ten ounces, the volume decreasing in the act of solution. A simple and practical way to test this is to place a small quantity of strong ammonia and some water in a narrow-mouthed bottle, and placing the finger on the neck thoroughly mix by agitation. Upon attempting to remove the finger it will be found to adhere by the suction caused by the partial vacuum arising from the condensation of volume. As a matter of fact, it is of quite as great importance in preparing percentage solutions of liquids to make the solution up to volume as in the case of solids. If this were not the case there would be little need for the hydrometers of Sikes or Beaumé or Cartier, or of the elaborate tables of calculations that accompany them, and Boniface might "break down" his spirits with a tithe of the trouble it now gives him.

In this case, however, we do not imagine the difference would be of a fatal character if the expansion of liquids was utterly ignored; but as Mr. Clark writes as a purist in the matter of accuracy, we merely point out that his method does not give a "true and correct" result.

While on the subject of ammonia, and in connexion with ten per cent. solutions, we may point out where we think a better system than that now existing of titrating the ammonia might be adopted. Ten per cent. strength for the pyro and bromide solutions has been chosen because the decimal system has rightly or wrongly come to be considered the simplest; though, for many purposes, especially in connexion with development and other operations where drachms and ounces are used, twelve and a half per cent., or one in eight, seems to us to possess greater advantages. But when we come to the solution of ammonia, if we make a ten per cent. mixture of the ordinary '880 preparation, it is inconveniently bulky, and, besides, at the best we are basing our calculations upon a very uncertain foundation, as the so-called '880 solution is very rarely anywhere near that strength, and if it is originally it does not long retain it.

The suggestion we have to make is not a new one, as we believe we have made it before, certainly we have acted upon it in our own practice for several years. It is to base our calculation of the strength of the ammonia solution upon the *real* alkali, or NH_3 , it contains instead of upon the very uncertain quantity represented by "liquor ammonia '880." If this be done a solution of a specific gravity of about '960 meets the requirements, being a ten per cent. solution of NH_3 , and this is formed sufficiently nearly by mixing one part of the strong liquid of about '894 with two of water. In this condition it is far more stable and less dangerous, and it is practically the strength at present used for actual developing purposes. All we ask is that this be generally recognised as the "ten per cent. ammonia solution" instead of "one in three."

The majority of amateurs, of course, cannot be expected to mix this solution and adjust its specific gravity with absolute accuracy, but in following the data given above they will at least be no worse off than they are at present. But if the dealers would make a stock article of solution of this strength *accurately titrated*, it would be a far more uniform and satisfactory preparation than that now sold.

In view of the large number of amateurs who are constantly joining the ranks, and as Mr. Clark's paper is likely to circulate freely among them, we have thought it well to call attention to statements and suggestions which are, to say the least, misleading, and at the same time to point out that the proposed new term—"one in ten"—is a distinction without a difference, and therefore needless.

REMOVING AN ADHERING PAPER NEGATIVE FROM ITS SUPPORT.

A FEW weeks ago we received from Captain Murray, of Tyndrum, a large plate of polished ebonite, on one side of which was squeezed a paper negative which had resisted all his attempts to get it removed. We, too, tried various means to effect a separation, but all in vain. Numerous expert friends were consulted as to suitable means for disuniting the two, but without any successful result being achieved, which was the more to be regretted as the negative was a large and somewhat important one.

Other negatives than the one sent to us having behaved in the same untoward manner, a happy thought seemed to have occurred to the gallant Captain, which we express in his own language: "Since the receipt of your letter this morning, in my desperation I warmed one of the ebonite plates I have here with negatives stuck fast on them; and I am delighted to say that I have just stripped off the negative quite easily! I am anxious to know if the remains of the one I sent to you can be taken off by the same means."

On receipt of this information we warmed the ebonite slab by holding it before the fire, with the pleasant result that when the temperature was raised to a little above blood heat the hitherto intractable negative peeled off with the most perfect ease.

At first we and others thought that the adhesion of the paper to the ebonite was caused by a residuum of moisture in the film; but when after lying face up on a dry shelf for a fortnight the adhesion was still of a character as markedly tenacious as at first, this hypothesis was felt to be untenable.

Prevention is doubtless better than cure; and this evil may, in a great measure, be prevented by a thorough cleaning of the ebonite plate, followed by rubbing over it some French

chalk, previous to squeegeeing down either a negative or a print; but it is satisfactory to learn that even when things are at the worst they may be met by the simple expedient adopted by Captain Murray.

A CORRESPONDENCE of some importance as bearing on photographic interests is at present appearing in the pages of the *Athenæum*, and will no doubt be followed with some attention by those connected with the class of work discussed—Photogravure. A species of attack is made upon the process on several grounds—it is mechanical; prints *ad libitum* can be produced; engraving and etching will be doomed; engravers will become extinct; and so on. This is merely a repetition of the old story: portrait painting was to be a lost art, and miniature painting useless. But what is the truth of the matter? Portrait painting never in this country attained the perfection it now exhibits; the curtain and pilaster that were the stock-in-trade of the portrait painter half a century ago have been laughed out of existence by the photographic parodies, and it is a distinct gain that the Miss Creelys of art have been elbowing completely out of the way by photography. So we may anticipate it will be as regards "photo-engraving" and pure engraving; the producers of the "horrible, lifeless, and mechanical" things that Professor Herkomer speaks of will go to the wall, and the noble art of engraving will be the better for their absence.

SIR HOWARD GRUBB read a paper at the Mathematical and Physical Science Section of the British Association meeting that gave important information regarding the requirements of astronomical photography. He said, in considering the best form of object glass, it was desirable to have as large a field as possible. He showed the value of Professor Stokes's suggestion to have an interchangeable front lens to the objective of the telescope, so as to enable it to be used for either class of work. He stated that no matter how good a clock was employed to move the instrument, it had to be supplemented by handwork; he was able to correct, by present appliances, any error to the twentieth part of a second, and believed that greater accuracy was useless.

At a meeting of the same section, Professor Rowlands gave a description of a mainly photographic map of the solar spectrum, at which he had been working for several years with concave gratings, of which, starting at a focal length of twelve feet, he finally chose one of twenty-one feet. The spectrum produced by gratings, as is well known, is not subject to the crushing up of some and the expanding of other parts, like that produced with prisms, and, in consequence, he found that so many lines were crowded into the ultra-violet region that it would be almost impossible to determine to which metals they belonged. Photography here has enabled such great truthfulness and exactitude to be obtained, that Professor Rowlands found it necessary to make a new standard, the old Ångström numbers being found not to match and not to be consistent with one another. Captain Abney, however, deprecated the altering the standard of wave-length.

AGAIN, solar spectroscopy negatives, by Mr. G. Higgs, were exhibited, the instrument having been made by that gentleman himself. Some idea of the results may be gained when it is learnt that between lines H_1 and H_2 twenty-one lines could be counted, while in four inches of spectrum, including the spaces between G and H, from nine hundred to a thousand lines may be counted.

AGAIN, at this section Lord Rayleigh read a paper which had a most important bearing upon a subject recently dealt with by us in these columns, the reflection at the back of the glass. One great cause of halation, it is known, is the reflection, at the back of the plate, of light dispersed by film, and to prevent this reflection a vehicle approaching in refractive index that of glass, and containing a black pigment, was recommended by us, the former to prevent reflection at the junction of surfaces, and the latter to absorb the light. Professor Rayleigh's paper showed that no substance was a

perfect preventive of reflection, even when its refractive index was exactly equal to that of the glass. He found great differences in reflecting power in this respect between clean and dirty glass; but in all cases there was some reflection. He says, where dispersion exists there is no reason to suppose that reflection should cease merely because the refractive index is equalised. If recently fractured glass should give the same result, it might be safely concluded that there was no residual film in play, and there would then be no doubt of the inaccuracy of Fresnel's law. We need not point out the important bearing of these remarks on the present state of the theory of the reflection at the back of the glass as bearing upon halation.

THE PHOTOGRAPHIC EXHIBITION.

II.

WE now commence a review of the pictures at the Society's Exhibition.

R. B. Berry (No. 2), *On the Lledr River*.—This picture is not equal to those shown last year by this exhibitor. The point of view chosen when rendered in black and white is not one calculated to satisfy one's ideal of local colour, and the leading lines of the picture are not pleasant.

W. H. Hyslop (No. 3), *Yachts—"Thistle"*.—Four studies of the now well-known yacht "Thistle," and the largest direct photographs of sailing vessels in the Gallery. The close proximity of the camera to each vessel reveals a great mastery over the difficulties which must arise under such circumstances. It may be assumed that the sea was green in colour, therefore the resulting photographs are rather dark in that particular. The same remark applies to one picture where the land seems to come in front of the yacht, and it would have been as well if the contact of the sky with the top of this land had been softened down by photographic means rather than with a brush; however, the pictures are very successful.

R. Keene (No. 4), *Interiors*.—This and other pictures by the same exhibitor evince an experienced hand in depicting interiors and landscapes. In the latter, the platinotype tone chosen illustrates its peculiar adaptability for rendering gradations of distances, but for interiors we think that a warmer tone would have produced more satisfactory results.

R. H. Lord (No. 8), *Portrait of Baby*.—This is one of those direct large pictures to which allusion has been made as characterising the present Exhibition. There is this advantage, that the whole of the many scales of gradation in the negative are brought out, whereas if an enlargement from a small negative had been produced they would not be so evident, or possess that quality which is so difficult to describe but which conveys such a pleasant charm. The pose of this picture is natural, but is it also natural that one half of the face should be in strong shade when the study is supposed to be taken out of doors?

Henry Stevens (No. 9), *China Vases with Begonias*.—A beautiful specimen of very good photographic work, where great contrasts of local colour have been reproduced with singular delicacy and many graduated depths of transparency—being very perfect in all its scientific aspects, but at the same time showing very little artistic selection or control, the subject being vases, and other pretty objects, with some leaves. Why do not photographers, with all the advantages of orthochromatic plates, attempt to make pictures of various coloured flowers, fruit, &c., where artistic skill can be shown in the arrangement of grouping, and in the avoidance of so many simple diagrams of beautiful objects, but which become more so when the glamour of design and pictorial light and shade are brought to bear upon them?

Luke Berry (No. 11), *Humble Fare*.—We notice this photograph just to emphasise what we have just been stating—that a diagram is not a picture.

C. F. Pritchard (No. 15), *Three Giants*, being simply the tops of Swiss mountains, three negatives having been printed from to form a panorama—to some extent very well put together, but at the same time showing evidence of how it has been done. As a matter of fact, of course these tops must be absolutely true; but when we think of the appalling grandeur of the originals and look upon pictures like

this one, we are not moved. We have nothing before us which demands our sympathy, and, with all due respect, we cannot tell what the extent of these *Giants* may be—whether they are only a few inches (as possibly might be modelled by some pieces of coal) or occupy a very considerable amount of space.

Matthew Whiting (No. 16), *Scotch and English Views*.—Twelve small pictures, which are far in advance of those shown last year by this veteran exhibitor, being very good in their photographic result, and in the two middle pictures very well selected and pictorial in form and general aspect of light and shade, the cows in one picture being remarkably good when considered in connexion with the other portions of the scene.

G. P. Cartland (No. 17), *Windsor Jubilee Celebrations*.—A medal has been awarded this series, stated to have been taken at eight p.m. In all, the merit must consist entirely in the production of a good chemical result by skill and good manipulation.

J. B. Hilditch (No. 20), *St. Paul's Cathedral*.—What would the Society's Exhibition be without the annual view of St. Paul's by this exhibitor we cannot say; but it must be admitted that the present picture is very fine in its character, and at such close quarters to have managed the equalisation of the focus implies a knowledge of the optical portion of the appliances, which has resulted in a very fine picture, which also is a good example of enlarging upon bromide paper, the bluish tone admirably suggesting the original itself.

G. Watmough Webster (No. 21), *Eaton Hall*.—A frame of four interiors, in platinotype, which assists the delicate detail of the work in a very marked way; but we think that for pictorial purposes a little warmer tone would be better, the present results suggesting their being shut up in portfolios.

W. W. Winter (No. 23), *My Mammy*, and (No. 60) *Dada's Tick, Tick*.—We put these two pictures together, as they invite being noticed on account of the same results in each. There is much delicate treatment of the white draperies, but the flesh tones are sacrificed in consequence; and here we will allude to the powerful effect for good or evil which mounting has upon the print. In these instances, if the mounts had been darker in tone than the dresses, the effect of the picture would have been most wonderfully enhanced.

W. Wainwright, jun. (No. 25), *Views*.—These consist of four very fine, well-chosen pictures, in platinotype. They are very pictorial in effect, and suggest the notion that they are engravings from paintings. In these works we have again exemplified the value of platinotype in rendering gradations of distances. The picture with cows in it is a beautiful example of force and delicacy united. Then, again, the warm tint upon which they are mounted gives value to the photograph which it surrounds. Altogether, these exhibits are very choice and good.

Harry Tolley (No. 30), *On the Lonely Shore*, and many other pictures from the same exhibitor. Here we have a series of nine pictures, all in platinotype. A medal having been awarded to No. 30, the subject being a rocky headland, making, with a foreground, a bay, on which the moaning sea for ever rolls. One solitary figure sits in the foreground and looks towards the projecting rock. Altogether, this picture commands our sympathies, and we look at it and wonder why it should be so. Here we have an artistic work in photography which is something more than a bare record of facts. All the other exhibits are very good, being most excellent work as far as the appliances go; but there is one, a snow scene, which conveys some little sentiment. Two small figures intensify the effect of snow everywhere. Altogether, this series is most successful, both from the technical and artistic point of view.

J. Blain Scott (Nos. 36 and 37). *Portraits*.—Here we have instances of platinotype assisting a negative in producing better results than with silver printing. The work by this exhibitor this year is far in advance of previous exhibits, and this, we think, is due to the fact of platinotype giving more atmosphere than silver, and consequently there is an absence of those unfathomable depths of blackness which we recollect to have formerly seen. The pose of each figure is very natural, but we must once again object to the white mounts, which give the high lights on the pictures a dirty look.

F. W. Edwards (No. 39), after G. Tinworth.—This, and another exhibit of a similar subject, are good examples of photographic work

direct from the artist's original clay designs, and also are cleverly printed in platinotype, where the colour has been most judiciously adapted to the subject portrayed.

H. P. Robinson (No. 40), *Carolling*.—Once more we have an exhibit from this master in composition photography, and which, if looked at with educated artistic knowledge, will satisfy both the requirements of the painter and the photographer. The subject consists of two females traversing a common, whose shadows on the grass convey the fact of their being on a slight incline, and singing a carol as they go. In the background are some sheep grazing, and at the extreme distance a rather low horizon of small trees, which insensibly fade into the sky, which is kept very quiet, the whole suggesting spring-time, when all things have an undeveloped character about them; and a tinge of sadness pervades the figures, who must be compelled by the surroundings to sing "sotto voce." Well, in short, this is the poetry or sentiment of the picture, and well has it been carried out. Thus far the painter will recognise art, and the photographer will appreciate the difficulties overcome in the arranging and printing from several negatives, as also the choice of the colour (platinotype), which throws another idyllic charm over the whole of the picture, which has been most artistically conceived, and, photographically, exceedingly well carried out.

THE APPARATUS.—I.

THE apparatus on exhibition this year having been selected by a Committee from a considerable quantity sent for the purpose, there is a proportionately greater number of novelties in this department than could possibly otherwise have been the case, as we understand that novelty was a factor in the principle of selection, conjoined, it need not be said, with efficiency.

We are pleased to observe among the names of exhibitors several whose productions appear here for the first time.

Roller slides and detective cameras are present in noticeable force and variety; camera stands combining the qualities of portability and rigidity; shutters having every degree of instantaneity of action; cameras replete with ingenuity; camera cases; plate boxes; bottle cases, and even photographers' watches, together with numerous appliances to facilitate working—all have a place in this collection.

Under the name of the "Aurora Camera," we find a very unpretending-looking camera of the detective class, exhibited by

H. Sharland, who is understood to be the manufacturer and wholesale agent. It is designed by Mr. Samuels, several of whose patented appliances are utilised in its construction. When folded up it forms a square box of such small dimensions as, if wrapped in paper and carried in the hand, might easily be mistaken for a box of cigars. The camera contains at the back a reservoir capable of holding twelve or more sensitised plates, quarter-plate size, and by a very simple contrivance they can be exposed one after the other without any danger of the unexposed plates being affected by the light, and there is no complicated mechanism to get out of order. The focussing is effected by a concealed lever which is moved to marks indicated by the distance of the object to be photographed.

When the first plate in the series has been exposed a button outside of the camera is run up in a sunk groove, by which the exposed plate, in its sheath, is raised up in a thin opaque bag, so as to be grasped by finger and thumb and transferred to a receptacle at the back of the others, the next in order taking its place at the focal plane. The cuts

above show the camera both when closed and open, although in practice the lens does not protrude through the front as shown.

Some exhibits of Mr. William Tylar, of Birmingham, next claim attention. One is a series of portable developing trays, formed of

Willesden paper, or, more correctly, cardboard. These trays, of which we gave some account in our issue of the 23rd ult., are employed in connexion with a very convenient plate-lifting frame, by the aid of which every operation, from development to the final washing of the plate, can be performed without the fingers coming in contact with either the plates or the chemicals used. The drawing shows its construction. A plate-washing frame is also exhibited by Mr. Tylar. Of this we also append a drawing. The serrated edges by which the plates are kept separate are protected by indiarubber, rendering scratching impossible. It is constructed of japanned wire. A metal printing frame is also shown by the same exhibitor. Spring clips, as shown in the drawing, serve to keep the negative in close contact with

the metal back, and to permit of the progress of the printing being observed with facility. Tylar's metal dark slides are likewise exhibited, but they are now so well known as to need no description.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

NEARLY every enlargement, no matter how carefully produced, will be found to require the assistance of the brush to endow it with a finished appearance. There are very many systems of enlarging, but none which gives to the *plain* enlargement sufficient effect or brilliancy to be independent of the brush or pencil. In the process of enlarging, no matter how perfect the original may be, many blemishes will be sure to assert themselves which will require rectification at the hands of an artist. Sometimes the general texture of the whole picture will present to the eye a most unnatural coarseness; other times this coarseness may be local, simply limited to the face. In the former case the *quality* of the original (that is assuming the enlarging to have been properly done) will be responsible for the result, but the latter, in most cases, may be traceable to the carelessness or want of skill on the part of the retoucher who had the working up of the original negative. So long, however, as the *likeness*, in the latter case, has not been greatly injured, a little skilful work with the brush will set everything right.

In the working up of an enlargement it is a matter of the utmost importance that we should secure a *tint* approaching, as nearly as possible, to the tone of the photograph we are about to work upon. Indeed, this tint should be exactly the *same* as that of the photograph, or else we may fail to produce a harmonious whole when finished, and so have no reward for all the time and labour we may have expended on the *working up*.

There are many combinations for securing the tints best suited for working up these enlargements, but two or three will suffice to be given upon this occasion. Assuming that the enlargement we are about to work upon is the *usual* photographic colour, the following will be found equal to the task of matching all shades of the same. Naturally if the photograph be of a warm tone, the warmer colours will predominate in the mixture, while, on the contrary, should it incline to a [cold tone the cooler colours must necessarily assert themselves.

Almost any tint may be obtained by the skilful mixture or combination of *lampblack*, *lake*, and *warm sepia*. Another very useful and good tint may be made by the help of *neutral tint*, *sepia*, and *brown madder*; colours which lend themselves to almost any tint that may be required. The combination which finds most favour upon the Continent is *principally* formed from *lake*, *Indian ink*, and *neutral tint*. I said "*principally*," and that may appear strange at first sight; but I will account for my saying so. Artists' colourmen in Germany have introduced a combination of colours which they term *photographic colour*, that is a tint somewhat resembling that of the ordinary photograph. There are several shades of this colour, some warmer and some cooler, but I have always found that they wanted *toning* before using, as *by themselves* I do not consider them a success; but they are exceedingly useful in combination with the three last-mentioned colours. Many of the best artists prefer using *burnt carmine* as their red.

For a short time carbon enlargements became somewhat fashionable printed in a red pigment with the intention, when worked up, of resembling some of the old red crayon drawings by some of the old masters. They are very pretty and effective, but of late have not found very much favour. To work them up a judicious combination of *Indian red* and *brown madder* will be found sufficient. These two tints are the *most general* for enlargements, but sometimes they are printed the exact tint of sepia, sometimes warm sepia, in which cases these colours used in their purity will suffice. In carbon enlarging almost any tints can be produced, and when such are of different shades from those just mentioned independent judgment must be used in matching the colour.

Before starting work, indeed it is the first thing to be done, pin the photograph to your drawing-board with the ordinary drawing-pins. It is a great advantage keeping your picture flat. It is very advisable, too, to keep a piece of soft, clean paper over the lower part, upon which you can rest your hand while painting without any fear of damaging your work. The fact of resting your hand upon the *surface* without anything to protect it will inevitably cause it to become greasy, and so almost impossible to work upon; even if you succeed there is always the fatal result of looking patchy.

* Continued from page 613.

In working up enlargements, you should always be provided with *guides*, that is to say, duplicate photographs. These you should place in such a manner that you can, without trouble, constantly refer to them. I may paraphrase the old saying, "Two heads are better than one" very truthfully by saying that "two guides are better than one;" one should be printed lightly to enable you to render the detail in the shadows, the other printed deeply in order to give the form and drawing (if any) in the lights.

Retouching of late years, as every one knows, has been considered almost indispensable to the production of successful modern-day photography, and when well and properly done is a decided advantage. I regret to say, through competition and bad pay, this branch of photography has fallen into considerable disrepute. The one who has no mean cause of complaint in this regard, is the colourist who has to work up an enlargement from a badly retouched negative. When a negative is *over retouched* (a very common occurrence), the likeness must inevitably suffer. In many such cases the resemblance is quite destroyed, but in all such it must be very seriously interfered with. I do not wish to be misunderstood in this particular regard, so beg to draw attention to the fact that this does not refer to really *good* retouching, but to the ordinary—I may say *very ordinary*—and cheap work as patronised by a large number of photographers.

Such work may be tolerable in the smaller sizes, but when it is enlarged it becomes impossible. A guide taken from such a negative is really useless, and following such while working up your picture will inevitably lead to failure. A hard struggle should, under such circumstances, be made to secure one or two prints from the negative before it is retouched. You will be well repaid for your struggle by the saving of alterations and worrying complaints.

Before starting with the colour, it is advisable to wash the surface with water passed over it with a large brush, to see how it takes; if evenly, let it dry, and it will then be ready for work. If the surface present a greasy or uneven appearance, there is a prepared size, Newman's, I believe, which is well adapted to rectify this. A wash of ox-gall will also give a clean surface to work on.

In working upon albumenised paper or carbon tissue, it will be found necessary when mixing your tint to include a little gum-water, in order to assimilate somewhat to the gloss upon the surface natural to such prints.

In the case of a very bad enlargement it may be necessary to pass a wash of colour over the major part of your picture, and then proceed in the way I will indicate for a more or less decent enlargement. Take your brush, a sable, and one not too small, and with a small quantity of the tint you have mixed begin to fill in any white or offensively light spots that may be in your photograph. Don't try to fill them in such a way that they will become flat or patchy, but with a view to breadth and effect. This refers naturally in most part to the background, coat, &c. This treatment will partake somewhat of the stipple, but when the defect is large, and so beyond the power of the *stipple* to mend, you must hatch over the defective space and afterwards even up with a stipple, if such be necessary.

The colour in use should never be too moist, still it must work easily in the brush; also very little colour should be used at the time.

If the photograph under treatment should be an enlargement from a very small or faded original, there will be considerably more trouble than in the case of an enlargement made under more favourable conditions. The surface will be found to present a general mottled or coarse appearance, all of which must be taken away before we can produce a pleasing result. With your brush very moderately filled with colour you must patiently and carefully proceed to even up all these inequalities; in other words, tone down the light spaces until a moderately even appearance is given to the entire picture. When working upon a carbon surface it will be found advisable at times to take out some of the darks with a knife, but more of that later on.

When you have carried this operation to a certain extent, take your guide and very carefully examine it, and compare it in detail with your enlargement, looking up and mending all the deficiencies that present themselves. These will be mostly observable in what may be termed *exaggerations*, imperfect drawing, and a general tendency to hardness of outline. There are at times such successful enlargements as to want but very little, simply brightening up and strengthening.

I mentioned "*hardness of outline*" just now, and a word or two on

that subject may not be amiss. It is laid down that in nature there is no such thing as an outline, or outer line, and on close observation the truth of this will become apparent. One tint meets another and melts imperceptibly into it, yet both are separate and distinct. A strongly cast shadow upon a light ground will be found to be simply the termination of the shadow, but it would be impossible to depict it by means of a hard line. Outline is, as it were, the boundary where one tint ends and another begins—the edge of a shadow; but in no case can a hard line represent itself. In the monochrome, when there is no help derived from the balance of one tint against another, as in coloured work, the tendency to outline is very remarkable, and must in the treatment of the enlargement be so subdued as not to be offensive to the laws of nature.

One will often find in enlargements (some processes more than others) that the shadows meet the lights much too abruptly, also that there is a general lack of half tone. In cases where this is very strongly marked, a faint wash may be passed over the entire picture, picking out the lights by removing the colour with a dry brush; or, better still, allowing the whole to dry, and then with the point of a piece of ink-eraser restore them. This faint wash will only impart a general tone or softness to the picture, but will not be sufficient to blend the shadows into the half tones. If your shadows are very strong they must be rubbed down with an eraser, and then the edges worked or stippled until a general harmony and roundness is secured, and which can only be the result of the proper gradation of tint. So much for the picture generally. We will now take it in detail, and examine the different treatment demanded by each feature.

REDMOND BARRATT.

(To be continued.)

STEREOSCOPIC PHOTOGRAPHY AND ITS REVIVAL.*

ONE of the first, if not *the* first point the photographer should give attention to, if he desires to obtain the most perfect effects in stereoscopic work, is the distance at which his lenses are mounted apart on the camera. Very many of the pictures sold in the past, and which helped to destroy the popularity of the stereoscope, were defective only in this respect, and that chiefly because the operator either in ignorance or carelessness treated every subject in precisely the same manner. Let us then consider the effects produced by varying the distance of the lenses.

As I pointed out in connexion with the stereoscope itself, the distance of the lenses apart for viewing the slides may be fixed, as owing to their size and to the fact that it is not necessary to look through the precise centre of the glasses, a fixed position will suit eyes placed at widely different distances. In the stereoscope, in fact, the distance of the lenses is chiefly a matter of comfort and exercises little influence on the appearance of the picture. In the camera, however, it is altogether different, the distance between the centres of the lenses deciding the amount of stereoscopic relief presented by the combined pictures, and this practically independent of the amount of separation existing in the mounted slide. A moment's reflection will show that the separation of the lenses on the camera front, or in other words the diversity in the points of view from which the two dissimilar pictures are taken, settles once and for all the amount of dissimilarity existing between them, and that the same amount of divergence is presented to the eyes when the pictures are viewed in the stereoscope and the same idea of relief conveyed to the brain, whether corresponding objects in either picture are two and a half or three and a half inches apart when mounted. The only difference in that respect is again one of comfort; the nearer the mounting distance is to the actual separation of the eyes the less will be the strain produced in their combination.

Naturally the best or proper distance of the two points of view is that of the eyes themselves, and if a fixed front is used and the points of view are to be the same for all classes of subject, near or distant, two and three-quarter inches will be found generally the most convenient. But the optical effect may often be improved by artificial means—that is, by a departure from absolute truth. Of course, the wider apart the points of view the greater will be the dissimilarity in

* Concluded from page 568.

the pictures, and the closer the objects the greater will be the effect, owing to the larger angle subtended. In gazing naturally upon a landscape, though the observer is sensible of a considerable effect of relief in the foreground objects, it becomes inappreciable as the distance increases, and, however rugged and broken may be the distant mountain side, it appears to the eye smooth and flat, because the axes of the eyes, when directed upon objects at such a distance, include so small an angle as to be practically parallel. In proportion as that angle is increased by separating the eyes, if that were possible, or the lenses in the case of a photographic camera, so will the dissimilarity between the pictures and the sense of solidity and relief be increased. So for landscape work, especially of the type known as "open," the natural distance of the human eyes may be departed from to a very considerable degree, and for very far-removed objects the two views may be taken from points many yards apart. Thus the Warren de la Rue's stereoscopic pictures of the moon, published many years ago, were taken on different nights, or under circumstances owing to the alteration of the relative positions of earth and moon equivalent to a separation of the points of view by thousands of miles.

For landscape work solely it is advisable to have a good distance between the lenses, say three and a half or four inches or even more, and it is even allowable to have them fixed in that position because the exaggerated relief conferred upon foreground objects will not prove unpleasing. But for portraiture, groups, or small near objects, such an arrangement would be utterly unsuitable, the effects produced being grotesque in their want of truth. For instance, many years ago, I purchased, second-hand, a stereoscopic camera that had been specially constructed for a then leading amateur landscapist and in which the lenses were adjustable from four and a quarter to five and a quarter inches apart. For landscape purposes the instrument was all that could be desired, but upon using it to photograph a small statuette or group, including a seated female figure, I was startled to find her represented with a capacious lap extending to several yards, a chin projecting quite a yard, while from the top of the nose to the lip was a good foot.

Therefore, I consider that a perfect stereoscopic camera should be provided with an adjustable front enabling the lenses to be separated from two and three-quarters, or, better, two and a half inches to four or five; in fact I hold the adjustable front to be a *sine qua non*.

Next I come to the question of the best focal length for the lenses. There is no best, but the focus should be suited to the subject just as in monoscopic work. A pair of short focussed lenses will exaggerate the perspective of distant views, making mountains into molehills and foreground pebbles into gigantic rocks, while on the other hand lenses of too long focus will give with near views and "bits" which form some of the most charming subjects for the stereoscope, flat and jumbled-up pictures which only resemble carvings in low relief. It has been suggested that these defects may be remedied by viewing the finished pictures with lenses of the same focal length as those employed in their production, but how many people will find that their stereoscopes and cameras fall in with that convenient arrangement, or will think it worth while, like Mr. Chadwick, to adapt their photographic lenses to the stereoscope? It is better to have a selection of lenses to suit different subjects and to adhere to one pair for the stereoscope; or, where a single pair must suffice for the camera, to select a medium focus, say five to five and a half inches. A full equipment may range from three inches for interiors to seven and a half or even eight for distant views and marine studies.

Another important item is to see that the lenses are accurately mounted upon the camera front at precisely the same height from the base line of the plate. If this is not seen to, endless trouble will be experienced in trimming and mounting. I do not attach a great amount of importance to the absolute "pairing" of the lenses. I once had a pair of about four-and-a-half-inch focus that differed fully three-sixteenths of an inch and which I had to focus separately, but I could never find any defect in the combined pictures produced by them, nor did I ever experience any inconvenience or strain in looking at them.

Special importance is attached by some to the necessity for accurately levelling the camera in taking stereoscopic pictures, but beyond the reasons that prevail in connexion with single pictures I am aware of no others that affect a double picture. I have heard it

argued that a want of level in the direction of the plane of the picture or from side to side, will prevent the combination of the pictures in the stereoscope, but this is not the case, for if the two pictures be taken from points one above the other, instead of side by side, they will combine perfectly if properly mounted, though without proper stereoscopic effect. Even if the double negative be taken with a considerable slope from left to right, if the prints be trimmed properly no ill effect will accrue beyond the greater trouble involved in the trimming.

As regards levelling in the direction of the axis of the lens, or what is known as "tilting," the effect is precisely the same as in the case of a single picture, and when it is absolutely necessary to resort to tilting, the swing back must be employed. Nothing looks worse than a stereoscopic slide with leaning perpendiculars.

From various reasons in the old dry-plate days, and with wet plates as well, difficulty was frequently experienced in bringing the two halves of the negative to the same density, and consequently one half of the print was often much darker than the other. This might arise from defects in the optical arrangements, but was more frequently due to the collodion film being thicker at one end of the plate than the other, or to the developer having been applied unequally. These reasons are not now likely to prevail with gelatine plates, though another cause of unevenness between the two halves may now be found. In former days, with exposures counted by minutes, there was no difficulty in removing and replacing two caps so as to give practically equal exposures to either half of the plate; but, now when the time is reduced to a second or two, the feat becomes almost an impossibility, and some form of exposing shutter is a matter of absolute necessity, whether for instantaneous or "time" exposures. This presents no particular difficulty, except that in the case of an adjustable front for the separation of the lenses the shutter must work independently of the lens mount.

What has to be performed in the way of exercise of care in these matters referred to in connexion with the camera is done once for all, but when we come to trimming and mounting the prints it will be found that individual attention must be given to each one, and it is, perhaps, to the want of observance of the irksome little niceties in these operations that the imperfections of the great majority of stereoscopic slides are to be traced. But, after all, the trimming and mounting of a stereoscopic slide is as rapidly and accurately done as a single one, if done methodically. The following is the method I adopted for years, and by which I was able to trim or mount from three to four dozen prints in an hour.

The first thing to be done before cutting the prints is to mark them, that the respective halves may be subsequently identified. To do this lay the print face downwards upon the cutting-glass and mark the halves as they lie "R." and "L.," the left-hand half when looking at the face will thus be marked "right," and *vice versa* as required. The next operation is to provide a correct base line from which to work. The line of the rebate of the dark slide is often taken, but if the camera has not been level this will only be the commencement of trouble, for one print will be cut a trifle higher, or will contain a trifle more subject in the foreground than the other, and when mounted will either refuse to combine properly, or cause considerable strain on the eyes.

My plan is to select two corresponding objects in the foreground of the two halves of the print, a stick, a pebble, a turf or blade of grass, a flower, or any of the thousand and one such objects that may be found in any picture. Lay a straight edge against the two prints selected, and cut a clean bottom margin or base line. Now, whether the camera has been level or not, we may be sure that the two prints are cut level, and the worst fault that can happen will be a slight leaning, imperceptible except in architectural subjects, but no doubling of the image or strain on the eyes.

Now fold the double print in the centre, face outwards, using the new base line to secure accuracy, and with a suitable cutting shape trim the two halves at once, employing a sharp knife to ensure clean edges. It is in the trimming where a large amount of judgment is required in deciding and arranging the distance apart of similar objects in the two pictures when mounted. This distance does not necessarily coincide with the width of the trimmed picture, as it would do if each half contained precisely the same amount of subject

and they were mounted close together. On the contrary, the distance between similar objects is usually less than the width of the print, and this is arranged by so cutting the prints that the outer margins of the mounted prints, that is the right-hand side of the right picture and the left-hand of the left, show a small amount of subject that is not included in the other half. This has the advantage that it makes the picture when viewed in the stereoscope stand back from the mount as if looked at through a frame.

The distance of the corresponding objects will depend upon the distance of the lenses apart and the size of the trimmed print, and may be readily altered or adjusted by placing the cutting shape nearer to or further from the centre or fold of the doubled print; that is to say, the nearer the dividing line between the two prints is approached in trimming, the nearer will be the corresponding objects in the mounted prints, other things being equal. Thus, in the case of my $7\frac{1}{2} \times 5$ camera with the lenses placed in the centre of each half of the plate, i.e., at a distance of $3\frac{3}{4}$ inches between their centres, I find the following are the variations produced, supposing the prints to be trimmed to three inches square. Cut one-eighth of an inch from the fold or division line, mounted objects are $2\frac{1}{4}$ inches apart; a quarter of an inch, $2\frac{3}{4}$ inches; and three-eighths of an inch, three inches, which is as far apart as can be comfortably combined. These distances will of course vary, other things remaining the same, if the size of the trimmed print be altered, the difference being equal to what is taken off or added to the width of the two prints.

Variation of the distance of the lenses also will affect these figures, the nearer the lenses are placed the more distant will be the mounted objects. In landscape work then, it will be seen that it is advantageous to place the lenses as far apart as possible or convenient in order to secure the full stereoscopic effect. Whatever may be the size of the plate, perhaps the best general distance, if it has to be fixed, will be three inches; if adjustable, let the adjustment be from $2\frac{1}{2}$ inches to as much as can be obtained.

With regard to the size of the trimmed prints, I think the appearance of the slides is much improved by cutting the photograph as large as possible. I cut mine 3 inches wide by $3\frac{1}{2}$ high, and these dimensions, after allowing for the expansion of the paper in mounting, leave a margin at either end of three-eighths of an inch, and a little less than one-eighth at top and bottom. The inelegant appearance of many of the old slides trimmed to two and a half inches square was very noticeable, and arose from the use of small plates, sometimes as small as $5\frac{1}{2} \times 3$, and the difficulty of working clean to the edges. With gelatine plates I should think it would be possible to work the old "stereo size," $6\frac{1}{2} \times 3\frac{1}{2}$, or even $6\frac{1}{2} \times 3\frac{1}{4}$, and still trim to the size I have named.

I had intended saying something on the subject of transparencies, but have exceeded my space; I may at a future period return to that very charming branch of photography, as I fully believe next season will witness a real revival of the stereoscope.

C. BECKETT LLOYD.

COMPOSITION IN LANDSCAPE PHOTOGRAPHY.

Just the day for photography! The wind is still, not a breath shivers the delicate leaves of the Lombardy poplars; the sky is not quite cloudless, for numbers of small clouds float lazily over the blue, affording varieties of lighting, either all sunlight, all shade, or, by careful waiting and observation, a little of each—often useful when softness and sparkle are wanted in the same picture. I don't think I can do better than imagine you are with me. It may be like a legal fiction, most convenient. Besides, you know the scenery.

Fill your slides, look over your camera to see that everything is in order; for, however sure you may be that everything is right, it is always well to have an inspection before marching. To forget a crew, if you have a loose one, and only discover your loss when you are miles from home and the view before you is "perfect," is to promote possibly suicide, or certainly profanity. There are some things better left at home if you unfortunately possess them. One of them is any kind of actinometer. I never knew anything but harm from this instrument when used to help you to judge the exposure. Another perfectly useless worry can be got out of "exposure tables." It takes all the "go" out of a picture if you have to do a sum in arithmetic when you ought to be concentrating all your heart, and mind, and soul, on your subject. Knowledge of

exposures must come by experience if they are to be of any use. No calculations based on length of focus and stops are of any service to a practical photographer. All other things being equal they would be an infallible guide, but otherwise they are misleading. After the plate has been exposed and the excitement is over, it would be useful to make a few notes for further guidance. Such as kind of plate, lens, stop, and length of time, also of the light, and nature of the scene.

Besides the apparatus there is another very important help to picture making which is seldom thought of—some models. It does not matter much what kind they are, whether old men, young girls, or children, or mixed; the one thing of the utmost importance is that they shall be appropriate to the scene, for there must be no suggestion of sham about the finished results.

The illustration, which was done on a day that turned out unfit for good work with the camera, shows some of my models. A painter is making use of one of them, while two others are looking on.

We will have a lofty beginning to-day. Let us go to the top of the mountain—Moel-y-plas—a hillock you called it, with your transatlantic contempt for little things, but it is 1442 feet 8 inches high, according to the minutely exact calculations of the Ordnance survey, and at least affords us that sense of standing on a round world spoken of by the author of *Adam Bede* as one of the outdoor delights she most cared for. Shall we find a picture here? The hill is glorious with purple heather just coming into flower, green ferns and bracken, mingled with the orange and brown of last year's decay. New life springing from death. As we ascend we startle a covey of grouse which go whirling down the valley. We need not mind them now; next month their turn will come. The land dips into valleys all around us; to the north the lovely vale of Clwyd, beyond which, afar off, is a glimpse of the pale grey sea; to the south the Llanarmon valley running for miles in the direction of Chester; and to the west the grand range of mountains known as Snowdonia. We are standing on the oldest bit of Britain, from the geological formation down to the Druids. The scene calls up memories which every Welshman loves to dwell on. There rises up before us in mental vision Llewellyn and his dog, Owain Glyndwr, and King Arthur and his round table; but this is not what we are here for.

Where are we to point our camera? I cannot see anything that will afford a good subject. A magnificent view is before us "palpitating with actuality," but it is beyond our reach. It would be impossible to give any adequate representations of those distant hills, they would be dwarfed into insignificance, and, if relied on to come on the same plate as the foreground, overexposed to the verge of blackness. The foreground is insignificant in itself to make a picture, and the view, as a view, consists of the valleys and mountains. So we must remember the limitations of our art, and give up the impossible—but don't pack up the camera, for here comes our picture. Here is a group of children, five of them, gathering bilberries; we will give up the mountains for the present, and make a picture of the children. We will send one of our young-lady models to make friends with them, and rub off the edge of their shyness. That she is dressed in shabby clothes will be in her favour, the children will be more natural and familiar with her. We will select a spot where the undergrowth is not too dense, but broken up with plain patches of turf or bare earth. You have already made up your mind roughly how the group shall be arranged, have placed the camera approximately on the right spot, and roughly focussed, pulling out the top of the swing-back before focussing so as to get greater depth of definition from foreground to distance. Two children to the right

of the picture, three to the left, and to make a principal point, the trained model not quite in the middle of the picture, but a little to the left of the centre, and nearer the camera than the others. Let the principal figure be standing with her left arm outstretched over a large basket looking to the ground on the left, as if searching for berries or talking to one of the children. She, knowing what is expected of her, will not stand in an awkward attitude, resting equally on both feet, but you may rely on her when you have given her the leading idea to carry it out instantly. The sun is shining to the left front of the model, throwing out the figure dark, but touched with a brilliant edging of sunlight against the distant mountains. Take care in exposing to lift the cap as if it were hinged to the top of the hood of the lens, for it will then act as a sunshade. If the least touch of sunlight rests on the glass during exposure the plate will be hopelessly fogged. It is with the children that the trouble comes. This, however, we get over with a little patience, taking care that each figure appears to be as unconscious of the camera as possible. Now expose. Two, or perhaps three seconds.

That stupid child looked up just as you took off the cap to see why you are keeping her waiting so long. Quick! another plate before she is aware you mean another. That is the picture. It is often the second shot that brings down the bird.

To succeed with a picture of this kind requires quickness of decision and the faculty of seeing at once what ought to be done, and promptly acting on that insight. The photographer also must be able, without hesitation or waiting for words, to say, or oftener to shout, the right thing at the right time to the model. In fact the life of the picture depends on your doing absolutely the right thing in several directions on the spur of the moment. This faculty can only be attained by long practice, good knowledge of composition and light and shade, and keen observation of effect.

The illustration will serve to show the kind of rapid sketches you should get into the habit of making of any subject or arrangements that may strike you. They need not be accurately drawn or exhibit

any graces of style, all that is wanted is rapid notes and hints for future use. I have purposely introduced a weak point in the composition so that I may point a lesson. The composition is divided into two groups which seem to have no connexion. The attempt to join them by the addition of the basket is a failure. The lines are fairly right, but there is a want of unity—fatal to the picture.

In the picture described above the figures predominate over the landscape; we will now reverse the effect, and the landscape shall be of the most importance. We won't give up the mountains now we have taken the trouble to climb so high. Let us see if we can get a good picture by taking it on two plates instead of one. Some people say that combination printing is not quite orthodox, but let us break away sometimes, it is awfully dull to be always correct. It is not easy to an active mind to be satisfied with "the priceless merit of being commonplace." The difficulties of the subject before us are these: We have a near foreground of comparatively dark and non-actinic character, a blue sky with some small, strongly defined clouds, a distance composed of grey-blue mountains, and a middle distance; this latter part of the scene, however, is a long way off. The problem is, how to combine these apparently incompatible elements, giving the least prominence to the foreground. No lens would get the foreground and distance together with anything like a passable focus, and no dodging of the exposure afford both the widely different times they would require. These difficulties are easily surmounted by combination printing. Get the immediate foreground on one plate with an exposure of, say, ten seconds (for you will use a small stop), and all the other parts of the picture on another plate, and with an exposure, say, of one second. These exposures are only approximate. It would be better in practice in taking the distance to move the camera forward a little so to take in more than is required, this will facilitate the joining. I have fully described the various methods

of combination printing which may be of use to the landscape photographer in *Silver Printing*, and it would scarcely be worth while going over the subject again here.

H. P. ROBINSON.

—*Photographic Times*.

THE IDENTIFICATION OF CRIMINALS BY PHOTOGRAPHY.

THE *Observer* says that "The question of the best means of identifying habitual criminals is most important as a practical means for the repression of crime. In France and throughout Algeria they have adopted the *signalements anthropométriques* of M. Bertillon. His system consists of taking the measurements of certain bones which do not alter after manhood has been reached, such as the length and width of the head, the length of the little and middle fingers of the left hand, of the left foot and forearm, and the height of the body. Scars and marks, the colour of the eyes and hair, are also noted very carefully. Now M. Bertillon has found in his practical experience by the measurement of nearly 50,000 persons that the measurements of no two of them are alike. The instruments used, though inexpensive, are so accurate that the diameters of the head and the length of the fingers are measured to within one millimetre. One, however, of the most important advantages of M. Bertillon's system is the power it gives of classifying, by the aid of measurements, the photographs of habitual criminals. The photographs are divided into three classes, according to height—the large, the medium, and the small. Each of these classes is again and again subdivided, according to the length of the head, the width of the head, the length of the middle finger and left foot, into sub-classes of large, medium, and small, so that instead of looking through 50,000 photographs it is only necessary to examine ten to twelve, and if the portrait wanted be in the collection it can be found as quickly as a word can be looked out in a dictionary. The officials employed in the searches now make use of the figures alone; they satisfy themselves of the absolute similarity of the anthropometrical descriptions to a millimetre before they even look at a photograph, lest they should reject the right card through being misled by a deceitful resemblance. Since the introduction of the system nearly five years ago there has not been one single error of identification, and the number of prisoners recognised as giving a false name and *etat civil* has been 1500. Germany, Spain, Italy, and Denmark have adopted M. Bertillon's system, and it will probably become the recognised means for criminal identification throughout the world."

OPINION OF THE LONDON PRESS ON THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

[*The Graphic*.]

THIS year's Exhibition of the Photographic Society, though in some respects of a higher standard of technical excellence than its predecessors, is somewhat disappointing from a popular point of view. The multiplicity of portraits reminds us forcibly of the "Photographic Artist's" waiting room, while the yacht studies though interesting, as showing what instantaneous photography can do, are apt to become monotonous. At a time like the present when amateur photographers, to whom avowedly the recent marvellous improvement in photographic science is mainly due, are doing such excellent work at home, abroad, and in the colonies, surely it would be worth the while of the representative photographic society to make an effort to fill their walls with a more varied and more wisely chosen collection than that now on view in Pall Mall. We all know pretty well the stage of excellence which has been reached in the studio, and in country rambles within reach of home and a dark room, but specimens of photographs taken in a campaign, in the difficulties of travel, and in rarely visited lands under exceptional circumstances would be interesting alike to professionals and amateurs. It is for this reason that J. W. Lindt's admirable pictures of New Guinea are exceedingly welcome in the present Exhibition. They are well taken, and prove what good work can be done with the camera by geographical explorers. Alfred Isenberg shows some interesting views of Benares, and coming a little nearer home Miss Georgina French has some charming views of Venice. Messrs. Robinson and Thomson send a number of small photographs of *Picturesque Italy*, which deserve especial praise; while W. F. Donkin and Captain Abney both send some striking Swiss mountain views. Of English subjects there are some particularly good photographs of Thirlmere and Derwentwater, both by T. A. Green and H. Colliss Pettitt; numerous characteristic views in the Isle of Arran by Vernon Heath; a very pretty bit of foliage, *Holly St. Devon*, by T. M. Browning; some clever notes on the Norfolk Broads by Payne Jennings; and a wonderfully extensive view of Moel Wyn from Festiniog by Charles E. Nesham.

Foremost amongst the "picture" subjects is the *Carolling* of H. P. Robinson, which has excited considerable difference of opinion amongst photographers, but which, taken as a whole, must be praised for the gracefulness of its composition and the delicacy of its execution. Most of the others still retain that stiff, stark look about the figures which has ever been the stumbling-block in this branch of photography. Amongst the best are *A Finishing Touch*, by Lydell Sawyer; *The Potter*, by W. Thomas; *On the Lonely Shore*, by Harry Tolley; *Darning*, by John

Terras, after Adam Diston's well-known style; *Dat's a Lubby Shine*, by G. B. Wood; and, not least, country cottage studies by George Davidson, whose delicacy of printing in platinotype almost equals the effect of steel engraving. As we have said, however, it is in portraits that the strength of the Exhibition mainly lies, and prominent amongst the chief exhibitors are W. J. Byrne & Co., whose photographs taken direct at Lady Hood's house, are no less admirable than their life-size heads—to the latter of which the Judges have deservedly awarded a medal. E. Davey Lavender send some winsome full-length portraits of a little girl, H. S. Mendelssohn a graceful group of Mrs. Longstaff's children, V. H. Chintamon some Indian celebrities. G. West & Son, as usual, are distinguished by some good yachting studies, as also is W. H. Hyslop. Animal subjects are chiefly represented by A. R. Dresser, who shows a curious study of the sea-lion, and Thomas Fall, whose dog portraits are very good, while some instantaneous views of gulls in flight by Benjamin Wyles should serve as a lesson to many a marine artist. Of the scientific photographs we should mention the photo-micrographs of Andrew Pringle and of Fred. E. Evans, and the lightning photographs taken during the August thunderstorm by E. S. Sheppard. There is a great lack of architectural subjects, but we cannot conclude without giving a passing word of praise to S. H. R. Salmon for his interior of St. Bartholomew the Great, to G. Watmough Webster for his interior of Eaton Hall, and to Richard Keene for his interior of Hardwick Hall. One of the chief novelties is a scene from *David Garrick*, photographed by ordinary gaslight, by John F. Roberts, which has gained the distinction of a medal.

PATENTS COMPLETED.

IMPROVEMENTS IN CAMERAS.

No. 13,240. JOHN EDWARD THORNTON, 3, New Lorne-street, Moss Side, Manchester.—*October 18, 1886.*

THE objects of the improvements which are the subject of this invention are for a twofold purpose, hereinafter more definitely described; firstly, for facilitating the packing and unpacking of cameras and getting them into position for work, by reducing the number of loose parts; and, secondly, for facilitating the adjustment of the various parts when in use by providing more conveniences than hitherto for the operator. This invention is intended to form an addition, to be taken in connexion with my Specification dated the 24th February, 1886, and numbered 2670.

In constructing a photographic camera according to my invention, I form the baseboard with a circular opening in it as large as convenient without unduly weakening the parts; to the under side of this baseboard I attach another board of a suitable size and shape (which I call the turntable), and having a corresponding opening a little smaller than the one in baseboard, so that a projecting ledge is formed on the turntable on the inside edge of the opening. To this projecting ledge on the turntable I attach a ring or flange of any suitable material, but preferably of wood. This ring just fits easily in the baseboard opening, and comes nearly flush with the surface thereof. A thinner flange or ring, preferably of metal, is attached to the top edge of the wooden flange and overlaps the surface of baseboard just sufficient to form a binding projection to keep it in its place. The baseboard can thus revolve freely on the turntable, and a set-screw passing through the wooden flange and working into the metal one serves to clamp the baseboard and turntable together to keep the baseboard from revolving except when required. The order of attaching the flanges may be reversed if desired, and any other materials may be used for their construction, but I prefer them as herein described.

The under side of turntable may have recesses therein into which are inserted plates for attaching the legs to. These recesses and plates I place near the edge of turntable and extend them so as to come right up to the edges and be visible from the edges thereof. In the plates I form \angle -shaped recesses, the wide end of each coming to edges of turntable and the narrow end terminating in a hole into which the leg pin fits. The leg pins can thus be more readily placed in the holes than if the position of holes had to be looked for underneath the turntable, as the pins may be pushed in from the edges, the recesses guiding them to their places. This method is only applicable to those legs which have projecting pins thereon. For those legs having a fixed stay-pin or bar at the upper extremity I form the turntable with spring jaws to engage with the same as follows:—The stay-pin fits into a hollow or groove on the under side of turntable, and a spring metal catch, having a corresponding groove on its upper edge, presses against the turntable and holds the stay-pin in position in groove, at the same time allowing it to move tangentially. This device may be placed near the edges of turntable so that the stay may be pushed in between the jaws easily.

The usual extension frame of baseboard is worked by the usual racks and pinion, but I arrange the pinion so that it can be thrown out of gear with the racks and the frame pushed in or out without tedious racking. The end-bearings or plates in which the pinion works are slotted in such a manner that the pinion may fall sufficiently to just clear the teeth of racks when pushed

down. A small spring at either end of pinion, on the under side, operates to press it in gear with the racks, and a plate or other device, which may project to the outer edge of baseboard, is placed over pinion, so that it may be pressed down thereby.

The front board, which carries the lens, is caused to travel backward and forward as described in the before-mentioned specification. The bearings of the top pinion which works the front are formed in travelling angle-plates or runners, and the slotted stretchers which support the front are pivoted at their lower ends to these runners. The fork carrying the front is constructed so as to swing either backward or forward on its lower extremity as a centre, being pivoted by any of the following methods:—Firstly, the two bottom ends of fork have each a small boss attached, the said bosses being each cut part away, forming at their lower extremities a half-circle, so as to fit on to two shoulders formed on the pinion. Two short tubes are smoothly fitted on the pinion, also a spiral spring which works in the space formed between the two ends of tubes, and serves to press them apart. When the fork is placed in position on the pinion the tube ends spring on to the bosses or inner edges of fork, and so lock the fork on the pinion, at the same time allowing it to swing thereon. A projecting pin on each tube provides for drawing the tubes together when it is desired to detach the fork. Secondly, the sides of fork may be held rigidly apart by a hollow bar or half tube which will fit on to the pinion and lock thereon by catch springs. Thirdly, two flat springs, each having a small hole therein, may be attached to the runners and the fork provided with projecting pins to fit into the said holes, and so form pivots for the fork to swing on. Fourthly, the fork may fit on pinion, as described, and pins or bosses on the fork engage with springs attached to the runners to lock the fork on the pinion. Any other method of locking may be used which is found suitable, and I do not bind myself to any one of the methods described herein.

The sides of fork are slotted, and the front is made so as to rise and fall between the fork, being fixed at any height by two milled-headed screws, which pass through the slots in stretchers and fork and work into the sides of front board. These screws serve a double purpose, as when tightened they serve to hold the front board firm and rigid by means of the stretchers, and also to fix at any height, as described. When they are slackened the fork may be swung to any position. The front board is kept from swinging or vibrating between the sides of fork by pins or screws inserted in its sides and working in the slots in fork.

The front board is fitted with a revolving panel to carry one or more lenses (as described in the before-mentioned specification). A spring attached to front is made to engage with revolving panel so as to prevent it from revolving when not required. The top portion of front board above the revolving panel is so constructed as to slide or lift out, so that by raising it up a little the panel may be removed when necessary. A brass ring or flange may be attached to front so as to cover the edge of panel, and so effectually prevent light entering at the joint. This ring may be cut in two, so that the upper half may be attached to and rise with the sliding portion of front board. A cover or plate may be fixed to the front board behind the lens not in use, and act on by a spring or other device, so as to effectually exclude any light from passing through the said lens and at the same time not interfere with the free movement of the lens panel.

The extension frame of baseboard is made sufficiently large to allow the front board, fork, and stretchers, to go down into the recess or space formed therein. In order to get this recess large enough, instead of the usual wooden rails on the upper surface of baseboard for the purpose of guiding the extension frame, I construct the said guiding rails of angle-brass and attach them to the sides of baseboard, with the turned-over edges working in grooves in the sides of extension frame or on the top edge of same. This admits of the extension frame being made the same size as baseboard.

When it is desired to fold or pack the camera, the front screws are slackened, the fork disengaged from pinion, and the front and fork lowered into recess in the extension frame. The lenses, which remain attached, come through the circular aperture formed in baseboard, or, if desired, the lens panel may be lifted out (before the front is lowered) and placed face upwards in the recess in baseboard, so that when the camera is closed the lenses will project inside the bellows. The lens panel I prefer to make of such a size that it will just fit into the circular opening in baseboard, being prevented from falling through by the projecting flange connected with the turntable.

In order to allow the body of camera to swing or move in a horizontal plane, I hinge or pivot the same to two plates and also the stretchers which support it. These plates have radial slots in them. To the sides of baseboard I attach two angle-plates, which are bent and project over the top edge of extension frame, and so form supports for the flat slotted swing plates. A set-screw passes through the radial slot in each swing plate, and works in the supporting angle-plate beneath, and thus serve to clamp the swing-plates at any angle. Slotted stretchers and set-screws allow the vertical swing in the usual manner.

Instead of using loose or fixed spirit levels for adjusting the swing back and front, I place in a convenient position on the side of camera body and on the side of front board a small swinging or pivoted plate or pointer to indicate when the parts are plumb. I also place a similar plate on the revolving or square reversing adaptor, whichever may be used, so as to hang plumb whichever way up the adaptor is placed, for the purpose of getting the picture horizontal and parallel with the edge of plate.

Instead of making the dark slides to slide or push into a groove as usual, I make them so that they may be placed in position from the back, and when pressed forward into their place in camera they shall engage with one or more springs to lock them in position until released.

The focussing screen is made of a flexible material, which may be stretched on a frame or wound on a roller, as described in the before-mentioned specification. Instead of or as an auxiliary to the spring connected with the roller for winding and giving tension to the screen, one or more lengths of indiarubber may be attached at one end to the said roller and the other end to camera body, so as to wind the screen up by the tension of the indiarubber when the screen is released, and keep it “taut” when extended. One or more pieces of indiarubber may be attached to the screen to counteract the force or jerk when the screen is released.

AN IMPROVED PHOTOGRAPHIC CAMERA.
No. 13,549. WARWICK BROOKES, 350, Oxford-road, Manchester.—
October 23, 1886.

THIS invention relates to an improved combination and arrangement of parts constituting a portable photographic camera for taking instantaneous or other pictures.

The body of the camera is in the form of an oblong box, provided with a rabbet at the back to receive the ground-glass focussing frame and the dark slide. There is a recess at the bottom of the camera to contain the focussing frame when not in use.

The back is hinged at the top, and is provided with two side-pieces, so that when raised it forms a hood so as to dispense with the necessity for a focussing cloth.

The shutter of the dark slide is hinged to the frame, and it is provided with a slot and a band, beneath which (as the slide is placed in the camera) the end of an arm or lever is passed. This arm projects from a rod passing across the body of the camera (inside) and provided with a turn button on the outside, so that when the slide is placed in position, the sensitised plate can be exposed by turning this button so as to cause the arm to open the hinged shutter inside the camera.

An opening is provided in the back through which the shutter can be fastened or unfastened after it is placed in the camera and the back shut.

The lens is fitted to the front of the camera, and the focus is taken by moving the same to or fro by means of a turn button outside, the said button being fixed on a rod, at the other end of which is a pinion taking into the rack of the lens.

In the front of the lens is a frame hinged from above, and carrying the instantaneous shutter, and when longer exposures are required this hinged frame can be opened and closed so as to act as a cap to the lens. The instantaneous shutter is of the revolving type, and is released by a small catch underneath the camera.

The camera is fitted with a "view-finder," which consists of a hinged frame on the top near the front, and a movable arm or strip pivoted to the back and made with an eye-hole.

The hinged frame of the "view-finder" when shut lies in a recess on the top, and incloses and holds down a movable card or paper slip, upon which memoranda of the subjects and exposures can be made, and a small spring is also provided for holding a pencil to be used for that purpose.

The camera may be held in the hand close to the cheek, and by looking through the "view-finder," the subject may be followed, and the instantaneous exposure of the plate made at the proper time by pressing the catch, or if a longer exposure is required, it is provided with a screw for attaching it to a stand.

The claims are:—1. The herein-described improved photographic camera, embodying the combination of improvements herein specified. 2. The hinged hood for shading the focussing screen of a photographic camera when the hood is raised, without the use of a cloth, and for enclosing the dark back when the same is inserted into the camera body from the rear, as specified. 3. In a photographic camera, the combination with a dark back having a hinged flap shutter opening into the camera body, of the means substantially as herein described for effecting the opening and closing of the hinged shutter after the dark back is inserted. 4. In a box-body photographic camera the combined hinged flap and instantaneous shutter for long and short exposures respectively, the said flap enclosing the front of the body and the instantaneous shutter being mounted thereon, as specified. 5. A box-body photographic camera, having a lens front or frame capable of being racked forward or backward wholly within the body in combination with a combined hinged flap and instantaneous shutter enclosing such lens front or frame, substantially as specified.

IMPROVEMENTS IN THE CONSTRUCTION OF PHOTOGRAPHIC CAMERAS.
No. 14,262. HENRY PARK, 1, Orchard-buildings, Kingsland-road, Middlesex.—
November 5, 1886.

THE object of my invention is to effect improvements in the construction of folding photographic cameras, whereby they are rendered compact and portable, and improved facilities for manipulation are afforded.

I form the baseboard in two parts, the lower half of the board being made solid, and the upper (sliding) half being a rectangular frame provided with rabbets and racks as usual. The upper part of the baseboard is made to slide forward upon the lower baseboard.

The lower baseboard is fitted on each side with a metallic groove or slot. In each of these slots I fit a slide-bar, which carries the lower centre or pivot of the radial bar or link, and also a vertical bracket and a set screw. The set screw is used to fix the position of the slide-bar in the slot, and the bracket is fitted with a screw which forms one of the pivots for the back board.

The focussing pinion is fitted to the lower baseboard, and the front plate is fitted to the upper baseboard, to which it is fixed in any required position by set screws and nuts.

The bellows body is made parallel, and is attached to the front and back plates in the usual manner.

The main features of novelty in this invention are the outside metallic grooves in the baseboard; the slides which work therein; the brackets attached thereto carrying the working centres of the back board, this back board having double swing motion, which allows the back part of the camera to be put in any position on the baseboard as required when wide-angled lenses are used, readily and without detachment; also the adjusting links; also the means of folding the camera (no hinges being used), and the protection afforded to the focussing plate by the solidity of the lower baseboard when packed.

The camera is fitted with all the usual appliances for manipulating the same.

A HOLDER FOR LENS-DIAPHRAGMS IN CAMERAS.
No. 14,421. JOHN EDWARD THORNTON, 3, New Lorne-street, Moss Side, Manchester.—November 9, 1886.

THE object of this invention is for the purpose of dispensing with the necessity for having a loose case for the reception of lens-diaphragms or stops, such as is usually carried in the pocket.

In carrying out this invention I form a receptacle which I call the diaphragm-holder, which may be a plate having its edges turned over on three sides to hold the diaphragms in position, leaving the top open so that the diaphragms may be readily withdrawn. A spring, having a projection attached, is made to press against the diaphragms, and the projection, passing through the holes therein, prevents them being withdrawn till the spring and projection are pressed out of the way.

The holder may be made of metal, ebonite, or other suitable material, and may be attached to any part of the camera in a convenient position. In some cases I prefer to place it on the camera front near the lens, but generally I prefer to place it on the side of camera body.

If desired, the holder may be formed in the woodwork, by recessing or cutting it out, or in any other way which may be preferred.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION

THE usual weekly meeting was held on Thursday, the 29th ultimo,—Mr. A. Mackie in the chair.

Mr. H. N. SMITH exhibited several negatives taken with a pinhole pierced through a piece of tinfoil, and one negative was especially sharp and clear.

Professor STEBBING said some pinhole photographs of Notre Dame recently exhibited before the French Society were exceptionally good. An exposure was given of fifty minutes. How the pinhole was made influenced materially the image. After piercing the hole the burr should be carefully filed off.

Mr. J. B. B. WELLINGTON remarked that a greater part of the failures in pinhole photography were frequently due to the flimsy, makeshift nature of the camera employed.

Mr. A. L. HENDERSON said a client of his had recently sent him a Daguerreotype to clean; upon washing it in distilled water the film all round the edges of the plate blistered and peeled off. For cleaning he used a strong solution of cyanide followed by alcohol and allowed to dry spontaneously. The Daguerreotype was handed round for inspection; it appeared to have become oxidised on those parts where the film had peeled off.

Mr. J. TRAILL TAYLOR, in place of alcohol for drying a Daguerreotype plate, used distilled water and then held the plate over a spirit lamp.

Mr. W. M. ASHMAN thought the peeling of the film might be due to the plate being varnished.

Mr. W. E. DEBENHAM had never seen a plate of this kind varnished.

Mr. TAYLOR said the Daguerreotypes sent out by Mr. Mayall were always varnished; they were, however, not described as such, but stated to be enamelled.

Mr. J. J. BRIGINSHAW drew attention to the curious appearance presented by some lantern plates coated with collodio-bromide emulsion. After drying the film was full of minute holes and cracks. He had dried the plates by heat and also allowed them to dry spontaneously, the result being the same in each case. The emulsion was made from the same formula he had always used excepting that the silver was divided and added at two separate times. Was the failure to be ascribed to this departure?

Mr. DEBENHAM thought it was attributable to water in the film.

Mr. BRIGINSHAW remarked that he took every precaution to prevent this. He first soaked the emulsion after washing in alcohol, afterwards squeezing it through a fine handkerchief, using a lemon squeezer he kept for the purpose.

Mr. DEBENHAM said methylated spirit was answerable for many of the failures in collodio-bromide emulsions. If the emulsion was coated too thickly it would be liable to crack.

Professor STEBBING said coating in a damp room would cause markings of the film from the rapid evaporation of the ether and alcohol and the condensation on the film of the damp atmosphere of the room.

Mr. W. LANS, JUN., placed on the table prospectuses of the International Exhibition of Industry, Science, and Art, to be held at Glasgow in 1888. He gave particulars of the Photographic and Fine Art Sections and invited exhibits of pictures and photographs.

Professor STEBBING announced that a French Universal Exhibition would be held in 1889, and he suggested a committee being formed in England for the purpose of assisting intending exhibitors. In reply to a member, Professor Stebbing said a prize of 40*l*. had been offered for a process that would be an improvement upon the gelatino-bromide process, the process to be given to the world.

Mr. TAYLOR alluded in feeling terms to the death of Mr. J. G. Tunny, of Edinburgh. A resolution recording the sympathy and great grief felt by the members of the Association was passed, and the Hon. Secretary was directed to forward the same to the family of the deceased.

Mr. John Jackson, 13, Soho-square, was elected a member of the Association.

ANOTHER meeting was held on Thursday, the 6th instant,—Mr. J. Traill Taylor in the chair.

Mr. JAMES THOMPSON, of Liverpool, exhibited a whole-plate camera, which he stated combined several improvements, having a long focus and being very compact and light. The focus of the camera shown was twenty-one inches; this, Mr. Thompson said, could be increased if required. The handle for racking the camera was at the back, and when not in use could be doubled up and fitted into a recess of the baseboard. The camera was similar to the old Kinnear form, and in reversing required to be unscrewed from the baseboard each time.

A question from the box was read:—"How is mercury to be removed from a negative that has been intensified with this salt?"

It did not appear quite clear whether the questioner required to be informed as to the entire removal of the mercury from the film after application or whether partial reduction of density when too intense was required. In the latter case it was recommended to place the negative in a hypo bath until the necessary reduction was obtained.

Mr. L. MEDLAND gave some interesting particulars of his recent visit to Denmark and Russia, illustrated by a series of prints taken by him during his tour. The Russian views were obtained under great difficulties, and in one case he was taken before the chief of the police and only liberated after much parleying and considerable delay. Mr. Medland attributed a great deal of this suspicion to his pneumatic shutter, which was regarded as a kind of infernal machine. Altogether he expressed himself as being heartily glad to get out of the country. Photographing after this in Denmark, where he was allowed, without let or hindrance, to take what views he liked, even to the so-called fortifications, Mr. Medland regretted very much not taking a detective camera with him, and he advised intending tourists on the Continent to add a camera of this description to their outfit. The difficulties in Russia he found on inquiring only applied to tourists and not to local photographers.

To the question, was it possible to get perfectly sharp pictures from the deck of a vessel while the screw of the vessel was revolving, several members answered in the affirmative.

The CHAIRMAN said in a case of this kind if the camera was held in the hand it must not rest against any part of the vessel. On one occasion he took a shot from a railway carriage window, resting the camera against the side of the window. The picture was blurred. On the next occasion he held the camera in his hand and succeeded in getting a fairly sharp negative.

An interesting discussion followed, in which the Chairman, Mr. Thompson, and Mr. F. A. Bridge detailed their experiences with foreign officials and the devices resorted to in order to obtain certain views they wanted.

Mr. R. KEENE mentioned that at the visit of the members of the Photographic Convention to Edinburgh in July last he was not allowed to take his camera near a certain fortification.

The CHAIRMAN stated that permission to photograph in any of the London parks was very easily obtained by simply asking for it.

Mr. H. S. TRINKS exhibited some negatives taken with the new projecting microscopic eye-piece of Zeiss, of Jena; the results were very fine. He also exhibited several of the eye-pieces mentioned.

The CHAIRMAN, by request, gave a description of the Welsbach incandescent gaslight, some account of which will be found in a leading article in the present number.

One of the members promised to bring the light and show it at the meeting on the 20th instant.

CAMERA CLUB.

THURSDAY, October 6, was the first technical evening of the winter session at the Camera Club. Mr. Alfred Deed occupied the chair.

A paper, entitled *Where go, what take, and some other matters*, was read by Mr. W. ADCOCK, who, in opening his subject, referred to articles which had appeared in the photographic journals as to where to go with the camera. He held it absurd to go far away in search of work when it was to be found close at hand, and he then dwelt upon the beauties and opportunities, as he saw them, in public resorts in London, such as Regent-street being repaved, and Trafalgar-square on a summer's day. He hoped that some who did not care for rustic scene-hunting would think out subjects of an order that should employ some invention, some predetermined arrangement, and that they would devote themselves to the production of figure pictures, representing, if not dramas, at least minor episodes of real life. He had been charged with having a liking for somewhat vulgar subjects. He hoped in his treatment he had done something to refine them. Incidents of low life, the sorrows and struggles of the poor, had been portrayed by great painters—by some to the entire exclusion of all other subjects; and the vulgarity or refinement of the work was dependent upon its treatment by the artist. He saw no end to what might be done practically, whether by quick shots at groups, or by arrangement with individuals for posing, to carry out subjects determined on. He insisted on more interior work being done, and advantage taken of the fine interiors available in London. He then referred to landscape work, and apprehended that many photographers in the future would give the same thought and care to a subject as a Graham or a Vicat Cole. Very few exposures would be made, but the parts of the picture would be carefully studied and composed, and a far larger size than at present would be worked. He had a belief in a direct picture as distinct from an enlargement. One point he wished to emphasise, the desirability of using a plate less square, particularly for figure work. Plate makers should keep in stock sizes in which the breadth was to length as one to one and a half. In conclusion, the lecturer drew attention to the use of plain salted papers, and described his method of sensitising them. He also showed pictures upon grocers' tea paper, treated in this way, and rough prints upon blue paper.

The CHAIRMAN, in opening the discussion, spoke of the difficulties of working with anything but a detective camera in the streets of London. He had had some experience of the persistency and curiosity of a London crowd, and would not advise the planting of a camera in Regent-street. One point he hoped would receive full discussion, that of the respective advantages of large direct work and enlarging from small negatives.

Mr. D. P. RODGERS was all in favour of small cameras and enlarging, except for large heads. Apart from the convenience of light weight and ease of

manipulation in the field, small lenses were better in working than large ones. He found he could use $\frac{1}{25}$ instantaneously with his small lenses in the country and secure good exposure, where the large lens gave but a very faint impression on the plate. He thought he could show some enlargements from quarter-plate to whole-plate and 12 x 10, which could not be distinguished from direct work.

Mr. DAVISON highly appreciated Mr. Adcock's address, but felt that he had been taking Londoners to task for overlooking work to their hand without very fully seeing the difficulties of such work for men with daily avocations in town. Then again, the detective camera was not very likely to help one to works of art, though it might lead to very interesting bits being secured. He agreed with Mr. Adcock that there need be nothing vulgar in the treatment of low-life subjects, and also in his remark "how little it takes besides the treatment to make a picture;" but he thought Mr. Adcock ought to have added "how difficult, how impossible, it is to command this treatment." It was easy enough to recognise sentiment, pathos, or humour, in a subject, and also to fix it so as to secure interested attention from people of a sympathetic turn; but to treat the material so as to produce a work of art was a different matter, and not more than one or two photographers had anyway approached success in it. In regard to interiors Mr. Adcock had said "no other than a wide-angle lens was suited to interiors of much depth." He should have said that it was particularly in interiors having little depth that the wide angle was most essential. He did not think that enlarging would displace large direct photographs in artistic work. A picture generally had a scheme, and was worked out in minutest details, and enlarging would probably be felt to disturb the elements or alter the feeling conveyed by the work.

Mr. BLANCHENESS had tried some of the very work suggested by Mr. Adcock in Regent-street, but all his plates had proved under exposed.

Mr. SAGE did not like enlargements, nor could he advise outdoor work with a large camera, unless the operator enjoyed such chaff as an advice to "get inside and pull down the blind," &c., to which he himself had been subjected.

Mr. LYONEL CLARK was in favour of enlarging. He did not like sharpness in any one part of the picture or plate, but preferred a certain amount of fuzziness all over the picture. For instance, he would draw attention to one of Mr. Byrne's large direct heads now in the exhibition at Pall Mall (a portrait of an old gentleman), where the near part of the figure was sharp and detailed, and every hair clear as the lines on a small-scale map, and the off side was a snowy blotch. He thought he would have done better to have taken the portrait small, and to have enlarged it. The small lenses were much easier to construct, and gave greater depth of focus, if he might use that expression, which was really a misnomer, and meant a want of definition in any one plane. He then instituted a comparison showing that the enlargement from work done by a small lens would be expected to be sharper on the whole than that same large size done direct. He should suggest enlarging by daylight, and with the same lens as the small negative was taken with. He thought the best plan was to make an enlarged positive, say to 12 x 10, and then to copy again down to 10 x 8, that being the size required. It was impossible to get glass plates close enough together to make the transparency and final negative by contact. It would often be found that the best enlargements would be obtained from the poorest negatives, at least from the over exposed ones.

The CHAIRMAN said that a serious objection that might be taken to enlarging was that it meant a great deal of work.

Mr. RODGERS found that his enlarging was done very expeditiously with a lantern with large condenser, which he kept ready at all times for working with the oxy-hydrogen light. One point of interest he would like to raise (it was one he was at present uncertain about), whether a better result were obtained by direct enlargement upon paper from a negative, or by making an enlarged negative.

Mr. ADCOCK then went over the remarks that had been made, and met certain objections raised by the speakers. One point he was glad to find such general agreement upon, and that was the need for an alteration in the proportions of dry plates, and for the more general keeping in stock of the oblong forms of plates.

A cordial vote of thanks was passed to the lecturer.

On Thursday, October 20, at eight o'clock, lantern slides will be exhibited. Mr. Brooks will show an interesting series of interiors of Windsor Castle. Members will also be expected to bring slides for exhibition.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

At the meeting held on Tuesday, October 4, at Myddelton Hall, Islington, N., Mr. J. Traill Taylor, President, in the chair, Mr. L. MEDLAND asked the cause of some curious transparent spots which had appeared on some of his plates after fixing.

Mr. J. JACKSON suggested that the defect might have been the result of using the fixing bath too strong.

Mr. F. DUNSTONVILLE, of Madras, had experienced the same defect.

The PRESIDENT thought that if a strong fixing bath had been used the defect might be caused in the washing, by the change from a dense liquid to a rarer one, in the same way that blisters are produced on albumenised paper prints.

Mr. F. G. READER inquired if any one had had any experience of the use of zinc hypochlorite for eliminating hypo.

Mr. JACKSON had used chloride of zinc, but he found that it made the prints a bad colour.

The Hon. Secretary showed some negatives taken by means of "The Ready Fotografer," which was exhibited at the last meeting of the Society. They were considered very good specimens of pinhole photography.

In a short discussion on stripping films and paper negatives,

The PRESIDENT said that a paper negative squeezed on to ebonite had been sent him by Captain Murray, who wished to know how to strip it from the ebonite; it was found impossible to do this by the ordinary means. Captain Murray had, however, since written to the effect that he had been successful in treating similar refractory cases. He found that warming the ebonite would enable the negatives to be stripped easily. The President had tried the means suggested with complete success.

Mr. MEDLAND gave a most interesting and amusing account of his trip to and photographic adventures in Norway, Sweden, and Russia. He recommended any one desirous of a pleasant holiday to go to Stockholm, where plenty of work for the camera might be found, and there was not the slightest restriction to its use anywhere about the city. He would also recommend that Russia be avoided, as Russian officialism did not appear to take kindly to photography. His experience in St. Petersburg and Moscow showed that it was very difficult to appear in public with a tripod without incurring the risk of an involuntary trip to Siberia. On attempting to photograph some of the public buildings he was escorted to the police office, and, after interviewing various officials, was brought before Prince Dolgorouki, Chief of Police, who informed him that permission should have been applied for, and then, after an inquiry had been made as to the political status of the applicant, the matter would have received consideration.

Mr. W. B. PEARCE suggested that, to meet a difficulty Mr. Medland and, doubtless, others had experienced in purchasing chemicals in foreign countries, a list of the names of the chemicals, apparatus, &c., most likely to be wanted on a tour should be published, with a translation into various European languages.

The PRESIDENT said that such a glossary was already prepared for one of the annuals.

The next meeting will take place on Tuesday, October 18, when the officers for the ensuing year must be nominated. It will be a lantern night. Visitors are invited.

NORTH SURREY PHOTOGRAPHIC SOCIETY.

The first meeting of the present session of the above Society was held at the Greyhound Hotel, Dulwich, on Wednesday evening, October 5.—Mr. W. H. Walker in the chair. There was a full attendance.

It was announced that arrangements had been made for a demonstration of carbon printing.

In spite of the fact that there was no formal communication to the Society, there was an interesting and instructive discussion on the use and advantages of the Eastman stripping films, which had been extensively used by the members during the recess.

The next meeting will be held on Wednesday, October 19, Mr. Yates in the chair.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

The annual meeting was held on Tuesday, October 4, in the Masonic Hall, Surrey-street.

After an excellent dinner provided by the Steward, Mr. Turner, the chair was taken by Mr. W. B. Hatfield, in the absence of the President, Mr. T. S. Yeomans. There was a very good attendance of members, and, after routine business, the election of officers was proceeded with:—*President*: Councillor T. Firth.—*Vice-Presidents*: Messrs. T. S. Yeomans (retiring President) and A. S. Platts.—*Treasurer*: Mr. Charles Yeomans.—*Hon. Secretary*: Mr. J. W. Charlesworth, 227, Cemetery-road.—*Assistant Secretary*: Mr. E. Beck, Norfolk-row.

A vote of thanks to the retiring officers was passed, and a special vote of thanks was given Mr. Joseph Taylor, the retiring Hon. Secretary, for services rendered during a course of many years.

After the balloting for Council it was found that the following five were elected:—Messrs. W. H. Bacon, Joseph Taylor, Jonathan Taylor, W. B. Hatfield, and T. G. Hibbert.

Mr. W. J. Spink was elected a member.

The statement of accounts showed a considerable balance in favour of the Society.

In the yearly competition for the Society's medals for the best six pictures taken during the year, Mr. T. G. Hibbert was the fortunate member who carried off the silver medal, and deservedly so, his series being remarkable for artistic study and technical excellence. The bronze medal was awarded to Mr. Jonathan Taylor for a frame of well-selected views; the effect, however, was impaired by having one cloud in all six pictures. Dr. Morton's and Mr. B. J. Taylor's pictures showed very careful study, and ran very close for second.

NORTH STAFFORDSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION.

The inaugural meeting of the winter session was held on Wednesday, October 5, under the presidency of Mr. C. Alfieri.

A pleasant hour was spent in the ventilation of various subjects interesting to amateur photographers and in the examination of views of Moreton Old Hall, Cheshire, one of the finest specimens of the old half-timbered houses of the Elizabethan period now existing in the country.

A discussion subsequently took place upon the superior attractions of large pictures over those of small dimensions, the Vice-President giving preference to the former, while the President maintained that pictures of moderate dimensions, being more readily taken in by the eye in their entirety, were, *ceteris paribus*, more gratifying to the observer.

Referring to a well-known brand of dry plates, Mr. LEER said he had always failed to get sufficient density with them, notwithstanding the liberal use of pyro.

Mr. DRUMMOND stated that he had had a rather singular experience while developing an interior of a church taken on one of these plates, namely, that a text round the altar screen had appeared quite plainly on the negative in the early stages of development, but had disappeared altogether when the plate had been fully developed.

After some suggestions for an exhibition of members' work to be held in the near future, it was resolved that, by way of inaugurating the winter session of the Association, an exhibition of lantern slides be held at the Mechanics' Institution, Hauley, on Wednesday, the 19th instant.

The PRESIDENT having feelingly called the attention of the meeting to the fact that Mr. T. H. Hall, one of the earliest members of the Association, had

been removed by death from their midst, it was proposed that "The President, Vice-President, and Council of the North Staffordshire Amateur Photographic Association desire to convey to Mrs. Hall the assurance of their deep sympathy with her and her family in their recent bereavement, and to place on record their sense of the abilities and estimable qualities of the late Mr. T. H. Hall."

Messrs. Beech and Wright were elected members of the Association.

Correspondence.

Correspondents should never write on both sides of the paper.

THE PHOTOGRAPHIC EXHIBITION.

To the Editors.

GENTLEMEN,—In the leader on the Photographic Exhibition in to-day's BRITISH JOURNAL OF PHOTOGRAPHY, it is stated that no examples of the application of orthochromatic plates to landscape work are to be found in the Exhibition. Allow me to draw your attention to the fact that I exhibit two landscapes taken under the same conditions of lighting on ordinary plates and on plates bathed in a solution of erythrosine, a yellow screen being used in the latter case (278 and 279, 294 and 295). The prints are not large, and are hung low, and hence they have escaped your attention. The results show greater differences than might have been expected, the improvement in the rendering of distance and foliage being especially noticeable. I may add that during the past year I have made a number of experiments in this direction.—I am, yours, &c.,

The Yorkshire College, Leeds, October 7, 1887. C. H. BOTHAMLEY.

To the Editors.

GENTLEMEN,—Owing, I suppose, to some inadvertence on the part of the Assistant Secretary to whom I sent full particulars, my exhibit at the Photographic Society of Great Britain is erroneously described as lantern slide. Although they are capable of being utilised as lantern slides, that is not their intention; they are specially intended for window decoration, and for that reason they are mounted with a clear instead of an opaque margin.

They consist of the picture, by the Woodbury process, hermetically sealed between two glasses, the medium employed being of such a nature that it produces a ground-glass effect without obstructing the light in any material degree, and, moreover, renders the pictures bright on both sides, thus obviating the very disagreeable effect of a ground-glass backing.

I have not myself tried them as lantern slides to my satisfaction, as they require a condenser of rather larger size than usual, four and a half inches, but am inclined to think that then they would be extremely effective as lantern pictures.—I am, yours, &c.,

GEORGE SMITH.

26, Colebrooke-row, N., October 11, 1887.

PLATES FOR HOT CLIMATES.

To the Editors.

GENTLEMEN,—Perhaps the following remarks on the behaviour of dry plates in Calcutta may be of use to some of your readers.

During our cold season—or, say, from the middle of November to the middle of March—I have obtained very satisfactory results from all the well-known makes of plates which I have tried; but it is when our hot and rainy seasons are on us that working dry plates becomes a real difficulty. Slow plates I soon found to be practically useless during the two latter seasons, as when they did not turn into "dissolving views" in the developer they invariably did so in the after-washing process, even when ice was used. If perchance they escaped in the washing, the drying process resulted in the complete dissolution of the film.

The extra rapid and instantaneous plates were far better, as the films had much less tendency to melt than those of the slow plates, and good results might often be obtained with care, patience, ice, and alum. There was still, however, a great inclination to frilling, particularly in the final washing and drying processes.

For the last few years I have, however, been using *Tropical* or *Insoluble* plates, and these are, without exception, the finest plates I have ever used. Frilling or melting films never occur with them, and they stand an immense amount of rough handling and development. They are very easy to control, and yield negatives of any required density. No ice is required for them, and the alum bath is only necessary when the plate requires clearing. I have left these plates soaking in the same water for three days in the months of May, June, July, August, and September—not once, but frequently. I have then taken them out, wiped the water off the film with the back of my hand, then dried them both in the sun and over a kerosine lamp, and had them in the printing frame in perhaps a quarter of an hour after taking them out of the water. I use the simple pyro and ammonia developer, which I prefer to all the others I have ever tried.—I am, yours, &c.,

JNO. J. MEADE.

4, Hastings-street, Calcutta, September 19, 1887.

[The plates alluded to by our correspondent are an American production, and it is understood that their insolubility in warm water arises from the presence of chrome alum in the emulsion.—Eds.]

ROYAL CORNWALL POLYTECHNIC SOCIETY'S EXHIBITION REPORT.

To the Editors.

GENTLEMEN,—In your last issue I have just read the letter of your correspondent, Mr. H. P. Robinson, relating to the Judges' Report of the Photographic Section of the above Society.

The report, in its altered form, as published in a contemporary journal, I consider materially prejudicial to several of the exhibitors, and is entirely different to the correct report as published in THE BRITISH JOURNAL OF PHOTOGRAPHY on September 16.

Your correspondent's letter suggests that I should have stated to what extent and in what matter the said report had been altered. With your permission I will do so in parallel columns, without further comment, leaving your readers to form their own judgment thereon:—

Extracts of the report as published on September 16 in THE BRITISH JOURNAL OF PHOTOGRAPHY, which is a correct copy of the official report of the Judges:—

"PROFESSIONAL SECTION."

"No. 609 is an instantaneous picture of a large number of sea gulls on the wing, and this has been awarded a second silver medal. The birds are in every conceivable position, and most of them perfectly sharp, showing that the exposure must have been very rapid, and such a picture must prove of great value to the painter. This picture is by Mr. B. Wyles, of Southport. The same exhibitor has several other meritorious productions."

"No. 617, 'Carolling,' by Mr. H. P. Robinson, is a most artistic production, and must rank amongst that gentleman's works as one of the finest; it is full of poetry, and is printed in sepia, and too much cannot be said in its praise. As usual, he takes the highest award—the Society's first silver medal."

"Mr. J. B. Scott sends several artistic productions."

"Mr. J. Weir has several fairly good pictures."

"Mr. W. J. Byrne, of Richmond, sends some very high-class work. A first silver medal has been awarded to a direct picture of large size of the Hon. Frederick Tollemache. It is a most splendid specimen of untouched photography, the finest in the Exhibition. The frame above it, by the same artist, contains some specimens of photography (portrait studies) taken in ordinary rooms, &c., being perfect gems in their way, and cannot fail to attract attention."

"A second silver medal has been awarded to a picture of the Countess of Londonderry, by Mr. J. Lafayette, of Dublin. It is a perfect picture, and the retoucher's art has played a prominent part. There are several other magnificent works of the same order."

"Messrs. West & Son again send some of their yacht pictures, which are wonderful productions, but the Judges do not think they quite come up to their former exhibits."

Extracts of the report as published on September 16 in a contemporary journal, which is NOT a correct copy of the official report of the Judges:—

"Professional Section.—B. Wyles (of Southport) has several other meritorious productions."

"617, 'Carolling,' by H. P. Robinson, must rank amongst that gentleman's works as one of the most characteristic; it is printed in a sepia tint."

"West and Son again send some of their yacht pictures."

I am, yours, &c.,

WM. BROOKS.

October 10, 1887.

THE AREA SYSTEM OF GEORGE SMITH.

To the Editors.

GENTLEMEN,—It is to be regretted that Mr. George Smith has not taken the photographic public entirely into his confidence with regard to his system of numbering stops and lenses. If Mr. Smith was aware that the method he had given for finding the area number of a doublet lens was entirely an empirical one, and only gave correct results when the two lenses were of similar focus and when the separation was not taken into account, it would certainly appear that this fact should, at the outset, have received some notice from him, and that he should not have led his readers to infer that his system was universally applicable.

In a paper recently read by me at the North London Photographic Society, I pointed out the difficulties that would occur in applying the area system to a Darlot's universal series of lenses. I took as an example the five-inch and nine-inch combination used together. In this case the error amounted to twenty-five per cent. Mr. Smith in the

* These exhibitors have been entirely left out.

discussion on the paper, gave a general denial that such a percentage of error could exist. I then endeavoured—though without success—to convince him, and mentioned incidentally that in using the six and eighteen-inch lenses in combination, the error would amount to about one hundred per cent.

Your correspondent, Mr. Simon, has, however, been more fortunate, and has succeeded in obtaining from Mr. Smith an admission of the correctness of calculations which reveal an error in the area system of over one hundred per cent., though, remarks Mr. Smith, one of the lenses would actually require nine times the exposure of the other; as if that were an extenuation of the fact.

Mr. Smith, it appears, is not aware that sets of combination lenses are made and sold in which two lenses having very different focal lengths work quite as well as two having nearly the same focus. This, however, is the case; although, so far as the area system is concerned, it is of little consequence, for Mr. Smith predicts that if the system should become popular such doublets will not be employed—that is to say, photographers will find the area system so simple, and so far surpassing in merit any other method of numbering stops, that they will use only those lenses to which the system can be properly applied.

But, let me ask, Did we need another system of numbering stops? We had the uniform system, and this is an area system. Does Mr. Smith's plan possess any tangible advantage over the uniform system? True, the latter is the system recommended by the Photographic Society of Great Britain, and that we have, in using it, to deal with only one number—the stop number—instead of with two—a stop number and a lens number—as in the area system; but I fancy that these will, generally, be considered as advantages.

Mr. Smith claims it as an advantage peculiar to the area system that the stop numbers are based upon the unit one-sixty-fourth of an inch. The real unit is, however, $(\frac{1}{64})^2 \times 10 = \frac{1}{4096}$, or roughly $\frac{1}{4000}$ of a square inch. But the uniform system numbers are based upon the exact diameters of the stops, and, to most of us, it will be self-evident that the area system cannot be more accurate than that which is quite accurate. It must be further noticed that it is the fact of taking so small a unit that makes the area numbers so large.

In conclusion, it is certain that the area system is such that it cannot become popular, and that the time will never arrive when the cry shall be, "The system! the system!" instead of, as now, "The lens! the lens!"—I am, yours, &c.,

O. SMITH.

P.S.—I notice that I have omitted to refer to Mr. Simon's difficulty of having to carry into the field a separate set of stops for each of his lenses, but I cannot venture to trespass further on your space. If, however, you will put him into communication with me, I think I may be able to assist him.

To the Editors.

GENTLEMEN,—I have to thank Mr. George Smith for his prompt reply to my letter, but, at the same time, I must confess that I feel some disappointment at his inability to meet my difficulty.

Mr. Smith now explains at length that his system was intended to apply to a set of lenses which he considered suitable for his own work, but I can nowhere find in his previous writings on the subject that he makes any mention that his system is applicable only to some lenses, and not to all. So far, therefore, according to his own admission of the facts, Mr. Smith has attempted to lead the photographic public into adopting a system which is accurate only under certain conditions as to the construction of the lens, and which, when these conditions are not complied with, allows of the possibility of an error occurring, amounting, as I have shown, to considerably over a hundred per cent.

Mr. Smith characterises my letter as a "hoax," because it happens that my lens will not fit his system. If the word is permissible at all, surely it might be more appropriately applied to the system which will not fit my lens.—I am, yours, &c.,

S. SIMON.

TEN PER CENT. SOLUTIONS.

To the Editors.

GENTLEMEN,—In your last issue this subject is treated at length by Mr. Lionel Clark, with the effect of confusing what is a tolerably simple conception. The expression ten per cent. is certainly technical, but its meaning should be as well known as that of the also technical expression "a cup of coffee." The meaning usually attached to the phrase is that in ten minims of the solution there will be found one grain of the salt, if solid, or one minim if fluid, as ammonia.

Mr. Clark says, "One ounce of pyro dissolved in ten ounces of water is without doubt a ten per cent. solution by weight only." This statement is decidedly incorrect; the proportion is one ounce by weight of pyro in ten by weight of water, giving one in eleven of the solution, and therefore ten in one hundred and ten, instead of a hundred.

Take any table of specific gravities where the percentage is given, probably at intervals of five per cent. up to saturation; what does ten per cent. there mean? It means ten of the salt to ninety of water, all by weight, the total weight being 100, not the weight of the water employed. It is also overlooked that when a given bulk of water and salt are brought together a shrinkage occurs which is probably different for each kind of

salt (or other soluble substance); the result of this oversight is that one-tenth grain of pyro and ten minims of water are wrongly made out to measure ten minims only, and in like manner one ounce of pyro and nine fluid ounces one fluid drachm of water are considered to occupy only the original bulk of the water. What should be done is to *make up to nine ounces* one drachm of solution, and then ten minims will contain a grain of pyro.

In making up sulpho-pyrogallol, it is easy to err, by dissolving the sulphite in perhaps six ounces of water, neutralising and emptying into an ounce bottle of pyro, and thereupon finding that we have some twelve ounces of solution instead of nine ounces one drachm (=4380 minims). In the case of ammonia, take one fluid ounce and make up to ten, and we have what is required. This is not exactly one ounce to nine of water, as there is shrinkage to allow for, but this is quite near enough for all practical purposes.

I, for one, fail to see the utter confusion charged so liberally to our weights and measures. If I read of an ounce of pyro I am never in doubt as to whether a fluid ounce, troy, avoirdupois, or a wild animal is intended, nor do I think that people in the habit of using weights and measures fall often into error on this score.

Mr. Clark develops the French unit of long measure from the kilo through the litre; this should be *reversed*. The metre is an extremely accurate something or other, nobody seems to know what, as Captain Abney observed the other day at the British Association, and from it is derived the litre, and thence the gramme. The story is old, how in the rage for having everything new France adopted new weights and measures, recommenced the calendar with the year 1, rechristened the months, and made havoc generally. How their unit of measure was found to be wrong after coming into use, but no one proposes to re-rectify it.

Apart from the units employed, which are good enough when thoroughly understood (as are also the English units), the French system has the disadvantage of being decimal, of casting aside as useless the clearness obtained by the use of large multiple-units, and the aliquot sub-units, which have developed with the increasing affairs of mercantile nations. To quote prices per score, per dozen, by the quarter, though convenient, are to be discontinued as unscientific, and to ensure accuracy in our weightings and measurements we must go to the sea-level in winter time and work in a vacuum!

If other nations have followed the example of France in this matter, that is no reason why we should confuse our own population by doing the like; the fact of the adoption of the decimal system in something like the reverse order of commercial greatness of the nations tells against the system. I could urge much more on this subject, but fear to occupy your space to an undue extent.—I am, yours, &c.,

R. C. PHILLIPS.

4, Camp-street, Lower Broughton, Manchester, October 8, 1887.

LATENT LIGHT.

To the Editors.

GENTLEMEN,—If Mr. Winstanley will kindly refer to *A Dictionary of Photography*, edited by Thomas Sutton and G. Dawson in 1867, he will find at page 169 a notice on *Latent Light* which treats on the theory he introduces in your last issue as part of his experiments and investigations in 1875.—I am, yours, &c.,

H. D. ATKINSON.

62 and 64, Ludgate-hill, London, E.C., October 11, 1887.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a NOM DE PLUME as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

PHOTOGRAPHS REGISTERED:—

Debenham & Gould, Bournemouth.—Photograph of Lord Wolcott and party of speakers at Liberal meeting at Temple Coombe, on October 1, 1887.

J. S. Brown, Bridgewater.—Five photographs of town of Bridgewater and surrounding country.

W. Emmett, Stalybridge.—Photograph of R. H. Brown, M.A., Hon. Canon of Chester Cathedral.

H. COX.—We regret we cannot furnish the address required.

W. L. E.—An article on the subject of hydrokinone is in type for the forthcoming ALMANAC.

J. COLMAN.—Messrs. Houghton & Son, High Holborn, will supply you with non-actinic globes or chimneys for gas burners.

QUANDARY.—More data, than that the prints were mounted with starch, must be supplied to enable us to account for the fading.

G. A. W.—The spots are caused by insoluble particles in the tissue. Without knowing further particulars we cannot indicate the cause.

FRANCIS G. BRETT.—Any of the firms who make a specialty of producing enlargements will make yours on canvas. (See advertising columns.)

A. B. (Dulverton).—1. Mount the print with glue.—2. Cloud negatives on waxed paper when damaged may be restored by the application of heat.

F. WRIGHT.—We cannot undertake a qualitative analysis of the lettering on the mount you enclose. Send it to an analytic chemist with a fee of five guineas.

THOS. MCCANN.—In making the pyroxyline for collodion, reduce the quantity of water to two drachms. Your failure arose from the large quantity of water you employed.

J. S. S.—Flint glass is desirable. Radius cannot be given unless the whole conditions were known. Place the flat side next the sensitive plate. Send specimen of block work.

F. A. C.—The proportions of the two alkalies is of very little importance, or whether one is used to the entire exclusion of the other, so long as there is sufficient to produce the effect desired.

W. ROBBINS wishes to know how to make a varnish for negatives which will dry quickly and does not require the negative to be heated.—Such a varnish is made by simply dissolving dammar resin in benzole.

A NOVICE.—Until you are more conversant than you say you are with the exposure and development of the negative we should not advise you to attempt to make your own plates. You would probably find it false economy.

T. C. (Withington).—None of the elements composing a non-distorting wide-angle whole-plate lens can be utilised *singly* for producing a "wide-angle landscape lens" for plates that size. When thus employed a very narrow angle only would be included.

A. H. HALL.—The only objection to the use of citric acid, in conjunction with the pyro and sulphite developer, arises from the fact that the citrates are powerful retarders of development, and therefore it is preferable to employ some other acid in neutralising.

R. J. C. says he knows where he can purchase a twenty-cell Bunsen battery, quart size, cheap, and asks if that will produce an arc light strong enough to take portraits with at night.—A twenty-cell battery will certainly yield a small arc light, but not one strong enough to be of service in portraiture. Forty to fifty cells are necessary to give an efficient light for the purpose.

SLIDE asks whether lantern slides by the albumen process are best made by contact printing or by making them in the copying camera.—They may be produced by either method, but the plan usually adopted is to print them by superposition. If they are made in the camera the exposure is inconveniently long, and, as a rule, the colour obtained is not so good as when they are printed by contact.

C. WALLIS writes as follows: "I have a lump of silver which I have recovered from my residues by fusing them in a small clay furnace with the usual fluxes, and I want to know how much gold it contains, and its value, as I mixed the gold residues with the silver ones before fusing. How shall I proceed?"—Unless our correspondent is capable of making the assay himself (which we presume he is not by his putting the query), the best plan is to cut off a small piece of the metal—say, two or three pennyweights—and send it to an assayer, with instructions to make a "parting assay." This will give the proportions of the different metals. The charge will be but trifling—about one shilling and sixpence, we think.

L. D. writes: "I am anxious to construct a machine for coating gelatine plates, hitherto having done it by hand. Which kind would you recommend? I do not want to use steam power or a gas engine, as the quantity I need are only for home use. I have tried Starnes's plan but do not like it. Also, what kind of metal for making the trough and roller would you recommend as the least likely to injure the emulsion? Any help on the above I should be grateful for through your 'Answers to Correspondents' column."—There are several different forms of plate coating machines by different inventors. There are those of Swan, Edwards, Dodds, Cadett, Palmer, Burton, and others. The best plan will be to get the specifications of the patents and select the one that will best answer your requirements. Of course you will have to obtain a license from the patentee before constructing one for yourself. Usually the machines are driven by gas engines. Copper electroplated thickly with silver is the best for those portions of the machine which is in contact with the emulsion.

PHOTOGRAPHIC CLUB.—At the next meeting, on October 19, the subject for discussion will be *On the After-Treatment of Negatives*.

We have lately inspected what we may correctly term a huge work of art by Mr. G. W. Austen, of Queen's-road, Finsbury Park. It is a painting representing the annual banquet of the London Prudential Assurance Company, and includes the directors, various officials, and superintendents, numbering five hundred and fifty figures, all reproduced from single photographs specially taken with a view to the pose each is to assume in the group. This large picture is specially prepared, and has been reproduced by the carbon process, the size of the negative being 48×26. It is very successful throughout.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1433. VOL. XXXIV.—OCTOBER 21, 1887.

PHOTOGRAVURE *VERSUS* LINE ENGRAVING.

FOLLOWING up what we said last week about engraving, we observe that in the columns of the *Standard* one day lately a correspondent, Mr. F. Wedmore, in a long letter draws attention to, and laments, the decadence of line engraving. This he appears inclined to attribute not so much to the introduction of photography and photo-mechanical processes, as many suppose, as to the lack, at the present time, of skilled line engravers of the old school. However, Mr. Wedmore takes the opportunity to indulge in some adverse criticism on photography and photogravure.

In appealing to the purchasing public to avert the decay of engraving, he says: "The public must appraise photography, photogravure, and all their allied processes, at their true worth; must distinguish between the money value of the mechanism and the money value of the art; must think the shilling appropriately given here and the guinea there; must perceive that the mechanism, however seductive, has its limitations—is useful for this and ineffectual for that. The mechanism, when all is said, and its last service rendered and acknowledged, no more, to the understanding mind, takes the place of the art than, to the understanding ear, the advance of the barrel organ makes the Richter orchestra superfluous," &c. Again, he says, by its more interested supporters "we are told sometimes that the painter whose work it is proposed to translate prefers the method to engraving. That only shows that one may be an expert in one art and have no sympathy with another." This is somewhat rough upon those artists who appreciate the new art. Further on our critic says: "We are told, again, that the method is not mechanical after all. Our workmen are artists, in a sense. 'In a sense,' is the saving clause, and the sense is, that they are particularly neat workmen." The writer patronisingly remarks, however, that, "of course, no real student need be an enemy to photogravure. With all its developments, under all its newly-devised names, it has a place and a service. How marvellously has it reproduced certain work which was 'black and white' from the beginning!" &c.

Now no one can deplore the decline of line engraving more than we do; but if, as the writer just quoted asserts, there are no new engravers to take the place of the old ones, it is clear that there must be a good reason for it. Perhaps, one may be that few young men nowadays will enter any profession which takes many years of toil and study to acquire proficiency in, without a prospect of its ultimately proving remunerative. In face of the advances made in photographic engraving processes during the past few years, many, who might otherwise have been engravers, have had grave doubts on this point, so far at least as relates to line engraving.

One thing is certain, namely, that a photogravure picture cannot be looked upon in the same light as a line engraving any more than can a mezzotint or an aquatint; not because the one is in any way inferior to the other as a work of art, but because each is a different style of work, and is produced by a different method. In character, a photogravure assimilates more closely to a mezzotint or an aquatint—according to the process by which it is produced—than it does to line work. But it may really be classed as a style of its own; and it has taken such root with the general public that, however much it may be decried by some, it can now, and will continue to, hold its own as a separate and distinct style provided, of course, its high standard of excellence be maintained.

The fact that so many artists prefer to have their works reproduced by its agency is a sufficient proof of its excellence. Every painter, when a picture of his is engraved, is most jealous not only that the drawing and original touch are preserved, but that the colours and tints are correctly translated into monochrome. Until quite recently the translation of the colours of a painting in their true relation in a photogravure was largely dependent upon hand work, and here skilled engravers were necessary. Thanks to the advance made of late in orthochromatic photography, the hand work, in this direction, is now greatly minimised. However, we opine that engravers, and skilled ones, too, will still be required in the highest grades of photographic engraving, for notwithstanding the truthfulness with which the colours may be translated in the negative, there will still be some hand work required.

There is still another reason why photogravure is so popular. A large line plate will sometimes require several years to engrave, and of course it becomes a very costly affair, and in the end often proves, for this reason, unremunerative. It also frequently happens that by the time the prints are issued a considerable portion of the interest in the picture has abated. But a high-class photogravure plate may be produced in a very brief period, and the prints from it issued in a tithe of the time that would be required for a line plate—an immense advantage, commercially, with pictures of passing interest. Again, photogravure enables the public to obtain high-class engravings from works of art, and at a moderate price, which with the old style of work would frequently be impossible, because artists and publishers would not risk incurring the enormous expense of engraving from the fear that the publication would not prove sufficiently remunerative.

Although, as we have said before, the decadence of line engraving is much to be deplored, we must strongly protest against the invectives which are, at times, hurled at a new art, when it is capable of yielding such results as the two photo-

gravures—by distinctly different processes—for which medals have been awarded in the present Photographic Exhibition. These, it must be borne in mind, are not exceptional examples, for equally as good are to be seen in the shop windows and galleries of most printsellers and publishers.

THE WATER SUPPLY.

THE economics of water supply is to photographers a subject of vital interest, one on which centres the whole routine of work, be it in the extensive *ateliers* of the popular professional or on the more modest scale of the occasional amateur. It has, nevertheless, many aspects which are little regarded until the occurrence of some disaster or mishap, by drawing attention to it, causes a remedy to be provided for the faulty arrangement. A case which recently came under our notice is well worthy of description, as comprising several possibilities that might occur in everyday practice, and the recountal of which may serve to warn others. A professional photographer had a batch of between thirty and forty negatives placed to wash after fixing, and upon ranging them afterwards in the rack to dry, it was discovered that nearly every one was completely spoiled, the appearance being presented of the films having been dissolved away. Examination made, and inquiries instituted, soon enabled the true cause of the disaster to be brought to light. In the first place, the sink pipe of the dark room had become stopped up on account of the films of coloured collodion, washed off a number of backed plates, having accumulated so as to form a complete plug. Now it is evident that it is scarcely possible to imagine a more efficient mode of closing an efflux pipe than by allowing films of collodion to be washed into the sink, and then permitted to accumulate at any awkward bend or contraction. Yet, when collodion is used for backing purposes, it is a very probable thing that the precaution of removing it from the sink as it was washed off the plates is one that would not be taken by one out of twenty persons who had previously had no knowledge of the danger. The possibility of an overflow of water is one not to be lightly regarded, for, apart from the damage done to the photographer's own property, he often has to reckon with occupiers of rooms below him.

In the case we are narrating the collodion-wrought stoppage did occur, and until a plumber could be provided the exit pipe at that portion of the premises could not be utilised, the consequence being the removal of the washing tank to another portion of the premises, where were other water tanks and connected taps for carbon printing. The immediate cause of the disaster was as follows:—"Through some repairs being required to be made by the water company, the water supply was temporarily suspended, and a system of tanks (erected specially to provide against such a contingency) being in use, the stoppage was not noticed. Presently the tank ran completely dry, and the contents of an adjacent hot-water tank, fed from the cold, backed into the cold-water receptacle, and, of course, ran out of the open tap upon the doomed negatives. It is easy, after the event, to see that such a disaster was sure to happen; yet the tanks had been in use for years without anything of the sort occurring, or its probability having entered the mind of the owner.

Connected with the same subject of overflows are the syphon washing tanks, which are now constructed with such a wide exit aperture that they empty themselves in a few seconds of

time. Disaster may possibly be warded off if this timely word of caution draw attention to the need of looking closely to ascertain if the arrangements suffice to carry off a quick and heavy flush of water.

There are great differences in the quality of the water available for photographic purposes throughout the country, both as to its purity and its freedom from suspended matter. The former is a far more important consideration nowadays than it was in the time of collodion negatives, as then no one printed from a negative without first varnishing it; now many negatives are freely used with no protection whatever. The danger consists in the possibility of the water containing salts in solution which may impart a hygroscopic character to the film, with the consequence of stained negatives, or, still worse, adherence of the paper in places to the film, which is ruinous to any negative.

As to the mechanical impurity, the suspended particles, they will be little noticed in many cases of negative washing when it partakes of the perfunctory character which too often is brought under our notice; but when an hour, or two, or three, is given to the process, it is quite possible for negatives to be seriously interfered with by the deposit of a fine film of these suspended notes to such an extent that the shadows are robbed and the surface made so rugous as to prevent a cleanly varnished negative being produced. The water in some neighbourhoods is so objectionable in this direction that one photographer of our acquaintance always rubs every negative with a plug of cotton wool before it is put up to dry.

It is most probable that an easier method would be found in the plan of tying a piece of some woven fabric to act as a filter over the mouth of the tap, and to permit no water to be used except what flowed through it. The gentleman we speak of, however, has tried this method, and informs us that the water supply is so turbid that he would have to put fresh filters almost every day or the taps would cease to act. For carbon printing, however, with water of such quality, or want of it, there is an absolute necessity for filtration before use if clean prints are considered an essential to good work—the gelatinous surface being eminently adapted to hold small particles of matter, while, at the same time, there is no remedy against those particles imprisoned at the time of transfer.

The nuisance of lime salts in the water is well understood by those using oxalate developers. There are some photographers who keep their washing water in depositing tanks, in which a certain proportion of oxalate of ammonia has been previously dissolved.

In connexion with the water supply, the question of water meters is sure to come to the front, and where they are placed, the photographer usually finds he has a heavy bill to pay, and too often complains that his meter must be wrong. Now, it is quite certain that in the majority of cases his meter is not wrong, and that he uses a quantity of water far in excess of what he believes to be the case. We have come across several instances of so-called "injustice," in which the water meter is a very sore topic with the photographer.

We may conclude our remarks on this little discussed subject by reminding our readers that the time of frosts and burst water pipes is at hand. It behoves all whom it may concern to take all necessary precautions in time, and, above all, to remember that, contrary to the popular theory, it is the frost, and not the thaw, that bursts the pipes; hence, when a severe frost prevails, it is quite possible to avert the evil of an overflow by a timely examination of the pipes, when, if a burst

portion be discovered, it may be remedied before the thaw sets in and there are a dozen requests for a plumber for every one workman that is available.

THE knowledge of the destructive action of the products of gas combustion upon books—and by parity of reasoning upon photographs—cannot be too strongly impressed upon photographers; given an entire absence of gas and the silver prints of the world would have a nearly doubled lease of existence. The subject was recently well put before his audience by Mr. C. J. Woodward, who described a series of experiments at a meeting of the Library Association; and in the discussion following Professor Tilden, of Mason College, thought that in actual experience the injury was even greater, much greater, than in experiments, because of the rise and fall alternately of the temperature following the lighting and extinguishing the gas. When the gas was lighted a film of moisture was deposited on all exposed objects, which moisture contained small quantities of sulphuric acid; while the moisture evaporated the acid remained behind and accumulated by degrees till the books, &c., were spoiled.

OLD photographers, experienced in the mysteries of collodion manufacture, will be amused by the description of a recent patent for the manufacture of gun-cotton and its mode of solution by new and cheap solvents, when we inform them that the new method of manufacture consists in using sulphuric acid and nitrate of potash in lieu of the former acid and nitric acid, and that the new and cheap solvent is produced by distilling a mixture of methylated spirit, resin, gum benzoin, and castor oil at a temperature of about 300°! Further, the preamble suggests that while the product of the mixed-acids process is explosive, the substitute is not! Surely the patent laws want amending if they permit any one to take out a patent under such pretensions as these.

FOR many years past the popularity of pictures on opal glass has been a source of considerable profit to most portrait photographers. The public have, hitherto, been well content to pay a much greater price for these pictures than they would for similar work on paper, although the actual cost of production need not be proportionately greater. Now, we understand, many photographers fear there is a prospect of prices for this class of work becoming considerably reduced. During the last two or three years photographs on opal, chiefly copies of pictures, have been utilised for "Christmas and New Year's Cards," and sold for a small or a moderate price even when coloured. Now, portraits of celebrities are being made on opal and sold at about the same price as those on paper. A few days ago we saw in a stationer's window, in one of the most fashionable thoroughfares in the Metropolis, portraits of actors and actresses, printed in carbon on opal glass, and bearing the name of a well-known house, for sale, retail, the small size at one shilling and the cabinet size at two shillings each. Of course a carbon print on opal costs no more to produce than does one on paper, beyond the difference in price of the two materials—and now the glass is very cheap. However, it is a matter of opinion with many portraitists whether it is good policy, commercially, to issue this class of work at so low a price. But we presume that every one must be allowed to know his own business best.

THE press notices of the Photographic Exhibition have been fewer than usual this year. What has been said, however, is, on the whole, favourable to the Exhibition and the advancement made by the art. The *World*, whose opinion is exceptional in this respect, has some very severe strictures upon some of the pictures, the awards of the jurors, and the Society generally. With regard to retouching, our contemporary remarks, "As to the fashionable cooking and stippling of the sitters' faces until the texture of the skin is like nothing but that of white kid-gloves, the Society seems to regard it as a triumph of the art." He also comments strongly upon those pictures which for some months past have been used for advertising purposes, which it must be admitted they have, and which he condemns, being awarded a medal, and suggests that, "At this rate of judging, a new photographic

society will be needed unless the present one promptly mends its ways." What does the Photographic Society of Great Britain think of this?

WE, ourselves, have heard some very strong comments upon the amount of retouching which is to be seen on most of the portraits exhibited, both on the prints themselves as well as upon the negatives. Some persons have remarked that it is difficult to discover how much of the work is really due to the operator and how much to the retoucher. There is no question whatever that thousands of negatives are now passed in the dark room as being sufficiently good, when retouched, which would not twenty years ago have been tolerated for a moment except in third or fourth rate studios. As one of the primary objects of every photographic society is the advancement of the art, would it not be well, in future, to place at the disposal of the jurors a certain number of medals to be awarded only to pure photographs? What has been said with regard to retouching in portraiture applies to every other phase of photography in the Exhibition, including enlargements, photogravure, &c.

JUST now portraits of large dimensions, taken direct, are being produced in greater numbers than at any previous period, thanks to the rapidity of gelatine plates, which permits of lenses with a small angular aperture being employed. Many of these pictures are printed on the ordinary albumenised paper, but it is to be hoped that they will prove more permanent than the majority of the small silver prints now issued. As these pictures are now finding favour in public estimation, it will be a pity if their run of popularity should be cut short through their evanescence. When a picture costing but a few shillings fades, very little is thought of the matter, but when one costing as many guineas is in question the case will be very different. It is to be regretted that these large portraits are not printed by one or other of the permanent processes. Sitters cannot be expected to pay large amounts for portraits which will fade away after the lapse of a few years; sometimes even a few months is sufficient to produce a marked change in the appearance in some modern silver prints. This kind of thing will certainly tend to bring large direct portraiture quickly into disrepute.

THE efficient washing of such silver prints is by no means easy to accomplish. If they were treated as small ones usually are, they would frequently get torn or crumpled in the operation. Putting a number of large prints, or even a few, in a vessel of running water is a very unsatisfactory method, as, generally, they will be found sticking together, thus preventing the thorough elimination of the hyposulphite. The best plan of washing the "hypo" out of these prints is that recommended by us a few months back for removing the hyposulphite from bromide enlargements, when the squeegee is advantageously utilised. This plan involves a little more trouble than simply putting the prints in running water and leaving them for several hours, but it is far more efficient. With expensive pictures a little extra trouble can well be afforded. Moreover, as the washing by this method is quickly performed, the brilliancy of the picture is better preserved than when it is subjected to a prolonged soaking.

AN important feature in the present Pall Mall Exhibition is the generally improved taste displayed in the framing of the pictures. Many of the glaring eccentricities—not to say incongruities—shown on several former occasions, and upon which we strongly commented, are this year conspicuous by their absence. Hitherto, some exhibitors would seem to have imagined that the object of the picture was to show the frame off to the best advantage, instead of the frame setting off the picture. Plain unpolished oak, with a gold flat, appears to be the most favoured style of framing, and it is questionable if there is a better to be found for the majority of photographs. One great advantage of these frames for exhibition purposes is their durability; they will bear more rough usage without injury than most other frames, and if they do happen to get injured by rubbing, or are made dirty, a little water and a sponge, or a piece of glass paper, will soon put matters right.

THE PHOTOGRAPHIC EXHIBITION.

III.

LYDDELL SAWYER (No. 41), *Home, Sweet Home*, and five other genre pictures constitute the exhibits this year by this promising photographer, who has not shown any work for some years. We congratulate him upon the possession of that artistic faculty which, if accompanied with perseverance and persistent study, must, sooner or later, lead to success. There is much cleverness of design in the leading idea of each picture, although in some instances this has been slightly neutralised by a redundancy of accessories, which the painter can keep down by local colour, but which the photographer can only subdue by the objects themselves being altered in local colour; this constitutes a stumbling-block to many ambitious students in photographic picture making, examples of which are in this Exhibition. This picture of *Home, Sweet Home*, is the best of the series. A father reclining in his chair is holding the baby at arm's length, the mother kneeling on the ground at his side, both gazing at the baby. These are the materials forming the picture, which is aided in composition by the cradle and some drapery. We are sorry to find that the brush has been used too much to make good one or two minor defects; however, despite this, there is an evident attempt in this and the other pictures to compose and work out by photographic means pictorial aspirations. They are all printed in platinotype and in a well chosen, good engraving colour, which considerably enhances their effect.

George Davison (Nos. 64, 65, 66), *Cottage Studies*.—Here we have some good examples of picturesque bits, where the figures have been studied for just their proper position, and the whole dominated by sunshine, which is so valuable when photographed well, the shadows being liquid and transparent. Again we have here platinotype with an excellent colour. These series are marked "not for competition," showing (like others on the walls) that they are exhibited by the Judges of pictures.

M. Chubb (No. 70), *Christian Martyr*.—A three-quarter female figure leaning or tied to a thick pole or stake, being a very ambitious attempt to utilise photography for representing deep expression and poetical sentiment; but we do not sympathise with this young lady, and it must be a good model who could pose for such a picture. And, beyond that, there must be the moulding of the materials to the artistic conception of such a picture, which we fail to trace in this one.

J. C. Andrex (No. 72), *Vieus*.—A frame of small, very good views, by one of our veteran photographers, where the "objective" has been attended to more than the "subjective."

G. West & Son (Nos. 79 to 85), *Yachts, &c.*—We look forward year by year with anticipations of pleasure for the yachting season in Pall Mall East, and we are not disappointed. There we can enjoy pictorially the breezy atmosphere and the rolling waters, and follow the fast sailing yachts, as with sails outspread and bending masts they speed on their noiseless path. Given, then, the fact that these photographs can suggest these ideas, how much is due to the individual photographer who produces them? There must be great mastery over all the appliances, and a quick perception of some graceful position to be immediately secured, whatever may be the standpoint of view, whether on the deck of a comparatively steady steamer or in a boat rollicking about on a choppy sea; under any circumstances great praise is due to all who produce such beautiful pictures. Each of these pictures being separately framed enhances their pictorial value.

F. Whaley (No. 91), *Preparing for Boxing Night*.—This is another of those pictures requiring much study and executive skill to realise the subject. It is one where the realistic must of necessity pervade the whole of the presentment, and so far it is a fair example of what can be done by photography. But, again, we must observe that the accessories introduced (and this applies more particularly to the background) are much too powerful; they come forward, and the figures consequently do not stand out enough. They are embedded in masses of dark matter, which destroy the keeping of the various figures. It is a family all engaged upon preparing for the event. An elder daughter is dressing up a younger one for some character, the father is getting ready the clown's poker, whilst the mother is ironing some part of the dresses. A very good subject, and if the background had been much lighter in tone the effect would have been much greater.

F. Bedford Lemere (No. 92), *Interiors of Beau Manor*.—Very difficult subjects to get perfect results from; they are rather spotty in effect and are crowded with furniture, which detracts from that realisation of magnificence which the rooms themselves must undoubtedly possess. A softer effect in treatment would have much improved them.

William Parry (No. 97), *Chilian Armour-clad (Steam)*.—This is a very well executed picture, showing great mastery over appliances. The steam vessel is coming on slightly inclined away from the camera. The exposure must have been very short, and, therefore, the amount of detail on the ship is very good.

J. M. Nisbett (Nos. 99, 100, 101), *Studies*.—These are attempts at making pictures, which just deserve some little notice. They are too much like diagrams in pose, but still evince a departure into a higher phase of study, which may result in better work another year. William Brookes (No. 102), *Panel Portraits*.—These show again an attempt to go beyond the ordinary studio work, which will carry the exhibitor into still better results. In the same frame are four small studies of vessels, which are very pretty; as also some book illustrations, where figures and flowers are introduced with good design.

V. H. Chintamon (No. 103), *Indian Celebrities*.—These are panel portraits of some of our late Indian visitors, being men of culture, and evince some knowledge of art in their pose, and, considering the difficulties presented by local flesh colour, are very successful, and especially so in the expression of the mental individualities of the various personages.

Valentine Blanchard (No. 108), *Portrait*.—This portrait comes upon us with a vast amount of satisfaction as showing the result of much artistic skill in the pose and general treatment; particularly notice how expressively the hands have been arranged, and which evidently is most successful as a likeness. There is a quiet repose about this work which might serve as a model for imitation. Cellerier Syndicate (No. 117), *Portraits*.—There are several of these portraits (large panels) in the Exhibition which are very good examples of studio work, being cleverly manipulated, and arranged with good taste.

F. Downer (No. 121), *A Private Rehearsal*.—Another of those attempts at picture making which we have previously called attention to. Four boys getting ready their various musical instruments. A good idea, but falling short in that treatment which artistic perception calls for.

E. Davey Lavender (No. 124), *Gentleman in Fancy Dress*.—There are many excellent points about the figure, which is a large one (direct); the pose is good, and so are the hands, but the whole effect is ruined by the background, which (to a figure containing light and dark masses locally impossible to alter) requires to be modulated and adapted especially for that purpose. Strictly speaking, a proper background for this picture would exercise all the artistic ability of any painter.

School of Military Engineering (No. 134), *On the Thames*.—Four large pictures in one frame. The views are very well chosen, and would have been exceedingly pretty but for the masses of under exposed or under developed foliage which permeate the whole of the pictures. Most assuredly the natural originals must have suggested ideas of beauty and repose, which it must be conceded these photographs hardly do; and similar remarks must in all sincerity be made about No. 156, *Burnham Beeches*, also by the same exhibitors. Now the charm of these celebrated trees consists in that wonderful grey and peculiar colour which clothes them in such poetic and far-away beauty, therefore light and bright sunshine must attend upon them—this would vanish as night approached. Now which of these ideas are suggested by these photographs?

Werner & Son (Nos. 135 and 158), *Portraits*.—These are two pictures taken direct; and here we will further allude to the large direct portrait work which characterises this Exhibition. All are steps in the right direction, as a direct photograph possesses a peculiar rich quality which enlargements never have, and as far as the technical quality goes, as time advances great improvements will arise, not so much in the chemical as in the optical department. Therefore our remarks upon all large direct photographs will be almost from the art side. In the portraits now under consideration we think that if actual life size had been the scale (and this refers

most especially to the portrait of the gentleman) that they would have gained in power; being almost in profile, many difficulties have been done away with. This is quite right for form, but the quality of expression becomes somewhat reduced. And we must refer to the quality of the retouching, which upon these large heads is not so strictly in accordance with an educated artistic manipulation which such large work necessitates. These have far too much of an ivory surface, which is quite out of character with individuality, especially in gentlemen's faces. Nos. 136 and 157, by the same exhibitors, being three-quarter size, are more successful. The pose is very good, and the hands (that difficulty to most photographers) have been well arranged, but we think that the figures might (for the space occupied) have been taken larger with considerable more advantage. However, the whole set possess admirable qualities.

W. J. Byrne (No. 144), *At Home Photographs*.—Here in one frame are fifteen portraits at the homes of the sitters, and, as showing what can be done without a studio with all its possibilities of lighting, are very successful; at the same time, probably from all being mixed up together, each does not get its due meed of satisfaction. Many look as if "the shades of evening" had come o'er them and retire into obscurity.

Warwick Brookes (No. 145), *Portraits taken Direct*.—Again we have to review some more large work, and the optical difficulty previously alluded to comes in here with more force; otherwise the head of a gentleman is very good. A test for these direct large heads is this: Retire a long way off from the picture, and note whether the atmosphere intervening affects the light, and more especially the shadows or shade. Now in this instance the head of the gentleman acquires a vast amount of rotundity and solid appearance, the dark parts do not become obscure and the optical defects not so apparent. Respecting the lady's portrait taken smaller (whilst remarking that the arms are not well arranged), we wish to allude more particularly to the mouth, and this will apply to all the mouths of the large portraits of ladies. That they do not seem to give the life-like presentment, something is wanting; the modelling somehow must be wrong, or is due to the retouching, which has destroyed that most characteristic part of all mouths, the "termination" or "stop" at each side. Now, this is one of nature's most important markings and should receive every possible study.

E. Davey Lavender (No. 137), *Miss Tomlinson*.—This is another large direct portrait of a young lady where the background is made subservient to the figure. It has a little too much contrast, but the figure stands out. The skipping-rope held in both hands is laying on the ground, and produces a curious effect, acting as a kind of base. This is not artistic, and might have been easily altered. It shows how a small matter may otherwise spoil good work.

THE APPARATUS.—II.

MR. GÖRZ exhibits his improved camera and Volute shutter. Of the former we have already spoken on the occasion of its first production, but instead of using, as he intended, a vertical pinion and circular rack to guide the swing which is from a point near the centre, he now has a horizontal pinion and rack, the pinion going *over* the rack, so that the movement, though perfectly smooth, is one confined within the exact arc of the angle from the centre to the corners of the camera, the rack being, so to speak, wedged in between the pinion and the baseboard.

In the volute shutter we notice an arrangement for time exposure carried out with great nicety. On the fly wheel is fixed a small crank, which for any ordinary instantaneous exposure is entirely within the circumference of the fly wheel and allows this latter to make one complete revolution. When, however, turned round so as to come on the outside of the fly wheel it forms a stop, just at the moment when the shutter is fully open, being caught up by the locking lever and kept in that position until released by pressure on the air holder, when the shutter speedily closes. It is only necessary to keep the shutter at a tension of three or four turns to work this very handy time exposure, during which the shutter can be entirely left to itself.

There is also a view meter attached to the camera consisting of a linked or jointed frame of metal. This is raised from the back of the front board, and when looked at through an eye-piece suitably adjusted at the back of the camera, presents exactly the same amount of

subject matter to the operator as will be refracted by the lens on to the plate, the angle varying with the lens as the camera is racked out or in. This view meter can also be applied at the side of the camera.

Among the lens shutters is one by Messrs. Reynolds & Branson, of Leeds, constructed on the same principle as others of theirs which we have described with drawings on previous occasions. This one, however, while differing in certain details from the others, is also made for stereoscopic purposes.

Not having access to the locked case of lenses exhibited by Messrs. R. & J. Beck, we are of course unable to say anything concerning their merits. But a loose mount, without lenses, on the table affords one an opportunity of examining and admiring the working of the "Iris" diaphragm with which it is fitted.

For those who prefer to develop their negatives when away from home or on a tour, Messrs. G. Houghton & Son cater by their exhibition of a *multum in parvo* Photographic Development Portmanteau, fitted with every requirement for the purpose intended.

THE LATE MR. ROBERT HUNT.

HAVING just entered upon his eighty-first year, Mr. Robert Hunt, F.R.S., has passed away from amongst us.

Hunt's *Researches on Light*, published in 1844, when he was Secretary of the Royal Cornwall Polytechnic Institution, gave a powerful stimulus to the then incipient art of photography. We are well aware that it proved the means of many scientific men entering this field of research. Having passed into a second edition it then assumed the phase of *Hunt's Photography*, and formed one of the volumes of the *Encyclopædia Metropolitana*. For a long time, and in one or other of the several editions through which it passed, it was the handbook of the art most sought after, being especially valued on account of the historical matter in which it abounded.

Mr. Hunt in 1850 compiled with much care a general summary of the history of photography for the British Association, given in a tabulated form. From this we learn that he himself was an assiduous experimentalist during the years 1842, 1843, and 1844, in the last of which he discovered the developing powers of photosulphate of iron, which afterwards became, especially for wet collodion, such a power in the hands of working photographers. His labours embraced researches (for photographic purposes) in the salts of chromium, nickel, lead, manganese, copper, iron, mercury, platinum, gold, and silver.

He was one of the founders of the Photographic Society in 1853, and was a member of its first Council, and at its second meeting contributed a paper, *On the Principles upon which the Construction of Photographic Lenses should be Regulated*. He was the author of several works bearing on science; he contributed to several scientific periodicals; and as a lecturer was singularly attractive.

In his later years Mr. Hunt was Professor of Mechanical Science in the Government School of Mines, and up to the time of his death was Keeper of the mining records at the Museum of Practical Geology. For many years he has not mixed in photographic circles, nor taken any special interest in the art once so well loved by him.

He died on the 17th inst.

WRITING AND DRAWING ON GLASS.

IV.

Etching on a Collodion Film.—In the previous articles we have considered the subject of writing upon clear glass with pen and pencil; I propose in this one to discuss some of the methods that may be used to give a negative of a sketch—that is, a picture consisting of transparent clear lines upon an opaque black ground. If a good negative is secured, it is obvious that the required number of positive duplicates can be obtained by any photographic printing process. The usual way of producing such a negative is to make a positive drawing on paper, which is then photographed; but a simpler method is to etch the lines in an opaque film spread on glass. Such a film must evidently have special qualities. It must adhere sufficiently to the glass

to prevent chipping; it should be comparatively soft, so as not to offer much resistance to the etching needle; when completed, it should bear handling without suffering injury thereby; and in order that fine work may be done, it should form a very thin layer on the glass.

Collodion naturally suggests itself as being a suitable material for such a film, and to a certain extent it answers very well. Plain collodion, with the addition of a few drops of Canada balsam dissolved in benzole, adheres firmly to glass, and will bear being etched without chipping—the only drawback is that it is not very easy to produce an opaque ground with it. Probably the most perfect result would be obtained by depositing a layer of silver, as in the wet collodion process; but we will put this aside, as a simpler method is desirable. We can produce various colours with the aid of dyes, and if a coloured ground will suffice, nothing better can be had than dyed collodion. The dyes most suitable for this purpose are those soluble in alcohol, such as the magenta series, aurine, rosine, violet of methylaniline, &c., a greater depth of colour being obtainable thus than by using those soluble in cold water. The dye should be dissolved in a little alcohol before being added to the collodion; in the case of aniline blue, eosine, &c., which are insoluble in spirit, we must employ water instead—this should be used very sparingly, in order to avoid precipitation of the pyroxyline. The best way to dye a collodion film, if we desire a very dark or opaque tone, is to coat the glass with thick, colourless collodion, and when the film sets to immerse it in water until the greasiness disappears. The plate is then transferred to a strong solution of the dye in either alcohol or warm water. The film being in a spongy and porous condition it absorbs a large quantity of the colour, and a greater depth of tint can be had in this way than we should be able to secure by adding the dye direct to the collodion in the bottle. When sufficient colour has been acquired by the film the plate may be removed from the liquid and reared up to dry.

It will be found that a collodion film does not retain more than a definite amount of colour; if this amount is exceeded there will be a bronzed appearance on the surface, the colour will be dull, and the film will have lost its toughness, and is apt to chip if an attempt is made to etch it. Hence a thick film is required for a very deep colour. If the collodion should still chip or shell off, the plate may be dipped into a weak solution of gum or sugar and redried: this treatment will generally cure the fault.

Having secured a plate with a coloured film to our liking, we can proceed with the etching. For this purpose we require a tool, which may be a handsomely mounted affair bought from an artist's dealer, or we can use a large needle, or even a sharp-pointed penknife, with equally good results. The quality of the work depends, of course, on the skill of the draughtsman. It may be as well to state that strong light should not be used, as the finer lines would then look much thicker than they really are, owing to irradiation; and if these lines are made too fine, it will be necessary to give a protracted exposure in the printing to produce any visible effect. Such an exposure would tend to cause halation in the thicker lines, and a poor print would be the probable result.

When we have completed the etching, mastic varnish may be applied if a protective coat is desired; it would not be safe to use shellac varnish.

Etching on a Tinted Matt Ground.—If a coloured film of a semi-transparent nature is desired upon glass as a background to a sketch etched thereon, we can get excellent results by proceeding thus:—Gum sandarac is dissolved in methylated alcohol to the consistence of varnish, and the solution is mixed with an equal bulk of ether. This fluid is then brought to the required depth of colour by the addition of a concentrated tincture of dye, and finally plain collodion is added to the extent of about five per cent. A glass being cleaned, the above mixture is poured on the cold plate in the way matt varnish is used. The result is a very even matt film, of a pleasing colour, tending to greyneess; it is easily wiped off the glass, but the finest lines can be etched thereon without any chipping taking place. When finished, it may be protected with mastic or dammar varnish prepared with benzole—the latter will take away the matt appearance, but the colour will not be affected. The work done in this way, owing to the peculiar softness of the tint, has a more artistic appearance than

we should get by using plain dyed collodion. By varying the proportion of the ingredients different effects will be obtained; if the collodion is increased in quantity, the colour will be brighter, and the matt appearance less pronounced, and by adding a trace of Canada balsam to the solution, the film will adhere more firmly to the glass, and will be in less need of a protecting varnish.

Etching on Smoked Glass.—Perhaps the simplest and best known method of producing an opaque black layer on glass is to hold it over a smoky flame, so as to cause a deposit of carbon upon the surface. It is easy to get complete opacity by this means, and afterwards to produce an etching on the film. The chief difficulty lies in the varnishing, as some protection is absolutely necessary, owing to the extreme tenderness of the deposit, which can be removed by such slight force as a puff of wind. If we apply varnish we are almost certain to ruin the work, through displacement of the lampblack, and in the case of a clear glass smoked to opacity, the etching point will be apt to remove too much of the pigment, so that fine lines cannot be easily produced.

The use of a substratum of sugar or gelatine on the glass before it is smoked will improve matters, as the soot then adheres better, and less displacement will occur in the varnishing, especially if plain collodion is used; to assist the latter to flow the film may be previously impregnated with alcohol by holding the cold plate over boiling spirits of wine. Burning camphor can be employed to produce the smoke, but perhaps the most convenient method is to use a benzoline sponge lamp; if the wick of the latter is well turned up, we can get smoke almost enough to suffocate a sweep. By the aid of the substratum on the glass before it is smoked, and the use of the alcohol vapour to assist the varnishing, we may obtain very good results; fine lines can be traced, complete opacity of the ground secured, and the work can be efficiently protected by varnish. But I can scarcely recommend the process, because there is an easier method open to us, which is as follows.

A clean glass plate is coated without being warmed, with a solution of gum dammar in ether; the exact strength of the varnish is immaterial, though it should not be too weak. When the ether has evaporated, we can light up our smoke factory—the benzoline lamp—and hold the glass, film downwards, in the flame, moving it about with a circular motion to prevent the heat being concentrated in one part, which would probably crack the plate. The centre of the flame consists of vapour of benzoline, which softens the dammar to such an extent that the soot is absorbed by the film as fast as it settles thereon. If this simple operation is properly done, a quarter or half plate sized glass can be smoked to opacity and will have a smooth, bright surface, which is in excellent condition for being etched, and is quite hard enough to form its own protection—that is, it does not require varnishing.

ALBERT WM. SCOTT.

PHOSPHORESCENCE AND PHOTOGRAPHY.*

August 12, 1875, *Experiment 5.*—Placed exposed uranium paper on sensitised side of silver paper, and examined after four-and-twenty hours. *Result:* Darkness on the *wrong* side still more marked; right side *bleached*. Ends (see the figure of the cross), general slight tint as from paper growing old. *Inference:* This being a repetition of Experiment 3 the inference is the same.

Experiment 6.—Bichromatised two sheets of paper. Dried one in the "dark," the other in the sunlight, and left the latter exposed for several hours. Placed a piece of the exposed paper at the bottom of the box already named. Covered the top of this latter with a piece of common writing-paper long kept in the dark and having a circular hole in the middle of it about the size of a penny piece. Covered this with the piece of bichromated paper, dried in the dark. Placed a book over all. Examined after eighteen hours. *Result:* No image whatever. *Inference:* That paper impregnated with bichromate of potash and exposed to light (with the result, of course, of reduction and change of colour) does not radiate to any material extent, if it radiates at all, energy capable of darkening the bichromated paper hitherto unexposed. This is but what one would naturally expect. The energy of the light, having been already used, is not as radiant energy available for use again.

* Concluded from page 620.

Experiment 7.—Placed bichromatised but unexposed sheet under an exposed uranium strip in the manner shown. Enclosed in a book and left for eighteen hours. *Result:* Decided printing under uranium paper. A very decided brown. *Inference:* That exposed uranium paper acts energetically by contact in the reduction of bichromate salts as well as those of silver.

August 14, 1875, Experiment 8.—Bichromatised a strip of paper, dried, and exposed to the light of two consecutive days, and placed on standard silver paper (see diagram, Fig. 3). Enclosed in book and examined after eighteen hours. *Result:* Discolouration of the silvered paper where the bichromatised paper was not, and no discolouration where it was. Discolouration where it was not equalled that of a piece of the same paper hung in the air of the dark room, and which had been discoloured by the circumstance of "keeping." *Inference:* That the exposed bichromatised paper had actually prevented the discolouration of the argentic paper.

Fig. 3.

Experiment 9.—Steeped paper in a solution of ferrocyanide of potassium, dried, and then immersed in a solution of iron protosulphate and dried again. The paper, of course, was Prussian blue. Exposed to two days' light and placed on standard silver strip (Fig. 3). *Result:* After eighteen hours of darkness same as the above, viz., tinted ("by the lapse of time") where not covered by the ferro paper, and tint equal to that of standard paper suspended in the "dark." But where covered by the iron paper the silvered paper was quite white, and seemingly even a little bleached. *Inference:* That silvered paper is also prevented from decolourisation "by the lapse of time" when in contact with paper impregnated with cyanide of iron which has been exposed to light (and, of course, very possibly when in contact with cyanide of iron paper, which has not).

Experiment 10.—Soaked paper in solution of ferrous sulphate, dried, and exposed to two days' light. Laid on standard silver paper as before. Examined after eighteen hours of isolation. *Result:* Very faint tint where the paper was seen only by transmission. *Inference:* That paper impregnated with iron protosulphate and exposed to light does act feebly on argentic chloride.

Experiment 11.—Card mount covered with very thin solution of isinglass, and then profusely sprinkled with bichromate of potash in very fine powder and in excess. Exposed for some hours to sunlight. Placed at the bottom of the four-inch box and both standard silver and bichromate paper placed upon the top. Examined after eighteen hours of isolation. *Result:* No visible effect. *Inference:* The crystals of bichromate, after exposure to the sunlight, do not to any appreciable extent radiate energy capable of inducing photographic action either on bichromate or argentic chloride papers.

August 16, 1875, Experiment 12.—Paper soaked in solution of uranium nitrate and exposed to the light of several days was placed on standard silver paper (Fig. 3). Examined after eighteen hours of isolation. *Result:* Preservation of the silvered paper on its contact face, but strong reduction on the wrong. *Inference:* That uranic nitrate paper, after prolonged exposure, suffers reduction in itself, and that its first action is reversed. The back reduction, however, is mysterious.

Experiment 13.—Paper was soaked in a solution of platinum bichloride, dried, and exposed to light for several hours. It was then placed on silvered paper as before, and after eighteen hours of darkness it was found to have preserved the paper in contact with it. Where not in contact the paper was discoloured. *Inference:* That platinised paper, after exposure to light (and probably without exposure), acts as a preservative of the sensitive paper in contact with it.

Experiment 14.—Paper was soaked in a solution of tartaric acid, dried, and exposed to the action of light. Placed in contact with standard silver paper, and isolated for four-and-twenty hours. Where in contact the paper was found to be uniformly darkened, and that considerably.

August 27, 1875, Experiment 15.—A sheet of plain photographic paper was cut in two, and one half hung for a week in a cellar from which all light had been excluded for many months,* and the other half was hung, also for a week, in a room to which sunlight had free access. Both halves were then salted in the cellar in the feeblest light—that of a reading lamp remotely placed—in which the operations could be performed. Prior to salting the halves had been marked in pencil, one with the letter A (the dark half), and the other with the letter B (the half which had been exposed to light). When dry, both halves were silvered in the feeblest of yellow light. After this they were hung remotely from each other for a week. *Result:* "A" remained quite white; "B" had gone deep brown. *Inference:* That the spontaneous discolouration of sensitive paper results from, or is largely contributed to by, the energy capable of radiation which it has previously received in the operations of its manufacture, i.e., from the radiant energy it has received and stored, and (of course) not from the "lapse of time." I propose in another article to summarise and discuss the results which I have here detailed. The experiments I have described will be admitted to be of interest and importance, and it is much to be regretted that in my prolonged absence on the Continent and elsewhere about nine-tenths of my records should have disappeared.

D. WINSTANLEY.

PHOTOGRAPHIC VARNISHES.

THE query recently put by Mr. Shane reminds us of our unfulfilled promise to write a sequel to our remarks upon varnishes in the article he refers to. We may here repeat what we then said, that our experiments upon varnishes have been most numerous, and have extended over a long period of time, hence whatever formula we now offer to our readers may be relied upon as the outcome of those experiments; more, they are in use by photographers of eminence to whom they have been given in times past.

Before giving these working formulæ we may refer to a class of recipes which is very popular among those who make their own varnish. We refer to those which consist simply in diluting "hard spirit varnish" by spirits of wine till the product is of the right strength for photographic purposes. There are one or two objections to these formulæ, which, to our mind, are insuperable—to wit, "spirit varnish," whether "white hard" or "brown hard," is an utterly indefinite compound, varying in composition at every varnish makers in the country. The main constituents of the brown are shellac and sandarac, with a certain modicum of a turpentine varnish, while the white has little besides sandarac, with, perhaps, Canada balsam. In the brown the sandarac is often replaced by common resin, while in some white of extreme quality, mastic is to be found occasionally. It will thus be seen that it is practically impossible for photographers to compare notes of experience on such formulæ.

To come now to the sheet-anchor of the photographic varnish maker, shellac, orange or white, let us say at once that our preference is in favour of a mixture of the two. It is a most simple matter for any one to try for himself the experiment of making three kinds of varnish, and trying their powers. The experiment, too, is instructive. Let three bottles be procured, and into each place, say, two ounces of alcohol, then add ninety grains of white shellac to one, the same quantity of orange shellac to the next, and an equal weight of sandarac to the third. After each quantum of resin is thoroughly dissolved, and the liquids either filtered or allowed to stand till clear, let a plain piece of glass be varnished with each. It will be found that the orange lac gives the hardest, the white lac the next, and the sandarac the softest. There need be no comparison of testimonies, let each try for himself. There cannot be a doubt of the result, beyond that so unsuitable will the sandarac be found, that if the plate be put away for a few weeks the sandarac will most probably have partially shelled away from the surface.

The white lac will be found to give the thinnest solution of the three, on account of there being in all white lac a far more considerable proportion of insoluble matter than in orange, although there is a wasteful amount of deposit in that resin. It is, therefore, evident that the proportion of white lac in a varnish is not represented by that in the formula itself. Here now is our recipe for a photographic varnish of which there has been made very many gallons in

* My residence in 1875 was at "The Doctor's Cottage," South Shore, Blackpool, near to which I am living now. At high tide and during storms the house was frequently surrounded by the sea. On these occasions it was necessary to "clay up" the cellar windows, doors, and so on. As I had no particular use for my cellars, I left the windows "clayed up" permanently, and it was in these cellars that my "dead dark" experiments were performed.

the old wet-plate days. For dry plates the quantity of spirit may be doubled, or even a still larger quantity added:—

STANDARD PHOTOGRAPHIC VARNISH.

White shellac	8 ounces.
Orange shellac	4 "
Sandarac	1 ounce.
Alcohol	60 ounces.

Place in a wide-mouthed bottle of at least half a gallon capacity, and add to it about half a pound of broken glass. Shake at intervals until dissolved, and, after allowing to settle for a month, decant. Some experimenters have recommended the addition of plaster of Paris, to hasten and render more complete the tedious process of precipitation, for which filtration forms no effective substitute on account of the pores of any filter that can be employed so rapidly filling up. The object of the broken glass is to prevent the whole mass of resin caking together into a compact gelatinous mass which would refuse to dissolve in any reasonable time.

The above varnish gives a fine, clear liquid which dries to a hard, glossy, brilliant, durable coating of slight colour, and which we have not seen excelled. It is quite possible to use the orange lac alone, but the colour of the varnish is then so deep that most operators object to it.

A word now as to the white lac. We have seen many samples which have been completely insoluble through long or improper storage after manufacture, a condition caused most probably by the traces of chlorine left after precipitation in the course of manufacture previously described. As soon as purchased white lac should be stored in water, where it may be kept in a soluble condition for years. The experienced hand can generally tell by its appearance whether it be insoluble or not, the defective condition being usually indicated by an absence of that appearance of dead opacity characterising a good sample, and sometimes being coated with a kind of semi-transparent skin.

For ambrotype pictures, ferrotypes when resistance to friction is no object and freedom from colour essential, the orange lac is to be replaced by the same weight of white lac, and the alcohol trebled in amount.

Retouching varnish may be made by adding to each ounce of the standard varnish eight drops of castor oil; this will give sufficient tooth to enable the pencil to bite. The varnish will naturally lose in hardness of surface, but will not be materially injured. But those who prefer a hard varnish on their negatives to be followed by the addition of a "medium" to prepare it for retouching, will be suited by the following:—

RETOUCHING MEDIUM.

Gum dammar	70 grains.
Yellow resin	6 "
Turpentine	4 ounces.

Shake occasionally till dissolved. The use of pieces of broken glass is here also advantageous. It will be noted that we omit the usual "Venice turpentine;" we do it for the simple reason that in most cases this substance is a fraud. The stuff sold under the name is merely a mixture of turpentine and yellow resin. Our own recommendation, however, for preparing for retouching is to use a little friction with powdered resin; a splendid surface will be obtained, upon which any kind of effect may be produced.

As wet collodion negatives, especially for enlargements, are by no means the curiosities that some modern photographers imagine, we may point out a difficulty that may arise with our standard, or, indeed, any varnish. It often happens that an old picture is required to be enlarged by reflected light, and a carbon print obtained from it. This is most readily done by taking a wet plate negative, slipping the film off (which is readily done after first treating it with a solution of citric acid of twenty per cent. strength), and reversing it on to another glass under water. Now we find that a negative so treated is in the most repellent condition that collodion ever assumes. The varnish must be poured over such a negative backwards and forwards for a considerable period, often for two or three minutes; if this be not done the glass side of the film will have a most peculiar mottled appearance, which will be reproduced in the print. Of course all varnishes are subject to the same peculiarity, but we here name it, as we do not remember the warning having been before published.

We may possibly save our readers the waste of some amount of time in useless experimenting by drawing attention to a mode of treating shellac which a year or two ago went the rounds of, we should imagine, every scientific periodical in the two hemispheres.

As we have already explained, there is a great deal of waste in the manufacture of shellac varnish, owing to the large amount of insoluble flocculent matter contained in lac resins, and which occupies

even after long standing, fully one-fourth of the bulk of the whole liquid, and this mere represents so much dead loss. The ubiquitous recommendation above named stated (which was true) that this precipitate was in the main a kind of wax insoluble in spirit, but soluble in benzole, petroleum, ether, &c., and further said (which was not true) that it might be removed by shaking up with benzole or petroleum ether with the varnish, which would then separate into two layers. The lighter, the benzole, at the top containing all the wax, the spirit at the bottom with all the resin. Now, as a matter of fact, benzole is quite soluble in alcohol, and is in consequence inapplicable to the purpose, and petroleum ether is soluble to a considerable extent, and, besides, when mixed with the crude varnish does not cause the distinct layers described. The method is utterly and entirely worthless.

We conclude our article by pointing out a very singular property of alcoholic shellac solution, which was discovered some years ago by Mr. G. Watmough Webster, F.C.S., but which appears to be less known than it should be. Every one is aware of the difficulty of getting rid of the last trace of resin when it is found necessary for some reason or another to remove the varnish from a negative. Unless a most wasteful amount of alcohol is used, a scum will form on the surface, caused by the water precipitating the light amount of resin, and if this scum be allowed to form, it entirely prevents regular action in any future intensification or other treatment of the negative. But if a small quantity of ammonia be added to an alcoholic solution of lac, water may be added in any proportion without causing any precipitation whatever. A little ammonia in the spirit used for dissolving a lac varnish off will therefore prevent any scum forming. We have tried this and found it to answer thoroughly.

We believe we have now fulfilled our promise, and given concise working formulæ for varnish, which are thoroughly practical, and which it would be difficult, if not impossible, to excel.

—*Photographic Times.*

SOME NOTES ON THE HISTORY OF THE DISCOVERY OF THE GELATINO-BROMIDE PROCESS.

GELATINE was used for photographic purposes in France by Gustave le Gray in 1849, and a little later in Germany by Dr. Halleur. They employed it as a substitute for albumen and for collodion, the glass plates being coated with iodised gelatine, dried, and then sensitised by immersion in a bath of silver nitrate. But gelatine is soluble in acetic acid, which was then universally employed in developing solutions, and the "disappearance" of the image upon plates so prepared (as recorded by Halleur) was probably due to this cause.

"E. R., of Tavistock," describes a similar method in the *Photographic Journal* for May, 1854.

Gaudin, in 1861, used gelatine as a material to prepare what he called a "photogene," i.e., a liquid which merely required pouring on a glass plate to yield a surface sensitive to light. In this idea we see the germ of emulsion photography.

In a patent taken out in 1865, W. H. Smith includes "gelatine or any gelatinous substance" as a material for coating the surfaces of wood, canvas, silk, glass, &c., a resinous solution being previously applied to fill up the pores. Nitrate of silver dissolved in alcohol and mixed with a chloride, a bromide, or an iodide, was mixed with the gelatine. After exposure in the camera, a toning solution was employed. This does not strike one as a very promising process, but still the mention of gelatine makes it interesting.

Next we come to the work of two men—W. H. Harrison and Thomas Sutton—who each held for a moment the key to the secret, only they seem not to have appreciated its full value. In January, 1863, my namesake wrote an article* on the *Philosophy of Dry Plates*, in which he details experiments made with the view to obtaining an answer to a question even yet unsolved: "Why should one organic solution give a rapid plate and another a slow one?" A very weak solution of gelatine was prepared, in which "a little bromide and iodide of cadmium was dissolved, after which some nitrate of silver was added in the dark. In fact, I wanted to have a solution which would give a good dry plate by simply coating a sheet of glass with it." Plates coated with this mixture, which was really an emulsion of bromide and iodide of silver, were dried and exposed in the camera and then developed by the alkaline method. "The picture came out very rapidly, and was of great intensity, but the rough and uneven surface of the film made it worthless." When a stronger solution of gelatine was used no pictures could be obtained, a result possibly due to the weakness of the developer then in vogue.

Between 1855 and 1871 few men wrote more upon photography

* THE BRITISH JOURNAL OF PHOTOGRAPHY, January 17, 1868.

than Thomas Sutton, first as editor of *Photographic Notes* and later as a frequent contributor to THE BRITISH JOURNAL OF PHOTOGRAPHY. In the latter periodical for July 14, 1871, Sutton refers with interest to Gaudin's ideas. He writes: "There is something very ingenious and promising in M. Gaudin's gelatine emulsion. Used with bromide of silver instead of iodide, it might turn out something grand. The objection to collodion is that when it is allowed to get dry upon the plate without having been wetted it dries to an almost impenetrable skin, which the developer has scarcely any power of entering, so that the image is thin and superficial. This would not occur with a gelatine film. There do not seem to be any difficulties in spreading it as there are in spreading albumen, for it is applied hot and quickly sets. Oxide of zinc gives a structureless and homogeneous film when made into an emulsion with gelatine; bromide of silver ought to do the same. A gelatino-bromide emulsion, slightly alkaline, would be exquisitely sensitive without any free nitrate, and tannin, with the aid of the alkali in the film, would no doubt develop it perhaps to sufficient density without silver. A great advantage would be that the film could be composed of a capital organifier through its entire substance, instead of having a mere layer of organifier upon the surface. The process is well worth trying; it seems to be right in theory throughout." Then follows a description of Gaudin's proposed gelatino-iodide process; and Sutton winds up with a paragraph in which his hopes are realistically enough expressed: "A tourist, employing the above process, would have his bromide of silver emulsion ready made in a semi-solid state, resembling *blanc-mange*; he would melt it by putting the bottle containing it into boiling water; he would then coat his plates at night for the next day, and put them at once into the plate box to get dry. No washing of the plates would be required, and that is one grand feature of the process. The next morning he would hang a yellow curtain before his window and put them into the dark slides, developing them at night. He would have no dangerous, explosive, strong-smelling, unhealthy collodion to carry about with him on his travels, and he might pack in a very small compass enough chemicals in a dry state to last him for a tour round the world. What a blessing it would be to be independent of collodion, and at the same time not to have to trust to the keeping qualities of dry plates! It may turn out that I have done well in digging up this old process of M. Alexis Gaudin, whose name be exalted as the author of collodion emulsions and photogenes!"

A few weeks later, Sutton writes (THE BRITISH JOURNAL OF PHOTOGRAPHY, September 22, 1871): "We seem to be advancing now towards a revolution, both in negative taking and printing, and gelatine may ere long prove to be as important an agent in the former process as it has proved to be in the latter. We have had 'gold *versus* old hypo,' 'collodion *versus* paper,' 'carbon *versus* silver' . . . and ere long it may be 'gelatine *versus* collodion.'"

Yes, Sutton was on the right track; but there is no evidence to show that he, any more than his predecessors, was successful in obtaining even a single decent negative by any process, relying mainly upon the use of gelatine and some salt of silver. Sutton did not live to see the complete realisation of his hopes. He died at Pwllheli, North Wales, on March 19, 1875. Of all the men of the past whom I should like to "call up" to see the modern development of photography, Sutton and Rejlander stand first. The scientific simplicity of the gelatino-bromide process would have appealed to the former as strongly as its capabilities for art work would have affected the latter, and each would have made noble use of our modern "dry plates."

W. JEROME HARRISON, F.G.S.

(To be continued.)

REMARKS ON PHOTOGRAPHIC CONVENTIONS BY A VETERAN.

I HAVE been asked to give my opinion as to whether the holding of conventions is beneficial to the fraternity. I say most emphatically, Yes. I wish no better evidence of this than the fact that when the good old N. P. A. gin-out, the photographers felt the need of another association, and organized one promptly. I believe it to be a grand thing to get together, show the best work of members, compare notes, discuss processes, &c. I believe it to be good management to change officers often, and always advocated such change in the N. P. A., but the Association thought differently. I have frequently given as my opinion that the offering of premiums, medals, &c., is not a good feature of the P. A. of A. It will always cause dissatisfaction, as my experience has shown me that nearly every photographer believes himself to be the best operator in this country, and if twenty competo

and each expects to get the medal for his superior work, nineteen will be disappointed, and there is trouble in the family.

Again. Where can you get men to act as judges? You could not ask practical photographers and members of the Association to act, as they might be influenced in deciding by friendship and favouritism shown. If thorough photographers are not selected as judges they are not competent to act, as has been seen in the exhibitions at institutes, fairs, &c. In such exhibitions the man making the best show of frames and gaudily dressed sitters usually gets the highest premium, even if his competitors show superior manipulation. Who but the man initiated in the difficult, delicate, mystic art is capable of deciding whether the exhibitor has succeeded in his work and produced these difficult, delicate effects in perfection.

By all means hold conventions. Have your meetings so interesting that the fraternity must attend to keep up with their competitors. Let the meeting be the principal attraction and not the quarrelling over medals, then every man attending will be benefited and must needs come again the next year.

Well do I remember when "Black," of Boston, stood up in our meetings to be catechised by 300 or 400 members, and good friend "Clemens" told the art of albumenising paper, saying how the old hens of Luzerne County laboured to lay eggs enough for his purpose, members sitting with pencil and paper making notes of all they heard. Then information was freely imparted, and I believe many men are to-day good workers because they used the information obtained at those meetings.

Friendship, kindness, goodwill are the watchwords. So mote it be.

RECOLLECTIONS OF PHOTOGRAPHY IN NEW YORK.

[The Reunion of the Photographic Societies of New York.]

I AM well aware that the most successful after-dinner speeches are those that contribute most to the mirthfulness of the occasion; speeches that are crowded with pleasantry and humour, and sparkle like the wine so often drank at such social gatherings. Now I must confess I am not gifted in this branch of speech making, and therefore can only say a few simple words in response to the toast our President has assigned to me. If, however, what I say shall tend to allay the jealousy or ill-feeling of any professional toward those who practice the art simply for their pleasure, I shall accomplish the main purpose of thus occupying a brief portion of your time. It often affords us pleasure to reflect on the scenes and events of our past life—the school in which we were first taught, the boys who were our playmates, and our first attempts to learn some business or profession in which we hoped to win success in the world. We can now think of the sports and loves of our youth without being angered by the petty cares that were then mingled with them; we can remember the bright hopes we entertained, the fancies we indulged, and the airy castles we built, without regretting that they have never been realised. We can now think of our first efforts in one or more of the various photographic processes that have been introduced in the last fifty years, processes that have so quickly followed each other that before one could be fully developed it must be laid aside for another. We can now think of our struggle in keeping pace with the rapid advances of the art, the difficulties we surmounted, and the disadvantages under which we laboured when we must needs be our own chemists and carpenters and our own teachers of optics and art. We can remember the balky chemicals, the faulty lenses, the cumbersome apparatus, and the inappropriate light and heat in which we were forced to work. We can remember how unsuccessful we often were in overcoming the abnormal action of the chemical compounds with which we had to deal; the perplexities and anxieties we passed through; and how, our imaginations being aroused, we were often led to condemn the chemicals rather than our want of dexterity and skill in the proper management of them.

All these difficulties, together with the thousand and one now forgotten, tended to keep the mind of the photographer in a state of continual suspense, and make his whole life a sea of disappointments, shallows, and uncertainties. All this we now glance back at and feel surprised that we were so perplexed and discomfited; for we can now look upon these failures from a more philosophic standpoint and perceive their uses in the development of the art. We can now see how the pioneers cut a roadway through the forests so that the whole continent of photography might be travelled with certainty and success. There are yet obstacles and difficulties to be overcome, but the brain force enlisted to surmount these is a hundredfold greater than ever before. The facilities for obtaining information by means of books, photographic associations and conventions, must greatly lessen the labour of every student as well as improve the quality of his work. There is no branch of the art now that has not its competent teachers and guide-books, and hence any who may feel disposed can easily become familiar with its secrets and enjoy the thousand delights and uses to which they lead.

Among the earliest impressions of my photographic history are the recollections of my exalted ideas of the honour of being a Daguerreotype

artist. And as I regarded the apparent or seeming simplicity of the art within the reach of my means and ability, I at once embarked in it, in order to win success. Thus in course of time I isolated myself from every other means of making a living, and however willingly I would have parted company with the profession, I could devise no means of accomplishing it without making a sacrifice more unbearable than the business itself.

Being thus cut off from all means of retreat, it was a forced march onward, until good luck so attended my efforts that I was content to bear the ills I had rather than to fly to others that I knew not of. Thus content gradually inspired me with a love for the art that has never waned, and though I now know there is neither much honour nor money to be won in its pursuit, it has a charm that will no doubt hold me "till death do us part."

At a time when there were only some five or six Daguerreotypists in the City of New York, I called on one of the most noted, whose place of business was on Broadway, only a few blocks from my own, and in course of conversation was severely censured by him for giving instruction in the art. His idea was that it should be kept a profound secret, that there were already too many in the business, and that he alone would undertake to make all the Daguerreotypes the city demanded. There is no doubt he could have done this and taken a less number of pictures in a month than is now taken in a single day by some of our leading photographers. In attempting to defend myself as best I could, I endeavoured to convince him that every one we could persuade to learn the business was not only fifty or a hundred dollars in our pockets, but, if they succeeded, their influence and money would tend to multiply the demand for pictures and more rapidly develop the capabilities of the art. I think, however, I failed to convince him of the truth of my philosophy, for he still continues the old cry that there are too many in the business, and that those who are in it are most greatly injured by the amateurs outside. It has never occurred to him that he is indebted to them for the best text-books on photography, for the largest portion of its literature, and for its most ingenious mechanical inventions and chemical compounds.

Every thoughtful photographer cannot fail to perceive that the amateur element, by means of its wealth, culture, and refinement, has added much to the dignity of the art and the volume of its capital. The professional should therefore cease to be envious of the amateur and seek rather to win his favour, for it is only by the union of both that the highest good of all can ever be accomplished.

J. B. GARDNER.

A HOLIDAY AMONG THE TURKS.

[A Communication to the Liverpool Amateur Photographic Association.]

LEAVING England on the 30th March last, my first stoppage was at Passau, which was an enforced stay of eight hours. Passau is on the Austrian frontier. I secured two good general photographs of the town from the Park, which commands a magnificent view of the surrounding country and of the Lesser Danube, which river flows through the town.

I was next brought to a stop at Vienna, as I had, unfortunately, not received my passport before leaving England, and this is an almost necessary article if one wishes to get through Roumania and the neighbouring countries without trouble or molestation. Vienna offers many opportunities to the amateur photographer, being one of the most magnificent cities in Europe. The streets are, as a rule, very wide, and the houses beautifully built. Unfortunately I was running about after my passport almost the whole of my stay. Leaving Vienna you pass through some very fine scenery, and one who has studied instantaneous photography has many opportunities of securing good views of the hilly scenery through which the train passes as you approach Varna. Here I met my friends, and having transferred our luggage to the steamer at Varna we sail to Constantinople.

A slight check bars our further progress at Karak, the entrance of the Bosphorus, as a report has spread that cholera has broken out at Buda-Pesth, through which city most of the travellers have passed. Accordingly we pass a very unpleasant three days in quarantine, with 200 crates of live fowls on our decks. When we are released and have secured our health certificates, for which we have the pleasure of paying half-a-crown each, we sail down the Bosphorus, passing some of the most magnificent scenery in the world, and at length approach, with a good deal of curiosity, the far-famed city of Constantinople and the land of the "unspeakable Turk."

Leaving my camera and its accessories on the ship, I took my personal luggage on shore, and together with some more passengers got my luggage passed for the large sum of one franc. Some days after I brought my camera on shore—but, oh, the trouble! First of all I had to see about seven Custom officers before getting one who would or could attend to my wants, and then they would see the plates I carried, if only the edges! It mattered not so long as they saw they were glass. Having appeased them by taking one out of my changing box, the next thing was the valuation of my goods, as the Turk, with an eye to the interests of his country (?), levies duty on anything not personal luggage. After about five hours all this business was finished—I took the camera on shore only to put it away, as I was thoroughly sick of the whole business. Then I heard that you can take nothing, not even luggage, up the Bosphorus in a row-

boat (or *caigne*) without a police permit, or *cheskerré*, and this added to the general suspiciousness of the Turks takes very much away from the pleasures of photography. When I did take my camera out I only secured a few photographs—one of a Turkish graveyard, which is very picturesque. When the Turk buries a body it is to leave it, uncared for, for evermore. The gravestones are broken and get scattered about, and no one ever puts the place in order. As most of the lower-class Turks cannot read, they have to carve symbols upon the stones to denote the sex and class of person—i.e., for a boy, the head of the stone is adorned with a fez; a girl, a branch of a tree or a twig; if a married woman with children, fruit is added to the branch. There are also various symbols to distinguish people who could read, or who had been to Mecca. Of course there is always more or less writing added.

The next view is of the towers at Roumelie Hissar. This is an ancient castle, and is the first piece of ground ever occupied by the Turks in Europe. It is said that from the hills on the Asiatic side of the Bosphorus the outline of the towers form the word Allah, which in English means God. Another view I secured was of Bebek, on the Bosphorus (a village which is almost entirely populated by English). I afterwards got one of the Mosque of St. Sofia in the distance, and the last was of the Galata Tower, an ancient building now used as a fire station. In the balcony at the top soldiers are continually pacing, night and day. When they see a fire, lanterns are hoisted (or, in daytime, flags) to denote whether the fire is in the town or on the Bosphorus.

Fires here are very numerous and of very great extent, as all (or nearly all) houses are built of wood, and the fire brigade are of a very primitive character. In one fire I saw there were 660 odd houses destroyed.

The bazaars here are very interesting; they are covered in, and form quite a small town, divided into streets, which have the drains running uncovered down the middle. As soon as you enter you are besieged by all sorts and conditions of guides, and interpreters, and would-be sellers, who speak almost every language under the sun. The best way to get rid of them, I and my friends found out, was to stand quite still and stare them out of countenance. The most stout-hearted never stood it above two minutes. Also, when buying goods, never pay their price, or they will account you a fool; offer them half the amount they ask, and as a rule you will secure the article you want. Don't show your money or purse if you want a reduction. Dogs here are also a great feature (although hydrophobia is almost unknown), and are the scavengers of the city. Each street has its colony, and if a dog comes out of his own street he has, as a rule, a bad time of it.

Leaving Constantinople, we sail down the Dardanelles on a most beautiful day, and are able to admire all the magnificent scenery offered to view. We arrive at Smyrna, to find that there is nothing at all to see in the town. The only thing to do is to secure mules and to ride out in the country. The first place of interest is the Seventh Church of Smyrna. The place and church take their name from the fact that it was about here St. Paul built one of the seven churches mentioned in the Bible. Securing a photograph of this and the aqueduct which supplies the town with water, we move on to Mount Pagus. This is a very high hill, and commands a splendid view of the town and the Bay of Smyrna and the surrounding country. On the right you can see Bournabad, an outlying district four miles from Smyrna, and the place where the three Englishmen were a few days ago captured by brigands. The castle (which the Turks are destroying by degrees) where we are now standing used to contain the old town of Smyrna, and was most strongly built. Securing several photographs of the castle and the fallen towers, and after taking a group of our party, we descend a most fearfully rough path on our return to the town. The way the mules run across gullies and rocks is marvellous, but they are accustomed to it, and barring an occasional upset they do their work nobly. One or two of them rather like sitting down in the middle of the road without warning you that they want to sit.

Our next excursion was by rail to Ephesus, one of the historical cities of the Bible. A day amongst the ruins of Ephesus does one more good than a dozen of the longest and driest sermons ever written. To look upon such ruins and to think that it was once one of the largest cities of the world, inspires one with awe and wonder. All the buildings were of marble, and the ground is literally strewn with lumps of brilliant marble and fallen pillars. There is nothing of the original town standing. I secure a photograph of the old Roman aqueduct before we mount our horses and move on. We first see the Roman Gymnasium, and then come upon what is shown as the grave of St. Luke. This was discovered by Mr. Wood, the great excavator, and is recognisable by the carved bull and cross which he says was the symbol of St. Luke. Next we see a font, which was used by St. John the Baptist. It is of marble, and is six or seven feet in diameter, and is carved out somewhat in the shape of a shallow basin. Here we dismount to secure some negatives of the fallen ruins, selecting some capitals and pillars most exquisitely carved as a subject.

Moving on (as time is very limited), we pass some underground passages, which we have no time to explore, and come, after a good mile's ride, to the ruins of the Temple of Diana, one of the seven wonders of the world. There is simply nothing of this glorious building left but the stone foundations. Curiously enough this is almost the only stone one sees at Ephesus, but, of course, the temple when standing must have been all of marble; but it is a known fact that all its pillars have been carried away to beautify such places as the Mosque of St. Sofia, and, to

speak more generally, Athens and Rome. Leaving this spot we demolish a substantial dinner which has been provided at the hotel, and proceed to inspect an old mosque—of later date than Ephesus itself. The mosque contains nothing interesting but an immense red granite pillar which has come from the Temple of Diana. This pillar is about twenty feet high, and took three people to span round the base. Sights of this kind suggest several thoughts; where did the granite pillar come from? and what could our architects of to-day teach the ancients about the science of building? After this we have to hurry back to Asstralouk Station to return to Smyrna, after spending here a most interesting and instructive day.

One word about brigands. Never go unless you are a large party—an armed cavass, or escort, is provided, but still he is not an army in himself, and the brigands are naturally a bold, bad lot. A few weeks after we were there the passengers of an English ship were standing on Asstralouk Station when a brigand chief was captured in their midst. He was headless three days after.

The next day we left Smyrna for England, and only had three hours to spend in Malta, and Gibraltar we passed at six in the morning before the sun had risen. This gave no fair chance of a photograph.

I would like to give a few hints about the sort of camera to take in case any one thinks of travelling over the same ground. I was troubled with a whole-plate. Take a pocket-detective camera and use lantern-size plates, and enlarge at home. If possible, use paper plates; also, I would advise the wearing of a coat somewhat after the style of that used by poachers. Then by putting your camera and all accessories in the pockets you would escape the troublesome Customs examination, and much consequent expense. Of course you would have to be careful to raise no suspicion by the bulkiness of your pockets, but by careful packing that could be easily avoided.

W. B. IRVIN.

NOTES FROM ABROAD.

(From our Special Correspondent.)

I.

LILGE, Tuesday.

Now that there is some prospect of a general International Congress of Photographers at the Paris Exhibition in 1889, and that there is a growing desire among English photographers to mix more with their brethren on the Continent, perhaps some practical information about travelling and life upon this side of the Channel may be useful. To this end it may be desirable to deal with the asserted difficulties in the way of travelling abroad which one hears most frequently mentioned in London, namely, sea-sickness, language, Custom House barriers, and expense, some of which impediments are, to a large extent, imaginary.

Within easy distance of London, from which, indeed, Calais or Boulogne-sur-Mer may be reached in from three to three and a half hours, are the shores of France, Belgium, and Holland, and of these, for photographers out for a holiday, Belgium decidedly presents most attractions within small distance from home. The Dutch language and the flat landscapes of the country are not likely to be particularly attractive to the photographic pleasure-seeker. Railway travelling is more expensive and the distances longer in France than in Belgium, and the more striking scenery of France is usually near its borders; in the interior there is frequently great sameness of scenery for hundreds of miles at a stretch; it is a rich, undulating country, flowing with milk and honey, and inhabited by a lively and refined people. Of architectural subjects for the camera it has rich store, but usually, except in the larger cities, scattered long distances apart. At a French seaside resort the photographer is better off than when spending a few weeks on the English coast, because the change is more thorough, the foreign manners and customs are new, the rock-bound coast is more picturesque, with cliffs not usually of chalk, and there are fine opportunities of photographing sunsets at sea. At English watering-places near London the sun sets inland. On the nearest parts of the French coast, however, the tourist is far from any French photographic society, or centre of photographic industry, of which, doubtless, he would like to see something while in the country. Rouen is the nearest place in which he would be likely to experience much gratification of the latter kind. The little town of Douai, with its photographic society, is, indeed, not so very far from Boulogne, but is more advantageously reached through Belgium. By starting from Antwerp the societies at the following places may be readily visited one after the other:—Antwerp, Brussels, Ghent, Douai.

The supposed difficulties with Custom House people are imaginary; a more civil and obliging set of men never drew breath, and baggage is overhauled twenty times more completely on the English side of the Channel than anywhere else; perhaps the search for dynamite may be the explanation. That which most approaches the English overhauling is not likely to be encountered until the boundary line between Switzerland and Italy is to be passed, say at Chiasso; even there, if the passenger has evidently come through from England, or some other distant country, he is not likely to be much troubled, and in any case will experience no incivility. The fact is that the frontiers of these two countries form a great smuggling district, keeping the Italian officials at their wits' ends to impede the illegitimate flow of tobacco, salt, and jewellery over the border. Over mountains and down precipices at uncertain times of the day and night flow the contraband articles;

workmen carry them concealed in loaves of bread intended apparently for their innocent dinners, carrier pigeons fly with them overhead, and it remains only to train the fishes in the rivers to establish a subaqueous traffic. All this would try the patience of a saint, and a saint the hot-tempered Italian is not. The Italian Government complains grievously, but the Swiss reply that it is not their duty to do Customs work for their neighbours, and that the better plan would be for the Italians to reduce their tariff so as to make smuggling less profitable; thus the situation is somewhat strained, and the quarrel is a pretty one as it stands. Once when I crossed the boundary in a steamboat on the Lago Maggiore my baggage was not examined by the Italian Custom House officer on board; he doubtless knew the difference between the English tourist and the local gentry, who needed more of his attention. When the French examine baggage, much of the work is often done out of the view of the possessor in rooms devoted to the purpose; they demand his keys, and he does not know to what extent his worldly goods are overhauled. They do not usually trouble themselves to examine small bags and parcels. It has been suggested that you may tell them to be careful in handling your belongings because you have but just recovered from the small-pox; any one who tries this plan had better report in these pages how it works. Some immoral people have suggested bribing the officials to get large quantities of luggage through rapidly; any one who attempts this with a German Custom House officer is liable to punishment by law.

Come we now to the question of sea-sickness; as a rule it is good for the liver, and the voyager is better in health afterwards. Some persons, however, with exceptional constitutions, suffer long afterwards; others, again, are never sea-sick at all. Cows are included in the latter category, their insides being so constructed that they cannot be sea-sick, but they suffer greatly. Cats and dogs are sometimes sea-sick. There is, perhaps, no actual preventative, although every one is ready to offer a safeguard to his neighbour. A man who takes an aperient draught three days before starting, and takes care to get himself into good condition, is better fitted to resist sea-sickness than one who has not done so. Suppose the water to be rough, the best thing the traveller can do is to lie down and wrap himself up before the ship leaves the port; place a basin handy, and do not get up until the ship reaches the other side of the Channel; this is the almost invariable plan with old stagers liable to the malady—when one gets too sick to be able to walk with ease, it is not at all easy to move about and to settle down comfortably. The best way of all of crossing the Channel is to go to Folkestone or Dover, and if the sea be rough wait one or two days till it is quite smooth; then cross it, and thereby cheat it of its prey and the fishes of their dinner.

A common error exists in the belief that the shorter sea passages reduce the evils of sea-sickness to a minimum; but upon arrival at the opposite coast, and being told to take up your bed and walk when you are in the throes of dissolution, you feel that the stern authorities might leave you to rest in your misery, and not force you to get up and crawl into an adjacent train; but the ship has to leave the quay, and the fates are inexorable. Upon the shorter routes the harbours are shallow on both sides, especially those upon the French coast, hence but small boats can be used, and these pitch and roll more than large ones. Then again, conflicting currents meet in the narrow parts of the Channel and tend to keep the waves in a general state of pitch and toss, so that occasionally people suffer more on this short trip than on a voyage upon the long Atlantic rollers to New York. On the other hand, if one of the longer routes with large boats be selected, say that by Southampton and Havre, or Harwich and Antwerp, you reach the ship at night just in time to go to bed, can stow yourself away comfortably, and if you are sick have it out in peace and quietness, then go to sleep for the rest of the night rocked on the cradle of the deep, and sweetly losing consciousness while listening to the lullaby of the waves. The deep-sea boats not only toss about less than the others, and in a general way have smoother water than off Dover, but off Harwich the sea has an exceptional tendency to keep smooth, the generally prevailing winds of the south of England being from the south-west, and from these by the route just stated the land affords shelter. In foggy weather the ships have to drop anchor in the Scheldt until it clears, river navigation in a fog being impracticable, hence, in November, there is the possibility of delay by this route; but the passengers have what the Americans call a "high old time" of it so long as the provisions last.

Although I am unaware of any drugs which prevent sea-sickness, there are mechanical means for almost entirely preventing it, but too expensive for general adoption in steamships because of the space occupied by the apparatus. Once it was my duty as the correspondent of an engineering journal to practically test some apparatus of this kind invented by a Belgian, and fitted up by the South-Eastern Railway Company upon one of their finest boats, the "Princess Alexandra." On approaching Folkestone I saw the sea white with foam, and in a particularly nasty condition for passengers liable to sea-sickness. The apparatus consisted of a couch, such as might be used in a drawing-room, slung to a ball and socket joint high above it, so as to be virtually a pendulum. The efficacy of the apparatus depended upon the considerable length of this pendulum. The whole arrangement was furthermore mounted upon a large square bellows, so devised that when the vessel pitched the ball and socket joint did not rise and fall to the same extent as the ship. On board this couch the appearance of the saloon and the other passengers was extraordinary; they and the sides of the

ship rose above and sank below me with the rolling of the vessel. I felt no symptoms of sea-sickness until the entrance to Boulogne Harbour was reached, when qualmish symptoms began. Soon afterwards I landed and walked quietly away, none the worse for the voyage; but as regards the rest of the unfortunate passengers, I never saw worse or more universal cases of sea-sickness.

THE BOMBAY AMATEUR PHOTOGRAPHIC EXHIBITION.

At the *conversazione* which preceded the opening of this Exhibition, Dr. Wellington Gray, the President of the Bombay Amateur Photographic Society, asked for the indulgence of the spectators in judging the pictures. The work of the amateur votary of any art is always considered a subject rather for encouragement than for censure; and the critic who would frown upon any shortcomings he may detect in the work of a professional, who has made a particular calling the business of his life, relaxes the standard of his judgment a great deal in favour of the man who follows an art as a pleasure and a recreation. When there are so many as three hundred exhibits, and all of them by amateurs, it goes without saying that some of them should be of very indifferent merit. But we do not think it will be denied that the general standard of excellence is high; and the value of whatever commendation that may be bestowed on that account is heightened by the fact that the Society which has organized the Exhibition, the first of its kind in India, is not yet a year old. The Committee had to select the exhibits from a very large number of aspirants to a place on the walls, and it is due to their judicious labours in the cause of the survival of the fittest that we find here an entire absence of specimens executed by the merest tyro. The Society numbers about sixty members at present; but we should not be surprised if one result of this Exhibition were to draw many recruits to its ranks. For there are many pictures exhibited here which may serve to bring home to one's mind the pleasures of photography. Numerous improvements have from time to time been introduced in photography, and while the beginner in these days has the good fortune to learn the art at a time when it has already reached an advanced state of perfection, he may hope to see before very long still more noteworthy improvements. Colour photography, for instance, may be said to be still a thing of the future. Many have applied their minds to discover the process, and the man who succeeds in making this discovery will certainly mark an era in the progress of this art.

The judges awarded the gold medal to Mr. George Ewing, a member of the Photographic Society of India. Dr. Wellington Gray carried off the silver medal. The other medals were awarded to Mr. E. Ferrers Nicholson and Mr. H. Bromley.

The Exhibition was a great success.

PATENTS COMPLETED

A NEW OR IMPROVED COMBINED PHOTOGRAPHIC CAMERA AND PHOTOGRAPHIC ENLARGING LANTERN AND MAGIC LANTERN.

No. 15,187. WALTER PHILIP O'REILLY, 399, Edgware-road, Middlesex.—*November 22, 1886.*

The object of my invention is to produce in one and the same apparatus a photographic camera, a photographic enlarging lantern, and a magic lantern.

According to my invention I make the bellows in such manner that it can be fitted and removed from the camera as required; for this purpose I provide a frame at each end of the bellows, such frame fitting into the two camera ends in grooves there provided for the purpose; when the frames are removed the bellows can be folded into a compact space. The inner surface of the camera is lined with tin plate or other suitable material, japanned or blackened, and when the apparatus is to be used as a magic lantern, a metal vessel, say a tin vessel, which may be made, for the sake of portability, in sections, is substituted for the bellows of the camera, having the necessary apertures formed in same for the chimney and for attaching same to the frame. The metal body fits into the grooves or spaces previously occupied by the bellows. The tin back and reflector is also inserted in the groove previously occupied by the dark slide. The conical front and slide holder are connected in any convenient manner to the camera front, which may be conveniently accomplished by placing on the camera front two screw heads or buttons at top and bottom thereof, and in such manner that the slide holder and conical tube containing the magic lantern can be, with the greatest facility, slipped over or removed from the screw heads or buttons. The tube of the camera lens is of large

enough diameter to contain the condenser for the magic lantern or photographic enlarging apparatus, and the lenses used for the condenser are separated and used separately for the camera.

The whole apparatus is fitted on a base, or stand, with means for adjustment provided, and to enable the camera to be placed in a vertical or horizontal position. This base, or stand, is available as a stand for the camera or magic lantern as may be required. The lamp for the lantern is carried, supported, and adjustable, in the well of the baseboard, and in this way the lantern is not so heated as is generally the case now when placed inside.

IMPROVEMENTS IN APPARATUS FOR PRINTING PHOTOGRAPHIC PICTURES.

(A Communication to me from abroad by Hans Brand, of Baireuth, in the Empire of Germany, Photographer to the Court of Bavaria.)

No. 16,012. EDMUND EDWARDS, 35, Southampton-buildings, Chancery-lane, Middlesex.—*December 7, 1886.*

This invention relates to apparatus for the rapid printing of photographic pictures upon paper, or other surfaces, rendered sensitive to light by bromide of silver and gelatine, or other means.

The improved apparatus is not intended for the reproduction of pictures by any of the known mechanical printing processes, but for the rapid and perfect production of positive prints of any dimensions upon highly sensitive material, where it is of importance that the exposure should be accurately timed, and all extraneous rays of light excluded.

The improved apparatus consists of a frame taking the place of one of the panes of an ordinary window, the remainder of which is darkened with some non-actinic material. Into this frame are fitted two hinged shutters, one opening outward, and the other inward into the dark chamber. The latter turns upon hinges at the bottom, and is held by a catch or bar at the top when closed. It has a central opening also, closed by a shutter hinged below, which carries the sensitive material upon which the picture is to be printed, and is covered with a non-actinic cloth. The shutter opening outward as well as that last described are held when closed by a double catch at the top of the outer frame, turning upon a pivot and held in its normal position by springs. At the lower side of the outer frame, which opens inward as described, is fixed a bracket carrying a spring, upon which the inner shutter carrying the sensitive surface falls when open.

The inner side of this last shutter carries a flat plate, or support, resting upon springs between them, and covered with a sufficient number of thicknesses of soft elastic material, such as velvet or plush, upon which the sensitised paper is laid, and held in its position by a thread carried by side wires or fastenings.

In the principal frame fitted into the window, as first described, is fitted a plate glass, across which are arranged two adjustable bars sliding at their ends in vertical grooves, in which they can be fixed in any position by screws. These bars hold the photographic negative.

To use the apparatus, the operator closes the shutter which opens outward by means of a wire, or bar and handle, passing through a light-tight opening, until the top of the shutter frame is held closed by the outer end of the top catch; the negative is then fixed in its place against the plate glass by the two adjustable bars, and the sensitised paper is adjusted in its position upon the elastic bed prepared for it. The latter is then raised until closed, when it is held by the inner end of the top catch, the outer end of which at the same time releases the outer shutter, which falls outward. When the exposure has been sufficiently long, the outer shutter is closed by the handle, and in becoming locked by the top catch it releases the inner shutter and sensitised paper, which fall inward, when the print can be removed and a fresh sheet of sensitised material adjusted in position, and so on as often as desired.

IMPROVEMENTS IN DARK SLIDES FOR CAMERAS FOR PHOTOGRAPHIC PURPOSES.

No. 1637. GEORGE WILLIAM ELLIOTT, 12, Clarkehouse-road, Sheffield, Yorkshire.—*February 2, 1887.*

This invention has for its object the construction of dark slides for cameras for photographic purposes, so as greatly to reduce the cost of production, and also make them less bulky and more portable.

Dark slides for cameras have hitherto been made of wood or cardboard. Those made of cardboard being practically useless, and the use of wood rendering the others very costly, on account of the labour necessary for their construction, and bulky, on account of the thickness required to give the necessary strength for working.

These defects are obviated by this invention, which consists of constructing them of metallic sheets, or sheets of vulcanised fibre, vulcanite, or other suitable material capable of being folded, creased, stamped, or pressed into the required shape.

A piece of sheet tin or other suitable material of the required size is so stamped, or pressed, or folded on its edge as to form a groove for the sliding door or shutter, and at the same time be perfectly light-tight and of sufficient depth to allow of the sensitive plate being placed between the back of the slide and the sliding door.

Two of these pieces are placed at the required distance apart, according to the size of the slide or plate to be used, and are joined together by the piece forming the back of the slide.

The ends are made light-tight by the insertion of suitable material, such as cloth, bearing against the inside of the sliding door or shutter, or by being folded over in a similar manner to the sides. The whole slide, excepting the sliding door or shutter may be made of one piece stamped or pressed into shape, or may be any combination of pieces to suit the convenience of manufacture.

The sliding door or shutter has its two outside edges folded so as to work in the folds formed in the body part, the whole forming a level or flush surface and a perfectly light-tight joint.

A portion of the back is indented so as to bear against the sensitive plate, and, by means of the spring of the back plate, hold the sensitive plate in its position.

The folds forming the guides for the sliding door or shutter may be such that the slide may not require folding on its edges which work in these guides but be kept plain.

The claim is for making dark slides for cameras for photographic purposes of metallic sheets or other suitable material capable of being folded, creased, stamped, or pressed, and so folded, creased, stamped, or pressed into the required form to render a light-tight sliding joint, with the sliding shutter and its slides, substantially as described and illustrated herein.

[What says Mr. W. Tyler to this?—EDS.]

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, October 13, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. C. Heinrich Trinks presided.

Mr. L. Medland exhibited photographs he had taken recently in Russia and other parts of Northern Europe.

The CHAIRMAN exhibited a photo-micrograph of *Amphipleura*; the specimen had been mounted in phosphorus and photographed by the aid of a one-twelfth oil immersion. In such work, he said, it is often necessary to have absolute coincidence of position of the ground-glass and the sensitive plate. The simplest plan is to put the ground-glass first into the dark slide and to focus upon it, then focus upon plain glass with a few diamond scratches upon it, and, lastly, to substitute the sensitive plate.

Mr. J. J. BRIGINSHAW had made a good focussing screen by letting a slight flash of light from a paraffin lamp flame fall upon an ordinary sensitive plate, then developing and fixing the plate, and, lastly, steeping it in bichloride of mercury.

Mr. A. HADDON had found oiled finely ground glass to answer well.

The CHAIRMAN stated that in photo-micrography errors are often introduced by the action of change of temperature upon the spring of the fine adjustment screw of the microscope; the remedy is to remove the spring altogether.

The HON. SECRETARY had known alteration of the temperature of the stage of the microscope by a lamp six or eight inches off to throw objects out of focus.

The CHAIRMAN had tried the Welsbach light and found it to be rich in actinic rays. He had begun some experiments to take instantaneous photographs in the microscope, using "Henderson's thunder and lightning plates," and had found that the instantaneous shutter must be so mounted that it had no connexion with the microscope. He used a screen of yellow glass, so that he could watch the movements of living objects as projected upon the sensitive plate, and could make the exposure when they were in the best position to give an interesting picture. He focussed upon opal glass.

Mr. A. COWAN said that it was impossible to focus well upon opal glass.

Mr. HADDON remarked that Janssen and other astronomers focussed upon a screen coated with plaster of Paris; there was nothing better. He thought that with the screen of yellow glass there was a chance of fogging the plate, and that by means of a right-angled prism fixed to the bottom of the shutter, and falling with it, the movements of living things could be watched upon a screen at one side of the whole arrangement, and the shutter allowed to fall when the objects were in a good position for photographing.

The CHAIRMAN thought the suggestion to be excellent.

Mr. PLUMER wondered whether a binocular microscope could be used, the object being watched through one of the tubes, and photographed through the other at the selected moment.

Mr. COWAN called attention to the sale catalogue of Mr. Stevens, in which one of the lots was advertised as an "8×8 bellows cabinet lens, by Ross;" he should like to see that remarkable lens.

Mr. COLLINS exhibited a detective camera to which he had applied a roller slide.

Mr. A. L. HENDERSON wished that some one would manufacture an aluminium camera and slides, as patented long ago by Mr. Melhuish; aluminium could now be made, he believed, very cheaply.

Mr. F. W. COX could not account for an insensitive band about a quarter of an inch broad round a batch of plates he had bought.

Mr. COWAN said that they had been coated with imperfectly-washed emulsion.

Mr. HADDON had once tested by a tuning-fork arrangement a shutter said by its maker to give an exposure of one-one-hundred-and-twenty-fifth of a second; he found the real exposure to be one-twenty-eighth of a second.

CAMERA CLUB.

The paper read at the "Thursday evening," October 13, was by Mr. LYONEL CLARK, and was entitled *The Selection of Lenses*. Mr. Francis Cobb occupied the chair.

Between forty and fifty members and visitors came together to hear and discuss the subject, which the lecturer illustrated by diagrams and by a complete series of lenses.

Previous to the paper being read the CHAIRMAN gave particulars, as far as agreed upon, of the date of the second Conference, proposed to be held by the Club in the spring of 1888.

Mr. H. C. BOND exhibited some very interesting old photographs and negatives, Talbotypes of the first Exhibition in 1851; and Mr. Sage handed round an example of the ingenious little watch detective camera of Lancaster.

The CHAIRMAN then called on Mr. Clark for his lecture.

The lecturer followed out the laws of perspective that guide us in the selection of a picture, showing how lenses simply delineated what they saw. He pointed out the most suitable focal lengths for the different sizes of plates usually in use, and also spoke on the subject of the best form of lens to employ, whether for views, architecture, interiors, portraits, enlarging, or lantern work. He gave a few words of advice as to rules to be observed in choosing lenses, and recommended great care when the lenses had been bought. A large collection of different types of lenses were shown.

In the discussion which followed,

Mr. J. TRAILL TAYLOR made some remarks upon flare spots and upon several types of lenses, and said he had not much fear of the iris diaphragm of Messrs. Beck wearing so as to give flare, and even if it did it could easily be blackened again.

Dr. LINDSAY JOHNSON thought the best black for the purpose of blackening the edges of the apertures of stops worn bright was gasblack. His favourite lens for all landscape work was the portable symmetrical.

Mr. TAYLOR said lampblack, which was often used with varnish, gave a grey colour when dry; the best to use was vegetable black mixed with lacquer. These used in proper proportions gave the most diabolical black conceivable.

Mr. CHAMBERS referred to the ordinary uses of the rapid rectilinear and the wide-angle lenses, and gave some particulars also concerning the triple achromatic lens.

Mr. BECK said the iris diaphragm had stood the test of long usage in microscopic work. He considered it a great objection to gasblack that it rubbed off easily.

Mr. SPIERS said one class of lens had been omitted, the pinhole lens. He had brought down two of his own manufacture, with prints from negatives taken by them. (The examples handed round were soft and pleasing pictures, views in the Netherlands.)

Mr. SARGEANT wished to ask whether, if a wide-angle lens was used upon a plate of much smaller size than it was intended to cover, the excess of light in the camera tended to fog the plate.

Further questions were then put by Mr. DAVISON, and Mr. CLARK then replied along the whole line.

In conclusion, the CHAIRMAN moved a vote of thanks to Mr. Clark, and said he was sure that the paper and the discussion upon it that evening showed that their functions were extending far beyond those of an ordinary club, and that they would have to add to their title "Institute of Amateur Photographers," to signify the aims and intentions of the Camera Club, as being those of a scientific society in addition to its social objects.

On Thursday, October 27, Dr. G. Lindsay Johnson will read a paper entitled *Testing Lenses*. Practical demonstrations will also be given, the apparatus for testing the lenses being arranged beforehand in the Club.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

The ordinary meeting of the above was held in the Free Public Library on Thursday evening, the 13th instant.—The President, Mr. J. A. Forrest, in the chair.

Messrs. J. W. Simpson and E. M. Tunstall were elected members.

The President laid on the table a catalogue of books pertaining to photography, which had been compiled expressly for the Association by Mr. May, the Librarian of the Free Public Library. It was hoped that members would avail themselves extensively of the opportunity thus afforded them, many of the works being standard ones by recognised authorities on the art.

A lantern slide competition then took place. The offer of one of the Association's medals acting as a powerful incentive, a large number of members competed for the coveted prize. The work shown was of an unusually high order, and rendered the position of the Judges (Messrs. Phillips, Sayce, and Whalley) anything but a sinecure. When the slides had all been passed through the lantern they announced that those bearing the word "Kingston" were, in their opinion, entitled to the prize. On the sealed envelope bearing a similar mark being opened it was found that Mr. Paul Lange was the winner, the result being received with general applause.

In answer to a question, Mr. LANGE stated that he had used the Kingston lantern plate with soda developer; he had found them more expeditious than chloride ones when reducing from large negatives through the camera, a consideration when using daylight in the winter months.

The Judges regretted that the Association was only offering one medal, as they thought the slides of another exhibitor (Mr. John H. Day) were well entitled to a second prize.

The recognition of this gentleman's slides seems to confute a popular idea among photographers and dealers, that chloride plates will not keep for any length of time (hence, probably, the difficulty which frequently arises of procuring lantern plates during the summer), as it was understood that Mr. Day had used plates he had had in stock since last winter. He stated that he had found keeping to make them rather slower in sensitiveness than when freshly made, but as illustrated by his exhibit they showed no lack of vigour, and were unusually bright and sparkling.

The remainder of the evening was devoted to a further exhibition of members' slides, which lasted until a late hour.

Votes of thanks terminated the proceedings.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

At the meeting on the 21st ultimo, the President, Mr. T. Davey, in the chair, Mr. W. C. Hemmons was elected a member.

The CHAIRMAN read a letter received from the Hon. Secretary, asking the

Association to accept his resignation, as, in consequence of business and private engagements, he would be unable to devote sufficient time to the affairs of the Association. He proposed a vote of thanks to Mr. Daniel for his services, and that a letter should be sent him expressing the regret which the members felt at his resignation, remarking that Mr. Daniel had been Hon. Secretary for eleven years, and had worked hard to make the Association a success. This was carried unanimously.

Mr. E. Brightman was proposed as Hon. Secretary, and carried unanimously.

Mr. BRIGHTMAN said that, as one of the oldest members, he felt great interest in the Association, and that no effort should be wanting on his part to contribute to its continued success. In accepting the office he would be filling the post both of Hon. Secretary and Treasurer, but would be glad if some other member would take over the duties of Treasurer.

After some discussion it was decided that Mr. Brightman should still continue to act as Treasurer to the Association.

DERBY PHOTOGRAPHIC SOCIETY.

The annual meeting of this Society was held on Tuesday, October 11, at eight p.m., in Sykes's Restaurant, Victoria-street.—Mr. J. C. Merry presiding.

The Hon. SECRETARY read the annual report and balance sheet, which showed the Society to be in a flourishing condition, it now numbering 101 members, of whom 79 had paid their subscriptions, and the balance lying to the credit of the Society at Messrs. Crompton & Evans's Bank had increased from 9l. 15s. 7d. to 13l. 13s. 1d., and there were no outstanding debts. During the year a number of papers had been read and demonstrations given by the members, and great benefit had been derived therefrom. Outdoor meetings had been held during the summer months at Dale Abbey, Marketon, Staunton Harold and Calke Abbey, Cromford and Matlock, Monsal Dale and Crossbrook Dale, Haddon Hall, Wingfield Manor, Alton, and Weston-on-Trent, and were well attended by the members. The Society instituted a competition for the best picture taken at these outdoor meetings, to be decided by vote of the members. The pictures were arranged round the room that night for decision, which resulted as follows:—First certificate to Mr. C. Bourdin for a view on Lovers' Walks, Matlock, printed in platinumtype; second and third certificates to Mr. T. Scotton for view at Marketon, printed in platinumtype, and silver print of "Hermit's Cave," at Dale Abbey, respectively. The competition was a keen one between Mr. Bourdin and Mr. Scotton for the first certificate, the former obtaining it by one vote. The Society will print the best picture and present each member with a copy.

Votes of thanks were passed to the retiring officers and to the publishers of the *Photographic News* and *The British Journal of Photography* for sending weekly copies of their papers.

The following officers were elected:—*President*: Captain W. de W. Abney, R.E.—*Vice-Presidents*: Messrs. R. Keene, J. C. Merry, J. W. Price, and T. Scotton.—*Committee*: Messrs. C. Bourdin, H. Bennett, T. Hills, W. G. Haslam, and C. B. Keene.—*Hon. Secretary and Treasurer*: Mr. E. J. Lovejoy, 73, Grove-street.

The question box contained the following queries:—

"Will any member give the best mode of developing and the best developer to use?"

Left over till next meeting.

"Will any member give his experience in using different amounts of water in his developer?"

It was thought if one got a good developer and was used to it he should use no other; and the CHAIRMAN suggested that if a member take a plate, expose it, cut it into several pieces, and develop with different amounts of water in his developer, and compare the results, he would learn more by wasting one plate than by any information that could be given.

"What is the action of the developer upon an exposed gelatine emulsion plate?"

Mr. LOVEJOY (Secretary) replied that the developer continued the action set up by light and developed the latent image.

"Must the bromide in an emulsion be in excess of the silver salt or not?"

The CHAIRMAN said the proper proportions of the salts would be found in one of the annuals, but he should like to remark that if you do not get sufficient bromide in the emulsion the silver is lost, and it is the opposite if you get an excess of bromide.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

The annual autumn Exhibition of this Society was held in the large dining room of the Technical Schools, Bridge-street, on Thursday, the 13th instant.

There was a crowded attendance, which proved the great interest shown in the Exhibition by the members and their friends, and impressed upon the Council the necessity of providing larger rooms and much more space for next year.

The number of pictures shown exceeded four hundred, including one hundred and sixty which had been sent in for competition by twenty-eight members. These had been previously judged by three gentlemen (professionals), viz., Messrs. John Collier and Harold Baker, photographers, and Mr. Walter Breeden, an artist, who had kindly undertaken the critical selection.

The prize winners were as follows:—Class B, "Home portraiture," "Mitis;" Class C, "Best instantaneous picture," "Nemo;" Class D, "Best landscape taken during 1887," "Through the Wood;" Class E, "Best picture from stripping films," "One of the Crowd;" Class F, "Best contact print by development," "Platinum;" Class G, "Best enlargement," "Family Pet;" Class H, "Best transparency," "Slow and Sure."

On the envelopes containing the names of the owners of the different mottoes being opened, it was found the winner in Class B was E. Underwood, for his picture of *A Girl Reading*. Evidently the prize was awarded in this instance on account of the graceful pose of the figure, there being other equally good pictures from a photographic student's point of view, but lacking the pleasing position of this one. Honourable mention was awarded to "Amateur" (Thomas Taylor), for *No Partings Fonder*; "Nemo" (W. J. Harrison), for *Surrounded*; "Platinum" (Dr. Huxley), for *Children and Toy Cart*.

In Class C the prize was gained by W. J. Harrison for *Leapfrog*, the subject being boys playing at the game. The sharpness of the principal object is remarkable considering the short period of exposure. *A Waterfall in Norway* (E. H. Jaques) was commended; but whereas the photographer may take his

time over the production of a perfect picture of a waterfall, a game like leapfrog gives fewer opportunities, and demands a promptness of decision for the right moment of exposure. Honourable mention was also awarded for *A Steamer at Sea* (E. H. Jaques) and *Going for a Sail* (W. J. Harrison).

In Class D the prize was gained by W. D. Welford for his *In Bramble Wildernesses*, a picture well worthy of its success in every respect. Honourable mention was awarded for *Broome Village* (E. C. Middleton), *A Warwickshire Lane* (W. D. Welford), *Mapledurham Lock, on the Thames* (J. H. Pickard), *At Dittisham-on-Dart* (A. Pumphrey), *Broome* (A. R. Longmore), and *Chiddingstone, Kent* (J. C. Huxley).

In Class E the prize was taken by F. Dutton for a very good bromide print from an Eastman film negative (*Warwick Castle*), exhibiting great choice in the selection of subjects and careful manipulation. *Getting Boats over the Weir* (W. D. Welford) was commended.

In Class F, for "The best contact print by development," *Chiddingstone, Kent* (Dr. J. C. Huxley), gained the prize. It was a fine sepia platinumtype which showed all the qualities of a high-class steel engraving. Honourable mention was awarded to *Boulders and Ferns* (A. Constantine), *Chiddingstone* (J. C. Huxley), and *Cottage at Charlwood* (R. G. Evered).

Class G was not a successful one, the exhibits being few, no doubt owing to the fact that this class of work (enlargements) is generally done later in the winter months. The Judges suggested that in future the original negative should accompany the picture shown. In this class *Family Pet* (James P. Heaton) took the prize, and *The Steamer "Bonnie Princess"* (F. Hoskins), an instantaneous subject, was commended.

In Class H Mr. Heaton took the prize again for his transparency, *An Avenue on the Warwick Road*. Honourable mention was awarded to *Doredale* (J. H. Pickard), *Cottages at Thorpe* (E. C. Middleton), *Boys Swinging on Gate* (W. D. Welford), and *Fishing* (W. D. Welford).

Class A.—The prize in this class was given by Mr. W. J. Harrison (Vice-President) for the best photograph in the set of prize pictures B to H, to be voted for by the members. It was gained by Dr. Huxley for his picture in Class F, and received twenty-three votes in excess of any of the others.

A large number of pictures were lent for exhibition, including some very fine carbon enlargements by Mr. Harold Baker, and excellent and large platinumtypes of notabilities by Mr. John Collier.

The Exhibition was in every way a great success. Votes of thanks were given to the donors of the valuable prizes (Messrs. Harrison, Huxley, Hulme, Hiff, Jaques, Pickard, Place, Rooke, and Taylor), to the Judges, to the Committee, and to Mrs. Pickard for presenting the prizes.

During the evening the Hon. SECRETARY read a letter from Mr. John Collier, offering a prize for competition next year among the members for the best photograph illustrating a subject to be selected at the commencement of next season, and suggesting "All's well that ends well," or the word "Done," as suitable.

Correspondence.

LIABILITY OF PLATE MAKERS.

To the EDITORS.

GENTLEMEN,—I beg to submit for the consideration of my fellow professional workers, the question whether the time has not arrived that some united action should be taken to test the liability of plate makers for issuing inferior and defective plates. This day I have had several plates frill completely off the glass, and the thermometer at freezing, and alum freely used.

They were a fresh hatch of Belgian make, which bears good repute, and my loss thereby is several pounds, to say nothing of the humiliation of having to return the money and loss of prestige occasioned thereby. Most of us have had, unfortunately, a similar experience to mine, a whole day's work lost from some defects in the plates, whether English or foreign.

Cannot the makers be brought to book if it can clearly be traced home to them? I should be pleased to contribute ten pounds to any fund raised for the protection of photographers against the issue of inferior plates by makers, as now we are completely at their mercy.—I am, yours, &c.,
FRED. T. PALMER.

Clarence Studios, Kingston-on-Thames, October 12, 1887.

AMMONIA AND WATER.

To the EDITORS.

GENTLEMEN,—In the leader in your current issue on ten per cent. solutions, you say that one ounce of concentrated ammonia solution mixed with nine ounces of water will occupy less than ten ounces; and in proof of this you adduce a rough experiment in which the mixture is made in a bottle holding (as I gather from the description) more than ten ounces, a partial vacuum being thereby produced in the bottle on closing and shaking it. This is certainly the case. But it is due, not to any change in volume in the liquid, but to the fact that on pouring strong ammonia solution into an empty bottle sufficient gas escapes to expel part of the air from the bottle; on then pouring in some water and corking the bottle the gas is reabsorbed by the added water on shaking it up, and so a partial vacuum is produced.

I have just tried the experiment of mixing the liquids in a small stoppered flask with a narrow neck. I first half filled it with water, and then carefully filled it up to a mark on the neck with strong ammonia

solution, avoiding agitation as far as possible. On then putting in the stopper, shaking well, and cooling to the original temperature, the mixture still stood apparently at exactly the same mark. If there is any change of volume (as doubtless there is) it is far too small at any rate to be measured by rough experiments, even though made on a correct principle.

You will, I am sure, excuse my making this little criticism in the interests of accuracy. With the rest of your article I heartily agree, especially the suggestions in the final paragraphs.—I am, yours, &c.,

October 17, 1887.

W. F. DONKIN.

TEN PER CENT. SOLUTIONS.

To the Editors.

GENTLEMEN,—May I be permitted to offer a few remarks in reply to your editorial re an article of mine on *Ten per Cent. Solutions*, especially as I have to cry "*peccavi*" in some instances, though in the main I stick to the correctness of my reasoning?

I still hold that there is a difference between "ten per cent." and "one in ten," though by shearing my words of their context, this becomes less apparent. I said, "This is not . . . but rather a solution of one in ten, one grain of pyro in ten minims of water."* Now I still maintain this, and hold it is not a ten per cent. mixture by weight, for ten minims of the solution do not weigh ten grains, although they contain one grain of pyro; and it certainly is not a ten per cent. solution by bulk, for whilst ten minims of water cube .36 cubic inch, one grain of pyro does not cube .036 cubic inch.

I certainly argue that 100 cubic centimetres of solution containing one gramme of dry salt is neither a 100 per cent. solution by weight, for it will weigh more than 100 grammes; nor one by bulk, except the salt happened to have the same weight for bulk as the liquid.

My statement "one ounce of pyro dissolved in ten ounces of water is a ten per cent. solution by weight," is, of course, a mistake. It should be one ounce of pyro added to nine ounces of water. I have also made a most careless slip in giving directions how to make a one in ten solution. The article was written in a great hurry, and I had no chance of reading it. In a letter of mine re the same subject, written prior to this article, and published in the *Amateur Photographer* of the 7th, I have, however, stated this correctly.

You say further on, "The solution containing one ounce of pyro in a volume of ten fluid ounces is, despite Mr. Clark's statement to the contrary, strictly and accurately a ten per cent. solution both by weight and volume." This I distinctly challenge. Do you really mean that if we put our measure into a balance and weigh out an ounce of the solution it will contain one-tenth of an ounce of pyro? I maintain that the density of the solution being now greater than that of pure water, when we weigh out an ounce we shall get less bulk, and therefore less of the salt. And the same holds good as to bulk. Even supposing that we make up a real ten per cent. mixture by weight, that is, one ounce of pyro plus nine of water, and use a grain graduate, we are no better off, for the grain volume of solution will not weigh the same as the grain volume of water. Take an exaggerated case, gold and mercury. A ten per cent. mixture of these by weight made up as above, will not produce the same results as an ounce of gold dissolved in sufficient mercury to make a volume of ten fluid ounces, and yet the first is a ten per cent. mixture by weight! A further ten per cent. mixture could be made by measuring both the gold and mercury by bulk. I tried to point out these anomalies in my article, though I appear to have failed, at least judging by your criticism. And it was to evade them that I proposed to use (what I believe to be generally used) a solution ten minims of which shall contain one grain of the salt, and call it, for distinction's sake, a one in ten solution.—I am, yours, &c.,

LYONEL CLARK.

Camera Club.

THE PHOTOGRAPHIC EXHIBITION.

To the Editors.

GENTLEMEN,—The catalogue of the Photographic Society's Exhibition is carefully corrected by direct comparison of each entry with the original paper sent in by the exhibitor. In many cases it is impossible to insert the whole of the long titles or quotations given, or detailed descriptions of processes or apparatus, and it must be left to the discretion of the compilers of the catalogue to abbreviate such titles.

Mr. George Smith complains, in your current issue, that his exhibit is "erroneously described as lantern slides." On referring to Mr. Smith's entry form, I find these words:—"Lantern slides (Woodbury process), mounted as transparencies for window decoration." A description follows, much in the same terms as those used in Mr. Smith's letter to you.

It is obvious from this that the entry in the catalogue is, though brief, certainly not erroneous. As, however, my desire is not only to justify the Assistant Secretary, but also to meet the wishes of Mr. Smith (and every other exhibitor) as far as possible, I am glad to be able to somewhat extend the description of No. 696 in the proof of the catalogue just being sent to the printers for the members' edition.—I am, yours, &c.,

October 14, 1887.

W. F. DONKIN, Hon. Sec. P.S.G.B.

* Solution would have been a better word.

PHOTO-MICROGRAPHS AT PALL MALL.

To the Editors.

GENTLEMEN,—Having been awarded a medal for the above, I suppose I ought not to complain if some of the reviews seem to have missed the chief characteristics of my exhibits, and, therefore, have criticised them depreciatorily. May I therefore crave a little space to point out my chief aims in this work? These have been, 1st, the selection of rare and beautiful objects, not ordinary "commonplace" shilling slides; 2nd, to see what success was possible in the acknowledged difficult and rarely worked field of dark ground illumination, i.e., opaque objects by reflected light, and objects lit by spot lens or paraboloid; 3rd, the overcoming as far as possible that greatest of cruces in photo-micrography, the focussing of all planes with equal sharpness, even in extra deep objects such as, for instance, polycistina—opaque—taken with the one-inch O.G.

It was my success in these latter points—artistic and natural effects in illumination and great depth of focus—that elicited the very high praise accorded me at the Royal Microscopical Society (see their *Journal*, June, 1886, pages 557-560). It was disappointing, therefore, to find the *Times* and other papers giving my exhibits but superficial criticism, the reason being, I suppose, that the objects being of a class to be quickly recognised, and no special knowledge of the difficulties overcome being available, it was easiest to dismiss them perfunctorily as "commonplace," and "not above the average of such productions," and to accord all the praise to a class of work which, however well done, is still unintelligible to the great majority.

I refer, of course, to Mr. Pringle's beautiful specimens of bacteria and bacilli; but I would ask how many of the visitors (including the critics who see in them "difficult work and definite progress") are able to gauge the accuracy of these photographs, or their truthfulness in rendering the living originals?

None but actual students and workers can at all appreciate (I don't mean enjoy) them at their real value. "Definite progress" means, if anything, progress beyond other work of the same kind. Are these, then, better than Dr. Crookshank's as shown at the Royal Microscopical Society? Personally, I take no interest in bacteria, they have no structure to pay for care in delineation, I do not believe they ever have had or ever will have the slightest value therapeutically, and I am glad to find that they are fast losing their interest and value pathologically; even the redoubtable Pasteur is past his zenith, rival experts and theorists are already decrying the value of his processes and supposed results. I may confess that Mr. Pringle's beautiful photographs charmed me most as specimens of exquisite decorative designs; the character and display of the image, the very artistic printing and mounting, struck me very forcibly in this light.

The depreciatory opinion of my exhibits passed in the *Photographic News* (7th inst.) contrasts very curiously with the same paper's remarks on some of the same objects when shown at the Royal Microscopical Society. "These photo-micrographs were of singular beauty and excellence, the principal feature being that, though the objects were opaque and the surface irregular, yet all the irregularities were in focus" (see *Year-Book*, 1887, page 156).

I find that the limit to the successful showing of widely divergent planes in focus together, is so soon reached with the present style of object glasses, that I think it must be this effect that is alluded to by Dr. Klein, when he says (as you quote in *JOURNAL*, August 19, page 516), that "no real advance has yet been made in producing photographs to take the place of accurate drawings of objects under high powers." It is only too evident to workers that the higher the power employed the greater apparent divergence in planes; therefore, as there is no probability of optical laws being altered for our special needs, it must be only with a new style in object glasses that further success in this direction can be reached, perhaps, as Dr. Klein says, "with the now apochromatic objectives and projection eye-pieces by Zeiss, better results may be looked for."—I am, yours, &c.,

FRED. H. EVANS.

158, Osbaldeston-road, Stamford Hill, N., October 17, 1887.

A PHOTOGRAPHIC CONFERENCE.

To the Editors.

GENTLEMEN,—Would you be good enough to permit it to be announced in the *JOURNAL* that the Committee of the Camera Club has decided to organize a Spring Photographic Conference in 1888 similar to that held in 1887? An influential committee of members has been appointed to carry out the necessary arrangements.

The Conference will be held on Tuesday and Wednesday, 13th and 14th March, in the Hall of the Society of Arts, the use of which has again been kindly granted by the Council.

The President of the Club, Captain W. de W. Abney, will preside, and the proceedings will commence each day at 2 p.m. At the same time there will be held in the Library of the Society of Arts an exhibition of apparatus and one of members' photographs, the latter at the Club rooms.

Lantern slides will be shown on the evening of the first day of the Conference, and at the conclusion of the second day the Annual Club Dinner will be held.

On the Monday evening previous to the Conference a Smoking Concert will be given at the Club-house.

Further particulars will be announced later.—We are, yours, &c.,

G. DAVISON, } Hon. Secs.
E. G. SPIERS, }

Camera Club, 21, Bedford-street, W.C., October 17, 1887.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED :—

J. Browning, Exeter.—Three photographs of Exeter Cathedral.
F. Hoare, Cirencester.—One photograph of J. Sewell, Esq., of Cirencester.
F. Shemeld, Sheffield.—One design for label (paper). One design for label (cardboard).

WM. A. BRICE.—Specification being proceeded with.

GEO. BAINES.—Prepared ox-gall is supplied by all artists' colourmen.

RHINE STUDIO.—We are not acquainted with the "Phoenix dry plate ferros," so, of course, cannot suggest an improvement in their development.

A. B.—Probably you did not make the solution of gum arabic thick enough. If you have used starch for so many years successfully, why make a change? You can have nothing better.

T. COAN.—We have seen lenses by A. which were equal to those by B. as effective working tools, but of course they have not the same commercial value. Better test before purchasing.

W. WALLIS.—1. We recommend you to join the London and Provincial Photographic Society; the subscription is five shillings a-year.—2. See correspondence in the present number.

MR. A. BOWLER sends us samples of sensitised paper prepared by him. Although barely sufficient to enable us to give it a thorough trial, yet from what we saw it seems to be a good brand.

FOX.—As the sulphite of soda is in the state you say it is useless for photographic purposes. We cannot explain the cause why the faces of your portraits are "all black." Better send us an example to see.

BROMIDE.—Bromide paper is usually coated by elaborate and expensive machinery; but the small sizes you require may be coated by floating the paper on the emulsion. Those who supply the paper will tell you if they will cut it to your sizes.

AN ANXIOUS INQUIRER.—The photograph shows the studio to be a good one, and one that is very convenient to work in. If you get flat pictures it is clear that you are not managing the light properly. Send us a few examples of your work, and we will try and indicate where you are wrong.

QUANDARY.—If the operations were carefully carried out the prints would certainly not have faded in so short a time. The formulae appear all right but the fixing bath is much weaker than is generally used. We presume, however, that you allowed an approximately longer immersion on this account.

A. J. CORRIE.—1. A candle placed behind one thickness of red calico, over which there is no covering, is certainly not a safe light to develop by, if the development is a protracted one—this may possibly be the source of your trouble.—2. Light from some source or other was the cause of the fogging of the negative you forwarded.

W. COLES asks: "Is a speaking tube practicable to communicate between distances a hundred feet apart? If so, what should be the diameter of tube?"—We should say that a speaking tube will answer quite well for that distance, and that a three-quarter or an inch tube will be the best size. Perhaps some correspondent who has had practical experience in this direction will give the benefit of his experience.

J. E. O. asks how much carbonate of soda he ought to add to the last washing water prior to toning; also how to tell whether the toning bath is neutral or otherwise.—If the prints are treated with soda before toning a small quantity only should be used. A crystal the size of a filbert in a quart of water is sufficient. The condition of the bath as regards its neutrality can be ascertained by testing it with litmus paper.

T. GULLIVER.—We have seen a very bright disc of about five or six feet produced with the microscopic lantern mentioned, mixed gases and a rather low power objective having been employed. For such low powers a portrait combination suitable for postage-stamp or locket portraits answers very effectively. It is necessary to have a plano-convex condenser near to the stage. This condenser should be adjustable as to distance from stage.

ASSISTANT writes: "I have a negative (dry plate) that has been coated with enamel collodion and afterwards varnished in the usual way, but having to take off the varnish afterwards for enlarging purposes, I find I cannot remove the collodion, and it has also left the negative all cracks. I have tried ether and alcohol without success, and consequently am in a fix, as the party cannot rest. Would you kindly give me your advice on the matter?"—If a mixture of ether and alcohol will not remove the collodion we fear the case is hopeless. Perhaps revarnishing the negative may restore it to something like its original condition.

C. B. writes: "I have been using lately a ferrous oxalate developer, made up as at page 203 of the ALMANAC for 1886, but I find I have invariably to intensify the negatives before printing. Is it always necessary to intensify with this developer, or is the formula at fault? I find also, that if mixed and left to stand for a few days, iron is deposited and the developer becomes useless."—In reply: The formula is a very good one. It is seldom that negatives developed with this developer require intensification. The thinness, in our correspondent's case, is possibly due to under development or error in the exposure. The oxalate and iron solutions should only be mixed just before using, as the mixture quickly loses its energy. If "C. B." is in the habit of mixing them days before use, the thinness of the image is fully accounted for.

J. COURTIER.—The value of the stops expressed in terms of the focus of the lens are got by dividing the focus of the lens by the diameter of the stop. Thus, in a sixteen-inch lens a stop of one inch in diameter is $\frac{1}{16}$, but Mr. Burton's table is only of use to give an idea of exposure, and is calculated for no particular kind of plate but only gives an approximate ratio. The U. S. numbers of your stops are open aperture, .878 : 1, 1.72 : 2, 2.25 : 2, 4 : 4, 9 : 5, 36 : 6, 148. Page 343 explains itself.

GREENHORNE says: "I was told by a friend the other day that any dry plate could be rendered extra quick by immersing it for about half a minute in weak ammonia water. Is that so? I tried and fancied it caused the plate to darken after the development, especially after mercurial intensification. Am I right in my conjecture? Would you kindly inform me if the process spoken of is true, or do you know of any process that would render dry plates (ordinary) extra quick? If so, please oblige me. My lens being only quarter-plate of six-inch focus, is it possible to get a good full-length portrait on a $6\frac{3}{4} \times 4\frac{1}{2}$ plate without distortion with the glasses reversed as for a view lens?"—In reply: The sensitiveness of some plates may be slightly increased by the ammonia treatment, but not all. It is far better to purchase extra rapid plates than to attempt to increase the sensitiveness of slow ones. The six-inch focus lens will not take a half-plate portrait without straining. However, if one of the components be used as a single lens, stopped down, and with its convex side next the ground-glass, it will answer the purpose very well. We are assuming that the lens is a double combination.

A CORRESPONDENT writing from Halliwell, Bolton, says: "1. I have noticed when taking an interior of a church, a second image of the east window on the negative close to the real one. It was taken on a backed plate with Dallmeyer's triplet lens, and a medium-sized stop. Could you tell me the reason, and what I could do to avoid it? It has not appeared on all negatives taken of interiors of churches, and it is rather disappointing, as I did not find it out till unable to take another.—2. I should be glad to know how much of a solution of hyppo (four ounces to the pint of water) it takes to thoroughly fix each sheet of paper, as when I have a good many prints to fix at one time I am doubtful how much solution to use to fix them properly without having a great excess."—In reply: 1. This is caused by a minute hole in the camera front, presumably an ill-fitting screw.—2. Without knowing how much chloride of silver there is in the paper to be dissolved, it is impossible to say. But as hyposulphite of soda is so very cheap, it is usual to use a very large excess over what is known to be the theoretical quantity required. This is with a view to greater stability of the prints.

HOGARTH writes as follows: "Being desirous of photographing a series of lantern slides on 'Hogarth's works,' for trade purposes, I will be much obliged if you will be able to inform me in your 'Answers to Correspondents' whether I am able to copy the engravings in the following work, and offering the slides for sale, without infringing any copyright, &c. The book in question is, *The Complete Works of William Hogarth in a series of 150 superb engravings on steel from the original pictures*. With an introductory essay by James Hannay, and descriptive letterpress by Rev. J. Trusler and F. Roberts. Published by the London Printing and Publishing Company, London and New York. About three years ago I wrote to the 'London Printing and Publishing Company' respecting this work, and asked them if permission could be obtained for taking slides from the engravings in the book, and they replied 'that they would give me permission on payment of 2s.' I did not write to them again, but thought I would ask you if the work was copyright, and if it was really necessary that I should have to pay this fee?"—In reply: The copyright in Hogarth's works expired years ago. But this appears to be a modern work, and in which there may possibly be some sort of copyright; there certainly would be in the letterpress. There is nothing whatever to prevent you from copying the original plates, which, of course, are far more valuable than modern replicas.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, October 26, 1887, will be on *Orthochromatic Photography*, on which a paper will be read by Mr. J. B. B. Wellington.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The usual monthly technical meeting of this Society will take place on Tuesday next, October 25, at eight p.m., when the apparatus now in the Exhibition will be shown and explained. Also, on the same evening, the adjourned special general meeting, for the consideration of the proposed new rules, will take place at six p.m.

GEORGE NELSON, DALE, & Co.—This firm of gelatine manufacturers, of Emscote Mills, Warwick, and 14, Dowgate-hill, London, has been registered as a Limited Liability Company, under the style of George Nelson, Dale, & Co., Limited. There will be no public issue of shares, the whole being taken up by the existing partners. No change will take place in the management of the business.

LAST Monday evening the optical lantern was brought into use at the Exhibition for the first time this season, when "Schauchieff's" electric battery (to which a medal was awarded last year by the Society) was used with remarkable success, an arc lamp, supplied by Woodhouse and Rawson, having been arranged to work inside the Society's lantern. We understand that next Monday evening, October 24, the members of the Amateur Field Club will, in accordance with their annual custom, exhibit slides in the lantern.

No. 1434. VOL. XXXIV.—OCTOBER 28, 1887.

PHOTOGRAVURE.

DURING the different visits we have paid to the present Photographic Exhibition, we have heard quite sufficient to convince us that a majority of the admirers of the photogravures there shown—although many of them are evidently amateur photographers—have no very clear conception as to how they are produced. We have often overheard such remarks as the following:—"Oh, very beautiful, but they are not printed direct from the negative;" "They are printed in some way from gelatine;" "They are done by some secret process, they are not photographs at all;" &c. Many appear to be utterly ignorant of the fact that the impressions are produced from metallic plates in printers' ink, and in an ordinary copperplate press, in the same way as are line or mezzotint engravings.

It would, we are fully aware, be an act of supererogation with the majority of our readers to explain what is photogravure. It is, however, for the enlightenment of novices in matters photographic—such as have but recently entered the ranks of photography—that the present article is written. It may be explained in commencing that there are two distinct classes of photographic engraving; one in which the design is in relief, as in the case of woodcuts, where the impressions are obtained by surface printing, and the other where it is in intaglio, the prints being taken in the same way as they are from an engraved steel or copper plate. To the latter class the name of photogravure is now generally applied.

The production of intaglio plates may be divided into two different classes; in the one the image is etched or bitten into the plate with a corrosive material, and in the other the printing plate is made by depositing metal, by the electrotype process, upon a design which has been obtained in relief in gelatine. The former plan was introduced and patented by Fox Talbot so long ago as 1852, and the latter by Paul Pretsch in 1854. These two systems, it may be mentioned, really form the basis of most, if not all, of the modern intaglio photographic engraving processes.

Talbot's method, by which he produced some excellent results at that period, consisted in coating a metal plate with bichromated gelatine. After the image had been printed in this it was treated with a corroding fluid which penetrated the film freely where the light had not acted, and so attacked the metal, while it was resisted by those parts which had been protected, in proportion to the light action modifying the condition of the film. In his first process Talbot employed a solution of bichloride of platinum, and, in his later patent, he claimed the use of perchloride of iron as the etching medium. Now it is not sufficient merely to produce the image in intaglio, but it must also possess a grain or rough surface to hold the

ink. A Woodburytype block, for instance, cannot be used for intaglio printing because, on account of its smoothness, it would not retain the ink.

Talbot obtained his grain, first of all, by printing the picture through gauze, but, later on, by dusting over the film, after it was printed, a resin in fine powder, and then heating the plate till the former was just melted and rendered adherent. The particles of resinous matter acting as a resist caused the image, when bitten in, to have a fine grain. Talbot's method may really be considered practically as the basis of all the modern intaglio etching processes. In most of these processes, as now worked, the resinous material is applied direct to the metal plate, and the gelatinous image developed upon it after the manner of a carbon print.

The electrotyping method may be classed under two heads, namely, where the necessary grain is produced chemically, as in the method of Pretsch, or mechanically, as in the processes of Woodbury or of Waterhouse. By the former method the relief image is obtained in, so to speak, a reticulated or granulated state, and this grain, in the electrotype, forms the ink holding surface. What may be termed the mechanical grain was secured by Woodbury by mixing a gritty material with the gelatine with which the relief was made, so that when the image was developed, instead of having a smooth surface, it possessed a rough or gritty one, which was reproduced in the electrotype intaglio or printing plate.

Waterhouse obtains his grain by dusting over a wet carbon print, developed on a metal plate, a gritty substance—powdered glass or emery, for example. When the whole is dry, the gritty matter, which has caused the image to be grained or roughened, is removed. The granularity thus caused forms the tooth which retains the ink in the electrotyped plate, from which the impressions are produced.

The method of printing from an intaglio plate differs entirely from that of printing from a relief one. In the latter case the ink is simply applied with a roller to the raised image, and the print is then taken from it in an ordinary type printing press. In the former the ink is applied to the whole of the plate. It is then carefully wiped off from the surface, leaving it undisturbed in the intaglio portions. On the *inked in* plate a sheet of paper is placed, and the whole passed through a rolling press, with several thicknesses of fine woollen blanket interposed between the back of the paper and the roller. The elasticity of the blanket causes the paper to be forced, with great pressure, into contact with the ink, which then adheres to it.

In the foregoing we have only given a brief sketch of the systems by which photogravure prints are produced. Of

course there are many modifications of these methods, and those who work them, commercially, studiously keep the details of them as profound trade secrets. But, in most cases, if the secret were out, it would be found that it really consisted more in the skill of the operator than in anything which had not, at one time or other, been published in our columns.

THE question we raised with regard to ten per cent. solutions was as to whether it was practically worth while to raise an outcry about a difficulty that does not exist. Mr. Lyonel Clark thought it necessary to distinguish between "ten per cent." and "one in ten" solutions, and alleged that it was a practical impossibility to make a true ten per cent. solution of a solid salt. As a matter of fact, it is perfectly easy to make percentage solutions *either* by weight or volume, but not to combine the two, and we were wrong in saying that a solution containing one ounce of pyro in a volume of ten fluid ounces is *strictly and accurately* a ten per cent. solution both by weight and volume. It is strictly so by volume if properly used, and *practically* so by weight, though not *accurately*; the error being far less than the original one Mr. Clark sought to remedy. Our contention is, that setting on one side entirely the question of theoretical accuracy in percentage solutions, the differences that occur are not such as to sensibly affect development. Mr. Clark, however, comes forward as the champion of extreme accuracy, but after crying "*peccavi*" in his letter of last week to certain errors we pointed out, and which he attributes to hurry in writing, he still errs when he says in the second paragraph of his letter that "ten minims of water cube .36 cubic inch." As a cubic inch of distilled water weighs about 252.5 grains, Mr. Clark's figures require dividing by ten.

PROFESSOR DONKIN'S experiment, too, shows how little trouble is likely to arise in development from want of strict theoretical accuracy in these matters. We mentioned the theoretical shrinkage in volume on mixing ammonia and water, because Mr. Clark has stated that the mixture of these liquids in certain proportions made a true percentage solution; and we, in the interests of the strict accuracy he aimed at, pointed out that, by the laws of the expansion of liquids, such was not the case. We never for a moment supposed, however, that this valuation of volume would be of any moment to the photographer, who accepts and uses without experiencing any difficulty anything that is given to him under the name of "Liquor ammonia '880." Before we commence to be so very particular in our methods of weighing and measuring, let us take care that we have some definite material to work upon.

AN important communication on photo-astronomical matters, by Professor Pickering, the director of the Harvard College Observatory, has recently been published. It is upon a *New Form of Construction of Object-Glasses intended for Stellar Photography*, and is plainly indicative of the very important position now held by photography in regard to astronomical observation, as it is neither more nor less than a proposal to make important alterations in the curves of the object-glass, and this combined with arrangements for changing the position of one of its components. Professor Pickering points out that the ordinary corrections applied to astronomical object-glasses to avoid chromatic aberration unfit the lens for use in photographic operations. He indicates two modes of remedying the evil. The first is that adopted in the great Lick telescope (whose progress has been at its various stages brought before our readers): it consists in adding an extra lens of long focus to the usual object-glass when photographic work is required. But the great objection to this method is the large additional outlay it entails, besides the fact of its adding two extra surfaces, with their necessary reflections and possible increase of errors. There are many possessors of good telescopes, *in esse* not to speak of those *in posse*, who would not care to go to such an additional outlay for photographic purposes, but who yet would have no objection to adding, to some slight extent, to the cost of their instrument to fit it for stellar photography. Such observers will be suited by Professor Pickering's new design.

THE objectionable excess of correction for colour may, as is well known, be corrected by separating the components of the objective; but then, though there may not be two foci, a "chemical and a visual," there will be introduced increased spherical aberration, as the central rays will have a longer focus than the marginal. This error, however, is obviated in the second method named by Professor Pickering, by giving different curves to the two surfaces of the crown lens, and then, when the lenses are separated for photographic purposes, reversing the crown lens. This method has been tried and found to answer quite satisfactorily. Messrs. Alvan Clark & Sons first tried the effect with a small glass specially made under this new arrangement, and, finding it to answer, they made a large one, thirteen inches aperture and about one hundred and eighty focus. It has been found to give excellent definition for eye observation, and when the crown is removed three inches from the flint, and also reversed in position, it gives photographs of equal excellence. In ordinary work the two lenses are placed in contact, with the more convex side next the flint. When used for photographing, the convex side of the crown is made to face the plate and brought slightly nearer to it. It may be interesting to state the actual curves:—For the crown-glass lens the radii of the two surfaces are 86 and 77 respectively; for the concave side of the flint 73.8 inches; for the convex—that turned to the eye-piece—1020 inches.

THE bright iron and the steel-work of rolling presses and such-like photographic implements is, in a general way, not much in the way of getting rusted through disuse; but there are at the same time many photographers whose call for the use of such appliances is but spasmodic; to them, therefore, any plan which would enable them to feel secure from the danger of rust and stain, no matter how long a time their presses, &c., were left idle, would be most welcome. Some of the better class of instruments are provided with silvered plates and nickelised rollers, thus reducing the danger to a minimum; but all these things mean extra cost, and, besides, there are presses still in use that were designed long before the introduction of these luxurious additions, and they need looking after. For a steel plate for which a long rest is anticipated, it is well to prepare it in the fashion adopted by the makers when they send them out—the plate is heated and smeared with wax. The plan is perfect; but when it comes to a question of removing the wax there is a difficulty; time is required and temper usually displayed. A foreign journal describes a remedy, or, rather, antidote against rust, which would appear to be of real value. Aluminium is dissolved in palmitic acid, a product being obtained having the power of dissolving zinc. An alloy of aluminium and zinc is thus obtained, and if applied to the polished surface with a brush it prevents oxidation. Another writer shows that super-oxidised linoleic acid acts equally well and does not injure the metallic lustre.

THIS season of snow is rapidly approaching, and as the tradition of the intense purity of snow and, consequently, of its eminent suitability for the production of absolutely pure water by being melted, still largely prevails, it will not be without interest if we describe the result of a rather recent analysis of snow taken in the neighbourhood of a large city. On one day when snow fell there were present in it sulphuric and sulphurous acids, and in equal proportion; but upon examining it the next day all the latter acid had disappeared—it had been converted by oxidation into sulphuric acid. The result of the use of a weak solution of sulphuric acid (for that, in effect, is what would be obtained by the melting of such snow) under the impression that pure water was being used may be readily imagined.

THE production of cheap oxygen really appears to have become, on a commercial scale, *un fait accompli*, and the future possibilities of its use in matters photographic cannot be readily grasped in the mental vision. Of course limelight and optical lanterns at once suggest themselves, but they form a part—a small part only—of the possibilities linked with the production of cheap oxygen. The *Chemical Trade Journal* goes so far as to say that the selling cost is put down at about three shillings a thousand feet, but this, we need scarcely state, is not the price delivered at our doors. In calculating the price of coal gas at

so much per thousand feet, the fact is too often lost sight of that, after all, the chief item of the charge is the cost of delivery, a sum including all the interest of capital, cost of laying, and the wear and tear and keeping in condition of the hundreds of miles of gas mains underlying our streets. But, at the same time, such a sum as three shillings per thousand feet is enough to make all the magic-lantern makers in the world pause ere they construct another lantern intended to be used with oil—animal, vegetable, or mineral.

THE PHOTOGRAPHIC EXHIBITION.

IV.

THOMAS FALL (No. 149), "*Lion, Mastiff*."—This is the head of a dog enlarged, one of a series of five, all being life size. They are certainly very fine productions as far as they go, being only heads, but it is a pity that in some so much brush work has been found necessary to give detail to what otherwise would have been white patches. The framing of these photographs is very effective, being dark wood with gold mat and dark-grained wood mounts.

Robert Slingsby (No. 164), "*Waiting*."—This is the best picture out of the three by this exhibitor, who has been working with more strength in light and shade than formerly. The subject is a young lady ready equipped for a walk waiting for some one. With one exception the pose of this figure is expressive—we allude to the right arm raised so that the hand resting on the top of a screen is higher than the head; this position, which is not graceful, disturbs the idea of repose which the title should include.

Frank Salter (No. 168), "*The Bernina Range*."—A panoramic picture where three negatives have been very cleverly vignetted into each other; but some remarks we have already made on a similar subject will equally apply to this one. The senses are not appealed to for any sympathy.

W. J. Byrne (No. 184), "*Princess Hélène d'Orléans, &c.*"—A frame of three different direct portraits 24×18 . The pose of the princess is very simple and effective, but the shaded side of the head being too dark lacks rotundity; a light background being used intensifies this still more. Another lady is very well treated; she has a lace covering, but to secure detail the face has been under exposed, and consequently has been subjected to a vast amount of retouching. The gentleman's portrait is the best of the set, with a very light coat, grey hair, and the markings of age; these are all well rendered photographically. Again we observe that the brush has been used unsparingly on the ladies' photographs, otherwise they promise well for the future of direct large work.

George Mold (No. 189), "*St. Mary's Church, Banbury*."—A very well done and effective interior, where local difficulties have been mastered and an idea of grandeur suggested.

J. Hubert (Nos. 202 and 203), "*Who can be Playing*."—Two small pictures pictorially conceived and fairly carried out.

H. W. Macdonald (No. 204), "*On the Thames*."—Four small pictures of well chosen, pretty backgrounds, with a family boating party in each. Also very nicely arranged, but the effect is rather weakened by so many reflections on the placid surface of the water, which however good, disturbs that repose which the eye requires upon looking at pictorial scenes; otherwise these photographs are very satisfactory.

F. Whaley (No. 206), "*The Firstborn*."—Another successful attempt at picture making. A young mother whilst at needlework watching a baby in a cradle. The various objects in this photograph are well put together, and a soft tone pervades the scene (which would have received more value if a darker mount had been used), but it is too realistic. The painter would have introduced colour, which suggests so much more than monotone, and a more refined and delicate model would have been better from an imaginative point of view.

Symonds & Co. (No. 208), "*Yacht Racing Scenes*."—We have already made some remarks upon similar pictures which equally apply to these. But there is one matter appertaining to this collection which must be noticed; it arises from so many (nine) pictures being placed in one frame, the height of the sea line being different in each picture. This is very distressing to the eye, which would have been avoided if each picture had been framed separately. These are small matters,

but it is just the avoidance of them which helps to raise the pictorial value of photography at exhibitions.

G. Watmough Webster (No. 213), "*Eaton Hall Mantelpiece*."—We take notice of this picture with the simple remark that it is a very good example of technical excellence, and more particularly on account of the colour (platinotype), which suggests the original.

Vernon Heath (Nos. 214 to 225), "*Views, &c.*"—The pictures which this veteran photographer exhibits are technically good. The distances are rendered very pure and delicate, but somehow they do not quite convey that idea of space and barrenness which nature does. We can only attribute this failing to the absence of local colouring, and possibly to the scenes not being chosen with a view to that rugged contrast which should be the artist's study in such desolate places.

H. S. Mendelssohn (No. 228), "*H. Perigal, F.R.A.S.*"—This is a very fine study of a well-known scientist, the head being about six inches, and the white hair which confers such picturesqueness upon the original has been well rendered; but how comes it that a hand upon a book which is close to the edge of the picture, and in apparent advance of the face, should be so unaccountably small? This is very singular in effect, because wrong in fact.

T. A. Green (Nos. 234, 235, 236).—These are very nice pictures of the Lake District, being well chosen, the first showing a large extent of one of the lakes, and giving a most satisfactory idea of what this beautiful country is like; the second picture has strong contrasts between a foreground tree and some distance; whilst the third, to which a medal has been awarded, shows a vast mountainous range with some trees in the middle distance. They are in platinotype, which, as previously observed, seems so admirably adapted for giving aerial perspective.

S. G. Payne (No. 241), "*The Trout Pool*."—This is a very good subject and has been photographically well treated, but there is always some risk in managing a scene where one half consists of water, with the reflection of the upper portion strongly detailed. The painter by local colour can alter this effect, but the photographer, and more especially when the water is quite placid, is compelled to give a more powerful rendering, and this result is not satisfactory.

J. Gale (Nos. 245 to 252).—A series of most effective studies by this well-known artistic photographer, consisting of figures with building and landscape backgrounds. They are all cleverly arranged, but there are some parts which are too solidly black to be quite in keeping or in harmony with other parts full of exquisite detail. We could have wished that these pictures had been in platinotype, when possibly a still more artistic effect would have resulted.

H. Collis Pettitt (No. 267), "*Views of the English Lakeland*."—A series of six pictures, where again good results have been achieved by platinotype, which gives to masses of distant foliage such a retiring and soft character. A medal has been awarded these photographs, and they most certainly give some positive notion of the beauty as well as the ruggedness of the actual scenes. We venture to suggest that if panoramas of these subjects could be taken, they would then realise the natural scenes far beyond these instalments. Has Johnson's panoramic camera become a tale of the past? or is it that the modern photographer is ignorant of the existence of such a clever apparatus? At this time of day when the chemical side of photography has achieved so much success, that camera might now be utilised with some most successful results.

John F. Roberts (No. 268), "*Scenes from 'David Garrick'*."—A series of six small photographs; one half with the same background, the other half, also, with one scene. These pictures have been awarded a medal, not so much for any artistic or subjective treatment, but we presume simply for the attempt which has been made to photograph scenes on the stage, and are so far interesting. We do not know if orthochromatic plates were used, but should think that they would be found very necessary, because if the scenery has been painted to suit the electric light it will be done so with warmer colour. Another rather curious matter which these photographs reveal is that, however realistic the figures may be, they most certainly do not present much artistic posing, which is necessary to make them pictorial.

Francis Cobb (No. 272), "*Views in North Wales*."—A frame of six well chosen views. The contrast of water and foliage, however, is strong. Here again platinotype would have greatly assisted the result. And we must once more call attention to the disturbing in-

fluence produced by the close proximity of one picture to another; the eye cannot separate them, and they totally destroy each other.

G. West & Son (No. 276), *Panel Portraits*.—There is much softness in the treatment of these various studies, which, for studio work, are good specimens. But what a pity it is that hands should be cut in half, and arms come down abruptly to the base of the picture! Why cannot these matters be altered in pose, or modified by sunning down? But then the artistic instinct must come into action, and hence photography loses much.

Frederick Müller (Nos. 277 and 293), *Portraits*.—Here we have two frames of cabinet portraits, which, although very commercial in the style of frame arrangement, are really very good specimens of studio work, and, despite a vast amount of retouching, are very admirable in the relation of the figure to the size of picture, and we do not see any of that singular cutting in half of hands and other disagreeable matters just alluded to. These photographs are worth studying.

V. H. Chintamon (Nos. 281 and 288), *Indian Portraits*.—We mention these just to notice the valuable aid which photography now gives to a knowledge of such far distant and mighty personages as these pictures represent—they become thus deeply interesting. There are two more examples on the walls, but being enlargements very much worked upon, their merit does not rest upon photography.

W. J. Byrne (No. 283), *Direct Portraits, Life-size*.—Here we have three notable examples of the "direct" large work in this Exhibition previously alluded to. They are all very powerful in treatment. This may partly arise from the exposure necessary for such large heads not having been quite long enough, hence some parts in shade want luminosity. In one portrait a large amount of retouching has been necessary; the young lady's portrait to which a medal has been awarded being the best—it amounts to an artistic study—and great care has been exercised in preserving the delicate gradations of a white dress, whilst at the same time the flesh tones have not suffered. This is really a very fine picture, and in pose and arrangement goes far beyond ordinary portraiture. With such excellent results as these before us, we may look forward with anticipations of still more advanced direct large heads in the future.

Frederick Müller (No. 290), *Enlargement*.—This is another example of photographic work from Germany done by the Obernetter method, and it possesses most admirable qualities. We have in this picture a registration of an extended scale of tones, which results in a soft and flesh-like appearance, and this tender half tone is marked in some white drapery. The face, however, has been much retouched.

W. McLeish (No. 292), *Studies*.—Three large direct pictures, which command attention from their powerful light and shade and a general picturesqueness of artistic treatment which is very effective. Once more we must say that each of these subjects would have gained immensely if they had been separately framed, or even if a gold mat had been interposed between them. It comes like a shock to the eye to find a mass of light in one picture apparently being carried on into the next, and any possible good that may arise to the exhibitor by having all his works together is terribly discounted by the incongruity just alluded to, and this even is intensified by choosing dresses containing so much ornamental detail, which does away with breadth. There is a considerable amount of retouching and brush work on the flesh, but we suppose this must be pardoned in the early stage of such promising direct photography.

W. F. Donkin (No. 302), *Among the Chamouni Aiguilles*.—Here we have pictures of the tops of the Swiss mountains, most beautifully photographed, exquisite in detail, and the most perfect rendering of snow that nothing but a perfect mastery over technical matters could achieve, the result being such a *facsimile* of nature, that we shiver whilst looking at them. The printing on Obernetter's chloride paper seems admirably adapted for negatives of this character.

THE APPARATUS.—III.

ONE feature of a decidedly unique character is to be found in the present Exhibition, in contradistinction to any other which has preceded it. When so much has been done in regard to appliances for effecting the proper exposure of plates either in the outdoor or indoor camera, why should the photographer be longer left without the means of determining with accuracy the duration of his exposures?

Horological science has lent itself to recording the feats on the race-course, the measured "reach" of the river, the flight of a cannon-ball, the duration of a cab drive, the determination of the distance of the luminous precursor of the thunderclap, and why should its services not be invoked in aid of the photographer? Messrs. Lezard & Son, of Holborn-viaduct, answer this question and supply this want, by placing in the Exhibition a case of photochronoscopes, which, being secured from being handled and tampered with by the numerous visitors, cannot by them be examined. But as, through the courtesy of the Messrs. Lezard, we have been placed in an exceptional position for inspecting the mechanism and ascertaining the merits of the photochronoscope, we give the reader the benefit of our examination. First of all, it is a watch of the stem-winding or keyless genus, having an appearance similar to that shown in the accompanying cut. As a mere watch it is finished with extreme care—that

care, in short, which is devoted to the best class of chronographs—lever escapement, jewelled actions, compensated for changes of temperature, and the other ecceteras expected in a high-class piece of delicate mechanism. There is a long, poised, steel hand, as fine as a hair, which reposes at zero (at the twelve o'clock chapter), but which, upon pressing the gold button at the top of the pendant, instantly starts into action and continues its rotation around the dial, marking fifths of a second. Every time it makes one revolution, and just as it passes the zero point, another hand on the smaller circle below, and which, like its nimble brother that radiates from the centre, has been standing dormant at its own zero, immediately makes a start, and records the fact that the first minute has passed, another and similar start taking place simultaneous with each rotation of the second's hand. When the event, whatever it may be, that necessitates this recording of time has transpired, the same button is again pressed, the consequence of which is that these recording hands are instantly arrested in their motion, and entirely disengaged from the watch movement, which goes on recording time as usual. The position of the recording hands being noted, once more is the button pressed, by which action the two recording hands immediately fly to their original positions at their respective zeros, where they remain until they are started into life by the pressure upon the button. To the photographer these instruments, which are but little over the price of a watch of equal excellence, cannot fail of being exceedingly useful in recording exposures, the duration of development, or, indeed, anything necessitating an accurate measurement of time. It will be readily understood that all this can be done without looking at the chronoscope, or even taking it out of the pocket.

Marion & Co. exhibit somewhat extensively. Two of their exhibits having only a short time since been specially noticed by us we shall pass them over. These are Leisk's patent Sky Shutter, designed to give a longer exposure to the foreground than to the sky, and concerning which we may here say that we recently received from Mr. Leisk some specimens of instantaneous work done in the Shetland Isles, where he is located, and which testify to the excellence of the

shutter. The other is the Marion Universal Ten per Cent. Developing Set, of which we then gave a verbal description, that we are now

able to supplement by a sketch showing an inside view of the neat box in which the various developing requirements are packed.

The Granitine Dishes exhibited by this firm, one of which is broken so as to show the nature of the ware. It is of such hard material as to be quite impermeable by chemicals.

The Collapsible Dark-room Lamp, which this firm exhibits, adds another to the now rather numerous lamps of this class. As shown by the cut, it is composed of a bellows of ruby cloth, inside of which

is a spiral spring which, when released, opens out the body in a Jack-in-the-box fashion. A night-light burner in a tin box forms the source of illumination. Two views are shown in the cut, one being the lamp folded up and the other when expanded.

Another Marion exhibit is Warwick Brooke's Lantern Camera. It is made for plates three and a quarter inches square, and is on the "detective" principle. The lens, shutter, focussing screen, and dark slide are all enclosed in a box-like form. C is a sliding hood, which is lifted when focussing, and takes the place of the focussing cloth. E is the milled head of a pinion, which racks the lens backward or forward for focussing. A and B form the finder, and are closed down when the camera is not in use. The novel feature, however, is the mode of opening and closing the shutter of dark slide inside the camera itself. This is illustrated by the smaller cut, in which D is the end of a brass bar running through the camera underneath the frame into which the dark slide fits, and attached to this bar is a tongue of metal, G. In the shutter of the dark slide is a groove into

which this tongue fits. When the dark slide is to be put in the place of the focussing screen, the head D is turned back until the tongue is in nearly a horizontal position, but leaning slightly backwards, when the back is placed in position, taking care that the tongue passes into the slab. When the shutter is to be opened the small catch H is turned through a small hole underneath the finder A, and the head D being then turned towards the front by which the shutter opens

downwards, and lies down on the bottom of the camera clear of the rays from the lens. After exposure D is turned back, and the catch H being secured the slide may be removed.

There is a large Rolling Press with a steel plate 30 x 20 inches, also exhibited by Messrs. Marion. The workmanship is excellent. A tank for fixing or alum bath completes the exhibit of this firm. It is made of lead with the grooving of granitine, and is encased in a wooden box having a tap at bottom to draw off the liquids. The grooving can be lifted in or out of the box at pleasure.

ECHOES FROM THE SOCIETIES.

SOME sensible suggestions were made at a recent meeting of the London and Provincial Society with regard to lens mounts for tourists' purposes. First, with regard to the weight of the mount, what but the expense and the unwillingness on the part of makers to leave a fixed groove prevents the suggested adoption of aluminium? Its difference in colour would scarcely, I should imagine, be allowed to militate against it, for it is at least as pleasing to the eye as many of the tints of lacquer that we meet with in foreign and home-made lenses, and something would certainly be gained in lightness.

But for my own part, I do not think the question of weight is the one of greatest importance. With the larger sizes of lens it, of course, becomes a serious matter, but taking lenses all round, it is, I think, the bulk rather than the weight of the mount that requires reform. Let me not be misunderstood. I mean unnecessary bulk—bulk that might be reduced by the exercise of a very little ingenuity. I know that a lens must possess a certain diameter, and its elements must be separated a certain distance, or, if a single lens, the stop must be placed at a given distance, and that, therefore, the dimensions of the mount are, in a manner of speaking, fixed. But turn from lens

mounts to cameras. I take 12×10 pictures and use an eighteen-inch focus lens, but I do not find it necessary to carry about with me a camera that resembles a Newfoundland dog-kennel, and that requires a clothes-prop to reach from the focussing glass to the front. The old folding-body camera has long since disappeared from everywhere except Stevens's sale room, and camera makers have gone in for portability. Why cannot our opticians follow the example?

Of course, I am speaking of lenses generally, for no one can complain of the unnecessary bulk of lenses of the type of the portable series of symmetricals; then, again, one or two opticians have made a step in the direction indicated, by reverting to the old conical form of mount, but this is to me an unsightly form and never likely to come into general favour; besides which, though it may be a little lighter, it takes up just as much packing room. Grubb introduced a form of mount for his single lenses, many years ago, which comes nearest to my idea of portability, in which two tubes slide one within the other, telescope fashion, and which combined with its portability the power of varying the distance of the stop from the lens. I have had several large single lenses remounted on this plan, and find it very useful.

Mr. A. Haddon called attention to another point that might easily be improved upon, namely, the position of the flange; this, however, is a question which will bear debating in connexion with the form of camera. If the lens could be attached to the camera so that no portion projected, certain advantages would accrue, to wit, the camera could be packed without unshipping the lens, and a single instantaneous shutter or sky shade would suffice for any number of lenses so fitted to the same camera. But on the other hand, the system of camera fronts would have to be altered, in order to permit the easy removal or change of lenses, as well as access to the diaphragms, while with some cameras I know the loss of available focal length would be a serious matter. I remember one such camera years ago, in which the lens was mounted inside, the revolving diaphragm plate being flush with the camera front, and covered by a hinged flap, which served for exposing as well as sky shade. It struck me as a very convenient arrangement.

Certainly the alteration of the position of the flange, as Mr. Haddon suggests, to somewhere near the diaphragm slot would be a great improvement in connexion with shutters and sky shades, but it would possess the countervailing disadvantages I have spoken of. But why not make the flange carry a short tube or jacket projecting into the camera, in which the body of the lens mount could slide? Why not, in fact, revert to the old "sliding tube" mount? It could be made quite as light as many of the rigid settings of the present day, and with a few other modifications far more portable.

That must have been a curious rainbow the photograph of which was exhibited and discussed at the same meeting. It is described as a "broad, shaded band, nearly straight, from top to bottom of the picture." The description certainly does not answer very closely to one's ordinary ideas of a rainbow; but I presume even rainbows have their vagaries, and those at the antipodes may differ in important respects from our own. Still it is rather "rough" on the artist to suggest that he had mistaken an intervening "rope or iron bar out of focus and near the camera" for a rainbow. This surpasses the feat of "seeing stars." But I should like to ask the gentlemen who "generally expressed" the rope-or-iron-bar opinion how *broad* the supposed representation of the rope would be if it were sharp enough or "fuzzy" enough to be taken for a rainbow, or how sharp it would be if its breadth were correct? In other words, is it possible to so photograph a rope or bar as to leave any doubt as to what it is?

The description speaks of the alleged rainbow as a "shaded" band, and certainly we should expect some such effect to be produced upon a sensitive film by a rainbow, but an intervening rope or bar would produce a *clear* band outlined against the sky. Finally, I scarcely think it possible that an intelligent individual could possibly make such an egregious blunder. That class of fool does not exist in nature, but is made in imagination.

Mr. Briginshaw's experience with similar bands upon paper negatives does not appear to have much connexion with rainbows, but it does suggest to me recollections of similar mysteries long unexplained, but extremely simple when the cause has been explained. A screw-hole crack or leak in the body of the camera, a loose piece of lining,

or a hundred similar accidents, have been known to puzzle an ordinarily "cute" individual for a long time. But a little mystery of my own is worth relating on account of a most singular coincidence that gave a supernatural tinge to the whole affair. In the old stereoscopic days I had undertaken to photograph the grave of a deceased friend in a suburban cemetery, and proceeded to carry out my promise, using my then favourite stereoscopic camera, one of $7\frac{1}{2} \times 4\frac{1}{2}$ dimensions. Upon developing the plate, all was right except a light blur immediately over the headstone and against a dark shrub in the background. A few days later I repeated the trial, making on this occasion two exposures, and my astonishment may be imagined when, on development, I found both the new pictures showed the same mark. The following day I paid another visit to the cemetery, taking with me a print from one of my negatives to compare with the surroundings, in the hope that I might find some explanation, possibly something to cause a reflection on to that part of the plate. The obtrusive mark, I should say, appeared only in one half of the negative, and always the same half. I examined the camera front carefully for holes, but as the phenomenon only appeared in the case of that subject, I was compelled to connect it with the subject.

On that visit I exposed six plates for purposes of experiment, and I cannot say I was surprised to find they all gave the same result. But I now began to fancy I could trace a resemblance between the ghostly blur and the top of an ornamental headstone, and, confident I had found a clue, I hurried off to the cemetery first thing next morning to make another examination, for I had now got thoroughly interested in the matter. After an inspection of the surroundings, sure enough I found, away to the right and behind the gravestone I had been taking, one the outline of which corresponded with my ghost, but I could conceive or invent no explanation of its presence in my picture, for it was far out of the field of view. I strolled up to close quarters to make a more minute comparison, when I was rather startled to find that the name on the stone *was the same as on the one I was photographing*, and a not very common name either. I am not superstitious, but I began to feel that I wished the defunct stranger had chosen some other agent than myself to bring about his introduction to possible relatives in his own immediate neighbourhood. I came to the conclusion I could not solve the mystery, made the best I could of the negatives I had taken, and in time forgot the matter except when I came across a print from my "ghost negative," as it came to be called.

Months after the explanation came. I was photographing a view with the same camera, and outlined against some dark foliage in one half of the picture I found a pond or piece of water that was located some yards to the right of the picture I was taking. My thoughts went back to the "ghost," and I commenced again to investigate, but with something more tangible to go upon, and the following was the result:—I had rejected the flexible division in the centre of my camera, and had substituted, for convenience sake in removing when I wished to take a single picture, a short rigid division of blackened metal fitting into a slot in the back frame of the camera. The lenses employed in taking my grave were of specially long focus for stereo work, employed in this instance because I had only one favourable point of view at some distance from the object. Using my ordinary lenses of $4\frac{1}{2} \times 6$ inches focus my short rigid division was all right, but when the camera was sufficiently extended for use with the longer lenses the marginal rays from the two lenses crossed in *front* of the division, and so reached the opposite compartments or divisions of the plate. In most ordinary subjects the double image thus formed was practically undetectable, but with a light object from one lens falling on a dark one from the other the effect was very noticeable, and these had been my conditions with the "ghost."

How to Manipulate the Camera in a Military Manner is a good sounding title, but after reading the article I want to know why Mr. Forrest didn't shorten it by calling it "How to Photograph like a Militiaman?"—it is just as *apropos*. Why "military" any more than "sporting"? Guns are used by sportsmen as well as military men. But I suppose Mr. Forrest, as a veteran and one who has to set an example to younger men, felt it would be wrong to lead them astray by telling them how to use the camera in a "sporting" way, the word having a strong flavour of the betting ring about it. However, whatever the manner of using may be, the weapon is far from

new, as I saw a similar one—only that it was a “repeater”—in Messrs. Sands & Hunter's shop eight or nine years ago, and was informed that it was made for one of the Arctic Exploration Expeditions.

I see it mentioned by Mr. S. G. B. Wollaston that he had failed in obtaining sufficient density in the high lights when developing plates four years after exposure, implying that the lapse of time had something to do with the effect. It would be interesting to investigate this question in a serious and systematic manner, because the result, if really attributable to the cause implied, is the very reverse of what we might expect and what actually occurs with dry collodion plates. If the invisible image does suffer from time, naturally we should anticipate that the feeblest portions—the least exposed—would suffer first, but in Mr. Wollaston's case it is the reverse. Is it not possible that unconscious change in developing habits may have something to do with it? I have found myself that after developing a number of plates of a certain character—say such as give density easily—that I experience a difficulty in manipulating a different sort, with which, however, I may be perfectly familiar. Perhaps the four-year-old plates were of the less easily intensified kind. MONITOR.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

It may be best to confine ourselves for the moment to the treatment of an enlargement in *monochrome* before launching into the more difficult line of pure water-colour painting. The subject I would suggest is a half-length figure on a *carbon* basis. I select this because the majority of enlargements nowadays are done in this style, owing to its permanency. It does not matter as to whether the subject be male or female, as we will treat all the prominent points that can suggest themselves in either.

It is only natural to suppose that the head should receive our first and best attention. On the successful treatment of it will depend the final success of our work. It is impossible, therefore, to bestow too much attention while working upon this portion of our picture in order to reproduce *nature* as closely as our degree of skill will allow.

One of the most extraordinary things in nature is the human head. It is really most marvellous (when we think of it) the endless varieties of form and expression which it is capable of representing. Then the face is only one half of the head, and yet an unceasing variety is observable in every one we may meet in a day's journey through life. Of course the face, or front of the head, is the more important part, yet, on close study, there will be found to be a vast amount of distinct individuality in the back view of the head. Now this individuality is a matter of the greatest importance to all portraits, and should arrest our first thoughts on beginning work. To preserve it carefully is absolutely essential to success. We may almost say there are no two faces alike. I think we may unhesitatingly say *no two heads* are alike. As a result of a fairly extended experience, I have found where there has been an almost phenomenal likeness between two faces, a moment's study of the formation of the head, as an entire, will disclose the most observable differences, which, on further consideration, will so impress you that you will wonder that you should ever have considered the people so much alike. Such is individuality, and you can easily see, therefore, the necessity for its due preserverance. Our treatment, therefore, should vary according to the subject we are about working upon. It must naturally suggest itself as very foolish to treat an old man's or old lady's head as you would a baby's or little girl's, nevertheless there are many who do so. Of course such treatment is only of the wax-doll school, which means simply “fining up,” or working out, the blemishes, producing generally a smooth surface, but leaving the whole, in result, devoid of character, and, as a necessary consequence, lifeless and uninteresting.

We will start now with the *forehead*. Breadth is always desirable in this feature, hence we should keep our touches as broad and bold as we can, and when they have a marked tendency in any direction, they should incline to the horizontal, as such treatment tends to give massiveness to the brow. If we let them incline to the perpendicular, narrowness will be the result. The modelling or any half tone denoting *shape* in the forehead should be most carefully preserved, as

the intellect of the original may be considerably represented by it. There is nothing, to my mind, which adds so much to a portrait as *shape*. Its absence in the portrait of a man of brains is absolutely fatal. When using the colour do not take up too much at a time in the brush, and do not let it be too liquid either. Keep it delicate in tone, and arrive at depth of colour rather by *repeating* than by *strength* in the first application. The result will be softer, and the effect less likely to be exaggerated.

In most carbon prints a grey tone will be observed to pervade the entire picture, thus necessitating the putting in of all the high lights. For the securing of these latter we should use an eraser. With this we proceed, after having put a point on it, to pick out the lights wherever they may appear necessary. The forehead, for example, over the eyebrows, down the nose; the eye, too, may require clearing and the strength of the *crow's-feet* may require reducing; the cheek-bone, too, also the chin and neck, and so on. It is a great advantage that in “working up” on carbon base all offensive shadows can be lightened so as to harmonise with the general tone of the picture. Were it not for this, there are many pictures which would be almost, if not quite, impossible to “work up,” as from their *hardness* it would be useless trying to arrive at softness or harmony, which, of course, are essential to a good result.

The eye will be the next feature, as we work down the head; but I think, personally, that although a certain amount should be done to it *now*, it should *not* be finished until the rest of the portrait is complete. When this is so, it will be found that the judicious adding of perhaps a little force or other effect may crown the success of the picture. In working this feature constant reference to the duplicate or guide should be made, which should to a great extent determine the depth of tone that you can work to. The pupil will, of course, want strengthening, and this must be accomplished with a few sure but delicate touches and keeping strictly to the form. The high lights, as a rule, in enlargements become very considerably exaggerated, and will therefore demand our attention; should the light therein not be sufficient, rub away the film with the eraser until a white surface comes through. If, however, you think a still higher light would improve the portrait after you have worked the eye with the photographic colour to its desired condition, a little Chinese white (Winsor & Newton's) upon the point of the brush may be advantageously used. Great care should be taken to avoid a *glare*, as it would deprive the eye of all semblance to nature. I have advised the use of a special Chinese white; I have lately made some experiments with several others, and have come to the conclusion that Winsor & Newton's is the best and most reliable. There is also a *reflected* light opposite the high light; care must be taken to keep them in proper relation or balance one to the other. The iris will in most cases require defining somewhat; this should be done by very faintly outlining it. Do not use a heavy colour for this, but rather arrive at the requisite depth by repetition of touch. One can spoil a big picture in a few moments, but even a small one must be worked slowly if destined to become a good or beautiful work.

A few faint touches, carefully placed to indicate the lashes of the upper lid, will do much to enhance the beauty of the eye. These touches must, however, be placed with great care; they must not be *wiry*, nor such as might give the idea of trying to represent each individual hair, but rather to express their presence by a soft shadow. These latter remarks apply equally to the treatment of the eyebrows, the strength of which may be determined by the guide. The definition of the eyebrows, and often the markings of the upper lid, will require carrying out; that is, they seem to terminate harshly and abruptly, and will therefore require our help to give them their natural appearance. There are many causes for these defects and cannot always be avoided. By reference to the guide, however, there will not be much trouble in setting them right. Of course we desire a certain degree of finish as well as effect in all our pictures, but we should be ever mindful that in portraiture the beginning and end of everything is *likeness*. The lines lying underneath the lower lid will be invariably found to require softening. This process of softening must never be carried too far, or the expression of the eye will be greatly diminished in force, if not altogether destroyed. It would be well, therefore, to soften these objectionable lines with an eraser and then work up the whole to a pleasing and satisfactory extent.

* Continued from page 647.

The nose will be our next trouble. It is a prominent feature, and one that has much to do with the success of a picture as a portrait. Too much care cannot be expended on securing the high light. Faultiness in this regard will be fatal to the portrait. The slightest deviation from its proper place or its correct form may entirely alter the character of the feature. The cavities of the nostrils will sometimes require a few dark touches to give them sufficient vigour, but on no account must they be made too dark, or have the appearance of being too plainly outlined. The nostril itself should be very delicately rounded and the cast shadow strengthened, but never made *too* dark. In all this work we should strive to make the whole resemble as nearly as possible the appearance of a good photograph, neither lines or touches plainly visible, but all blended softly together in a harmonious whole.

We next come to the mouth. A great deal depends upon the successful treatment of this important feature. Its importance varies considerably; in some it is of but slight importance, but with others it is all important. It will be well to secure a high light, with the eraser, on the lower lip; then the diffused and shapeless light there will have to be reduced into proper dimensions by careful work. If there are any harsh lights or offensive markings of any kind on the lips, they being the result of the skin being dry or cracked, they should all be softened away. Many times, but not always, the markings and separations of the lips will require a little touch to give them sufficient force. The shadows or markings running from the corners of the mouth will often offer a favourable chance for a little skilful treatment. We must always try, as much as possible, to raise the muscles of the face, and must, therefore, try to accentuate the upward curves, and soften, if we cannot safely obliterate, the downward ones. Near the centre of the upper lip there is generally a delicate light—sometimes it is very faint, indeed—but should always be preserved, as it is just sufficient to give life and expression to the entire mouth. The shadow formed under the lower lip should be softened and made to melt into the chin.

The lines running from the side of the nose in a downward direction are generally rather strongly marked; they must, therefore, be duly softened, and, when necessary, the muscle raised. In doing this, consult your guide, lest you might be tempted to go too far. In the majority of cases, it is not *altering* that is demanded, but simply *softening*.

The treatment of the frontal depression at the root of the nose should always receive due care. The furrows may be very considerably softened, but it may be ruin to take them away. These furrows are more usual in gentlemen's portraits, and will generally bear softening. They seldom enhance the beauty of the picture, so there is little danger of getting into trouble, even if you soften them too much. The frontal eminences above the eyebrows merit careful treatment, and care should be taken that the high lights on the forehead should not approach too high or near the hair. The cheek-bone should never be left too strongly marked, but worked into the cheek, the highest point of its light being under the eye.

Some look upon the chin as an easy matter, but care should be bestowed upon it; it is easily treated, but may be very easily spoiled. There is much character in this feature, and it should be preserved where necessary. Feebleness or strength of character may be greatly represented by this feature.

REDMOND BARRETT.

(To be continued.)

ON THINGS IN GENERAL.

FROM all appearances, photographic work with the microscope—how I do hate that cacophonous title “photo-micrography”—is likely to be well practised during the forthcoming winter, and very useful and very beautiful are some of the results capable of being achieved in this direction. It is surprising how much good work of this kind can be done with the slightest of added apparatus; but so much depends upon the possession of a due admixture of photographic and microscopic experience in those attempting this class of photographic work. A man may be an excellent photographer, and yet have not the slightest idea what, or how, he ought to see when certain objects are put before him; and as to being able to exhibit anything definite at all when high powers and test-

objects are in question, it would be simply impossible with a man inexperienced in microscopic manipulation. Hence, to expect that such an one, expert though he might be in photography, could sit down to a microscope, and, with or without extra apparatus, produce a first-class negative, or even a presentable one, of a fairly difficult object, for the scrutiny of microscopists, would be simply idle. To produce really important work this way, either two workers, each knowing his own department well, must combine their forces, or, single-handed, the photo-micrographist must be equally clever with camera and microscope. Now I will give one little piece of valuable advice to those who know a little of the latter and much of the former, and desire to combine their knowledge and endeavour to compete with old hands at the work. It is this: Whatever (mounted) object is attempted to be enlarged let the utmost pains be taken to see that the particular slide utilised be the very best of its sort it is possible to obtain. It is not enough to go to a first-rate mounter or dealer and pay the ordinary price for the average slide; a number must be carefully selected and compared, and one chosen containing the characteristic points in the highest perfection. One man may spend a whole week, for example, in trying to get the best possible negative of such a simple object as a blowfly's tongue, and yet egregiously fail in comparison with another who possesses a choice slide of the same subject, and takes, perhaps, a single negative only from it. I note that at one of the Society's meetings the Chairman is reported to have stated that there were occasions when absolute coincidence between the position of the front of the focussing screen and the sensitive surface were essential. There can be no doubt that such coincidence is desirable; but he would be a clever photographer who would be able to detect which of two negatives was taken at the so-called correct focus, and which at a sixteenth or even an eighth of an inch on one or the other side of it, when the scale of enlargement is large. Polemical matter apart, there can be no doubt as to the high quality of this work shown at the Exhibition in Pall Mall.

If any particular remark about the present set of pictures at Pall Mall may be here made, it is that they are striking from the good average of quality shown. There are, indeed, none of those glaring atrocities which never should have been hung, but which have disfigured previous Exhibitions, and almost the hangers.

The question of large heads direct *versus* enlarged, is pointedly raised by this present show. There are some direct heads, notably Müller's prize picture, which exhibit artistic feeling and veracious delineation in a high degree, but again there are large heads which are simply hideous vulgarities and examples of what to avoid. No doubt the larger the cameras and the more expensive the lenses the more the professional photographer is likely to handicap the average amateur in any competition the former may imagine himself to be subjected to, but that is not the correct standpoint to view the matter from. Direct life-size heads must be viewed first by results, and secondly by facility in obtaining the results. Granted two processes of greatly varying simplicity in their operation, and producing absolutely equal results, it is incontestable that the palm should be awarded to the least difficult. So it is with the subject under discussion. So far direct pictures are a long way the best of the two, but that is not to say that such will always be the case. I hold that the man who can invent a process of enlarging or perfect his own practice of ordinary modes in such a way as to enable him to produce pictures in which a shadow of difference in definition is the only point that distinguishes them from direct photographs is for more worthy of praise than the one who overcomes other difficulties, and takes beautiful photographs with a big camera.

Mr. Lyonel Clark, in his paper on the selection of lenses, advised his hearers that it was important that they should take great care of their lenses. A very useful and still needed piece of advice. It is most remarkable how careless some photographers are of valuable lenses. I have come across men who, as a simple matter-of-course, would slip an uncapped small lens in their pocket and travel about all day without protecting it, oblivious of dust, scratches, abrasions of the lacquer, and other possible and probable injuries it might sustain.

Mr. Dunmore's remarks upon the sizes of prints, in his article upon print trimming, are well worthy of perusal. “*Quantitas non qualitas* is a bad motto,” he says, and, further, “many really good pictures are damaged by this anxiety to have as much as possible of the subject

as can be made out of the negative. I advise that all the worthless parts of the print should be ruthlessly trimmed off, as it is better to sacrifice part than the whole." True, Mr. Dunmore. But it is too sadly true, also, that, so far as regards the pictures, the popular views, sold to the public, this advice is useless. Such pictures were sold by the yard: get a certain number of square inches for a certain small price, and the dealers would not be able to stand competition if they did not give their full quantum of picture, artistic or not. Mr. Adcock's remarks at the Camera Club on the subject of the most suitable proportions for dry plates have a somewhat similar bearing, and as some of the most popular selling sizes would fall in better with oblong plates, perhaps a consideration of the fact may lead the plate makers to take sizes into their consideration.

Mr. Palmer's suggestion that dry-plate makers should be made responsible for their sins may ultimately be realised: but I am afraid that the time is far distant when this will happen, they still form a rather close corporation, and sit upon the poor photographer as they like. It is not to be denied they are subject to all sorts of claims and complaints which are worse than groundless, but, granting that, there seems to be an opinion abroad among them to the effect that "we do our best, and if the plates do happen to be defective you really cannot blame us." It is a very unlikely thing, however, that a Belgian maker should be rendered amenable to an action for damages as proposed by Mr. Palmer.

A correspondent asks about the capabilities of using a speaking-tube a hundred feet long; he may rest perfectly satisfied of being quite safe in using one much longer than that. I have seen one in a photographer's premises a greater length than a hundred feet; it was, however, objected to by the lady in the reception room. Her objections were not founded on its inefficiency, but rather its too great efficiency; for, directly after it was put up, this lady, who was a Blue Ribbonite, said she did not like it because she could distinctly smell drink whenever the operator, who, though steady, was not of that persuasion, spoke through the tube.

WRITING AND DRAWING ON GLASS.

V.

Converting a Drawing on Clear Glass into a Negative.—The process of etching a negative on an opaque black ground is one that demands of the artist special skill, of a similar nature to that possessed by retouchers of portrait negatives. The deepest shadows of the design must be represented on the negative by an approach to clear glass, while the high lights are produced by simply leaving the film with its original opacity. This constitutes a serious drawback to the etching system, as it requires a special training to ensure the highest class of work, and most artists would prefer to make a line drawing on paper first, and to produce the negative from that sketch by the use of the camera. Photographing a pen-and-ink sketch on paper, however, is rarely so successful as to result in a print indistinguishable from the original; there is generally a slight haze over the print, and the finer lines are sometimes lost altogether in the reproduction.

The copying of maps, &c., by photography is consequently entrusted to those who make a speciality of such work, as the methods employed in portrait studios do not usually yield the class of negatives required for line subjects, the characteristics of which should be perfect opacity of the ground, and complete transparency of the lines.

While coating some glasses with an opaque film in the manner described in the latter end of the preceding chapter (see page 662), in which a layer of gum dammar is used to absorb the carbon deposited thereon by a smoky lamp, I found that a simple modification of the process enabled better results to be obtained, and did away with the difficulty previously referred to of etching on a black ground. I have ventured to apply the term "novel" to this method, on the strength of not having hitherto seen anything of the kind published. The plan is a very simple one, however, and I am aware that there is nothing new under the sun; but if not altogether original, it may be at any rate worth describing. The manipulation is easy, and the result is a negative possessing the desired qualities of clear lines on an opaque ground, without any tendency for the finest lines to become obliterated. It is, in short, the conversion of a

pen-and-ink sketch on glass into a negative having a decidedly "permanent" nature, its opacity being due to carbon, the king of black pigments.

It seems well within the bounds of possibility that some such method as this, conjoined with photography, may enable a new system of producing positive prints in "permanent carbon" to be worked, in which the hand-drawn sketch shall be replaced with one due to the actinism of light.

Here is the process as I have hitherto practised it:—A clean glass, of quarter or half-plate size, is coated with a varnish composed of gum dammar dissolved in ether. This is applied without heat in the first instance, but as soon as the ether has evaporated, warmth may be used to complete the drying. If the film does not absorb sufficient carbon when held in the lamp flame to produce opacity, it indicates that the varnish is too weak, and that more gum must be added—this adjustment is by no means a difficult matter. As soon as the solution is of the right strength, it may be filtered to free it from small particles of dust. When the dammar film is quite dry on the glass, we must not allow any dirt to settle on it, and should avoid touching the surface as carefully as if we were working the wet collodion process. Every grain of dust and every impression of the finger will cause corresponding defects in the negative, and will be faithfully represented as pinholes and the like on the opaque ground. This delicacy of the system constitutes at once its weakness and its strength—the latter, because we owe to it the certainty of the finest strokes of a pen being fully indicated in the negative.

A retouching desk may be used to support the glass at an angle of 45°, and a sheet of white paper placed horizontally behind it will enable us to see the progress of the work.

If a piece of ground or flashed opal glass is placed behind and in contact with the prepared plate, we shall be able to sketch away with as much freedom as if we were working on paper. The ink we are to use may be any of those described in the preceding article of this series, but preference can be given to the one prepared with lamp-black and sugar. The sugar should on no account be omitted, as it is the acting agent in the subsequent process of smoking the plate; it prevents the dammar from absorbing the soot in those places where it lies in the form of pen strokes. The sugar alone would serve as the ink if dissolved in water; but as it is necessary for the artist to see his work as it progresses, a little lampblack is added to the syrup to give it the required depth of colour.

The drawing should be reversed on the glass; what is intended to be on the right side of the subsequent print should be drawn on the left side of the plate. This constitutes a difficulty in the case of manuscript, such as a written letter or circular, few people being adepts in the art of writing backwards. So we may write on note paper in the first place with our special ink, to which a very little treacle or glycerine is added to leave the inscription in a slightly tacky condition. This paper is then pressed on the dammar film, so that a portion of the syrupy ink is transferred in a reversed form to the glass. It does not matter how little of the ink adheres so long as there is some trace of it left on the film.

Having completed our sketch or writing on the prepared glass, we may next proceed with the smoking—but not with tobacco. The simplest way is to use a benzoline sponge lamp, which answers very well for small work. For glasses larger than the half-plate size, however, there would be considerable risk of fracture if they were held in a small flame—for such plates a special apparatus may be made. We require a current of hot air, mixed largely with smoke and vapour of benzoline; this might be produced by fixing a metal tube or chimney over the lamp, with an arrangement for cutting off the draught similar to a Bunsen burner. The wick being well turned up we should have the soot rising mainly in the centre of the tube, hence diaphragms or deflectors may be inserted above the flame, so as to divide the smoke and mix it with the surrounding air as it ascends the chimney.

If the vapour of benzoline is insufficient in quantity the soot will not be absorbed by the film, but will settle on it in the loose dry condition it assumes on plain glass. The surface of the film, when smoked to opacity, should be bright, and it should bear being dusted with a cloth. In those places where the sugar lies in the form of ink lines, the film is protected from the soot, which does not sink in, and

can therefore be wiped off with a cloth afterwards, leaving the lines visible on the darker ground.

The last operation, which may be called the development, is to immerse the plate in cold water for a few minutes. This dissolves the sugary ink, and by the aid of gentle friction with a brush, or the finger end, every trace of it can be removed, carrying away, of course, the soot which had settled thereon. The lines will now be perfectly clear and transparent, while the ground, being unaffected by the washing process, remains as opaque as before. Extremely fine lines may require a longer soaking than the thicker lines, but I have never found them to become blocked up with the lampblack.

After the development, the plate may be dried; it scarcely needs varnishing, as the dammar film is a varnish in itself. Should any additional protection be desired, the plate might be dipped in a weak gelatine solution, and, when this sizing is dry, coated with shellac varnish.

The process can be applied to various uses besides the one we have been considering; coloured designs can be "blackened in" as lantern slides with an accuracy that handwork cannot compare with, while grey and shaded backgrounds can be likewise produced.

ALBERT WM. SCOTT.

ON THE IMPROVEMENT OF OVER-EXPOSED NEGATIVES.

[A Communication to the Photographic Club.]

ACCORDING to promise, I will now tell you of the very simple plan I have adopted for rescuing weak, over-exposed negatives from the waste—a process so simple that I hesitated to say anything about it until I had made inquiries if this or any other plan had been successfully adopted for the purpose, or if, on the contrary, the greater portion of such defective negatives were considered irremediable failures and looked upon as worthless, from a printer's point of view, at any rate. The only way of getting any passable result from a thin, over-exposed plate (if it was considered worth the trouble) was by making a transparency and copying that, a roundabout process, you must admit, if the original negative can be so altered and improved as to do away with the necessity of reproduction.

The process I am about to recommend is free from difficulty, being little else than already well-known processes somewhat differently applied; it is in fact so simple that one is forcibly reminded of the incident of Columbus and the egg. Negatives which by this plan can be satisfactorily treated are *over-exposed* ones, of which a goodly number are, no doubt, in existence, but a plate *chemically fogged*, or one to which the light has had access *before* exposure, would probably not be amenable to this treatment; however, I have not made any experiments to verify the opinion. Some improvement possibly might be made, but as to making a perfect negative of such, it is extremely doubtful, whereas in the case of over exposure it is an undoubted panacea.

If an ordinary over-exposed negative is intensified by any known method, it *may* be somewhat improved, but, at the same time, the deposit in the shadows will gain in strength, as well as the lights, and the result will be a very dense, slow-printing negative, and one from which perfect results are unlikely to be obtained, although somewhat better than the original before intensification. The effect of over exposure is, we all know, to gradually obliterate the image until a point is reached when a reversal of it takes place and the negative becomes a positive. It must be clearly understood I refer to the ordinary methods of development. In the development of a properly exposed plate, the reduction is first on the outer surface of the film, into which it gradually extends until the most reduced parts are visible at the back of the plate. If the development is continued for too long a time the portions much less acted upon by the light begin to show at the back also, and the resulting negative is too dense; this, however, depends in a measure on the thickness of the film. A proper development is one that gives sufficient density to the high lights without blocking up the shadows. The negative image in the gelatine film may be looked upon as a series of images in different strata overlying each other, the strongest lights penetrating lowest and deepest, the deepest shadows passing scarcely beyond the surface, and sometimes not so much as appearing to affect it at all. It therefore seems that the thickest films most rich in silver salt should give the strongest image with ordinary development; on the contrary, with a thin, poor film it is difficult to get a good, rich printing image with clear shadows, and the chances of blurring and halation are greatly increased.

Given, then, an average good plate and over exposure, my idea

is to remove the outer layers sufficiently deep to leave clear glass in the *deepest* shadows, and then intensify the remainder. The way of setting about it, and which I have found answers perfectly, is the following. Other plans, doubtless, might be adopted to effect the same result, but as the one I tried fully answered my expectations, I thought further search unnecessary. The appliances required are few and simple, being limited to a white dish and a lamp. A solution of five grains of hyposulphite of soda to the ounce of water in one receptacle, and a solution of the same strength of ferricyanide or red prussiate of potash in another, with plenty of clean water at hand, being ready, the negative to be operated on must first be carefully examined, and some part that we know should be nearly, if not quite, clear glass specially noted, as this will form the key to the reduction. The negative is now laid face uppermost in the white dish, the lamp being arranged to throw as good a light as possible on it. The hypo and ferricyanide solutions being mixed together are poured over it, the dish being gently rocked, and the process of reduction, which soon sets in, intently watched, and as soon as the portions noted at the beginning as the deepest shadows permit the white of the dish to shine through, remove the negative and immediately well wash it. It is best to stop a little short of the full effect desired, for the action will continue a little after removal from the solutions. A bit of white paper pressed against the back of the negative will aid in deciding if the reduction has been carried far enough; if not, it may be redipped until it has. Now well wash. Soak for an hour in several changes of water, and dry now if on a thorough examination the reduction has been considered right. Intensification may be proceeded with, according to Dr. Monckhoven's plan, with bichloride of mercury and cyanide of silver modified in this manner. The bichloride of mercury solution should be a cold, saturated solution at a temperature of 60°; to one ounce of this add twenty grains of bromide of potassium. Let the negative, now very ghostlike, remain in this until it is quite whitened throughout; remove and well wash, and then place it in the cyanide of silver solution, of double the usual strength, until the white image is replaced by a black one. Wash well, and the process is completed. If it is found insufficiently intensified, this process may be repeated, washing and drying between the repetitions. You will see there is nothing new in the use of either Mr. Howard Farmer's reducing or Monckhoven's intensifying plans, the novelty rests in the application of them.

There are, undoubtedly, thousands of negatives thrown aside as useless on account of over exposure, that will afford the useful and pleasant occupation of metamorphosing into good ones during the long evenings of the coming winter—it being essentially a process suited for artificial light—and the pleasure of seeing a negative given up as hopeless bloom into one without reproach may fairly divide the honours with making transparencies for microscopes or lantern slides, which are about the only photographic operations the majority of photographers can satisfactorily pursue during the gloomy winter season.

EDWARD DUNMORE.

SOME NOTES ON THE HISTORY OF THE DISCOVERY OF THE GELATINO-BROMIDE PROCESS.*

AND now we come to the work of the practical inventor of the gelatino-bromide of silver process—Dr. Richard Leach Maddox.† I should like to ask the Editor to reprint the original communication which laid the foundation of all our work of to-day, for the back volumes of THE BRITISH JOURNAL OF PHOTOGRAPHY are scarce, and complete sets fetch by auction between twenty and thirty guineas!

"AN EXPERIMENT WITH GELATINO-BROMIDE.‡

"The collodio-bromide processes have for some time held a considerable place in the pages of THE BRITISH JOURNAL OF PHOTOGRAPHY, and obtained such a prominent chance of being eventually the process of the day in the dry way, that a few remarks upon the application of another medium may perhaps not be uninteresting to the readers of the JOURNAL, though little more can be stated than the result of somewhat careless experiments tried at first on an exceedingly dull afternoon. It is not for a moment supposed to be new, for the chances of novelty in photography are small, seeing the legion of ardent workers and the ground already trodden by its devotees, so that for outsiders little remains except to take the result of labours so industriously and largely circulated through these pages and be thankful.

"Gelatine, which forms the medium of so many printing processes, and which, doubtless, is yet to form the base of many more, was tried in the place of collodion in this manner:—Thirty grains of Nelson's gelatine

* Continued from page 665.

† Born at Bath, August 4, 1816. May he live to be as old as Chevreul!

‡ From THE BRITISH JOURNAL OF PHOTOGRAPHY, September 8, 1871.

were washed in cold water, then left to swell for several hours, when all the water was poured off and the gelatine set in a wide-mouthed bottle, with the addition of four drachms of pure water and two small drops of *aqua regia*, and then placed in a basin of hot water for solution. Eight grains of bromide of cadmium dissolved in half a drachm of pure water were now added, and the solution stirred gently; fifteen grains of nitrate of silver were next dissolved in half a drachm of water in a test-tube and the whole taken into the dark room, when the latter was added to the former slowly, stirring the mixture the whole time. This gave a fine milky emulsion, and was left for a little while to settle. A few plates of glass well cleaned were next levelled on a metal plate put over a small lamp; they were, when fully warmed, coated by the emulsion spread to the edges by a glass rod, then returned to their places and left to dry. When dry, the plates had a thin, opalescent appearance, and the deposit of bromide seemed to be very evenly spread in the substance of the substratum.

"These plates were printed from in succession from different negatives, one of which had been taken years since on albumen with ox-gall and diluted phosphoric acid, sensitised in an acid nitrate bath, and developed with pyrogallio acid, furnishing a beautiful warm brown tint.

"The exposure varied from the first plate thirty seconds to a minute and a half, as the light was very poor. No vestige of an outline appeared on removal from the printing frame. The plates were dipped in water to wet the surface, and over them was poured a plain solution of pyrogallio acid, four grains to the ounce of water. Soon a faint but clear image was seen, which gradually intensified up to a certain point, then browned all over; hence the development in the others was stopped at an early stage, the plate washed and the development continued with fresh pyro, with one drop of a ten-grain solution of nitrate of silver, then rewashed and cleared by a solution of hyposulphite of soda.

"The resulting prints were very delicate in detail, of a colour varying between a bistre and olive tint, and after washing dried with a brilliant surface. The colour of the print varied greatly, according to the exposure. From the colour and delicacy it struck me that with care to strain the gelatine or use only the clearest portion, such a process might be utilised for transparencies for the lantern, and the sensitive plates be readily prepared.

"Some plates were fumed with ammonia; these fogged under the pyro solution. The proportions set down were only taken at random, and are certainly not as sensitive as might be procured under trials. The remaining emulsion was left shut up in a box in the dark room and tried on the third day after preparation; but the sensibility had, it seems, greatly diminished, though the emulsion, when rendered fluid by gently warming, appeared creamy and the bromide thoroughly suspended. Some of this was now applied to some pieces of paper by means of a glass rod, and hung up to surface dry, then dried fully on the warmed level plate and treated as sensitised paper.

"One kind of paper that evidently was largely adulterated by some earthy base dried without any brilliancy, but gave, under exposure of a negative for thirty seconds, very nicely-toned prints when developed with a weak solution of pyro, having very much the look of a neutral-toned carbon print without any glaze, and I think might be rendered useful on plain paper. Some old albumenised paper of Marion's was tried, the emulsion being poured both on the albumen side and, in other pieces, on the plain side, but the salting evidently greatly interfered, the resulting prints being dirty-looking and greyed all over.

"These papers, fumed with ammonia, turned grey under development. They printed very slowly, even in strong sunlight, and were none of them left long enough to develop into a full print. After washing they were cleared by weak hypo solution. It is very possible the iron developer may be employed for the glass prints, provided the usual acidification does not render the gelatine soft under development.

"The slowness may depend in part on the proportions of bromide and nitrate not being correctly balanced, especially as the ordinary, not the anhydrous, bromide was used, and on the quantities being too small for the proportion of gelatine. Whether the plate would be more sensitive if used when only surface dry is a question of experiment; also, whether other bromides than the one tried may not prove more advantageous in the presence of the neutral salt resulting from the decomposition, or the omission or decrease of the quantity of *aqua regia*. Very probably, also, the development by gallic acid and acetate of lead developer may furnish better results than the plain pyro.

"As there will be no chance of my being able to continue these experiments, they are placed in their crude state before the readers of the JOURNAL, and may eventually receive correction and improvement under abler hands. So far as can be judged, the process seems quite worth more carefully conducted experiments, and, if found advantageous, adds another handle to the photographer's wheel. R. L. MADDOX, M.D."

The editorial remarks (in the same number) were as follows, and show a full appreciation of the new method. It must be understood that Dr. Maddox's communication was accompanied by specimens of his results.

"The interesting experiments of Dr. R. L. Maddox on gelatino-bromide emulsion—the notes of which will be found in another column—will probably have the effect of turning attention to a comparatively neglected field for experiment with emulsion processes. Dr. Maddox uses a

gelatine collodion—if we may use the term—and in this suspends the finely-divided bromide of silver precipitate. The emulsion likewise contained an excess of nitrate of silver and a small proportion of *aqua regia*—the latter not being present, however in sufficient quantity to reduce the nitrate of silver very near to the neutral point. Plates coated with the emulsion, and the film dried, printed under a negative with tolerable rapidity, the image being invisible at first, but well brought out by plain pyrogallio acid. The necessary density was obtained by treatment with fresh pyrogallio acid, and the addition of a little nitrate of silver solution. Dr. Maddox used all his films in the dry condition, the gelatine in this case acting the part of the organifier or preservative, and sealing up the sensitive silver compound most effectually—in fact, more completely than ordinary collodion. We thus appear to have another 'driest-of-the-dry processes' at our disposal, capable of yielding plates superior in sensitiveness to those afforded by the different mode of operating referred to in another place. We venture to hope that some of our readers who may have time for experimenting in this direction will take up the line of work which Dr. Maddox has now relinquished, and, starting with the object of combining organifier and supporting layer in one, be able to work out a process even more convenient than any we possess already. Saving of time and labour must always be considered in photographic work, and the use of the gelatine layer gives some promise of success in the production of sensitive plates without the washing and preservative coating at present necessary."

W. JEROME HARRISON, F.G.S.
(To be continued.)

THIRD ANNUAL INTERNATIONAL AMATEUR PHOTOGRAPHIC EXHIBITION, 1887.

AWARDS.

Class I.—10l., Harry Tolley; Silver Medal, Surgeon-Major Mantell; Bronze Medal, George Davison; Bronze Medal, Miss E. Graham Stone; Bronze Medal, Frank Cooper; Commended, Messrs. A. James, S. Bourne, and Hood Daniel.

Class II.—(a) Silver Medal, Captain C. M. Harrison; Bronze Medal, W. Gaddum; *(b)* Bronze Medal, H. Harvey-George; Bronze Medal, O. S. Foster; Commended, Messrs. K. Kryzanowski and John Leisk.

Class III.—5l., Lieut. R. B. Croft, R.N.; Silver Medal, J. T. Hopwood; Bronze Medal, A. James; Bronze Medal, David Lewis; Bronze Medal (extra), Sir Robert G. Harvey and Miss F. Harvey; Commended, Messrs. Francis Ffrench Davis and Captain Brown.

Class IV.—Silver Medal, Rev. F. C. Lambert; Bronze Medal, Dr. E. W. Alabone; Bronze Medal, The Countess Oriola; Commended, Mr. Greensill Allen.

Class V.—Gold Medal, Howard J. Kennard; Silver Medal, J. T. Hopwood; Bronze Medal, Dr. Gray; Bronze Medal, Miss Miles; Bronze Medal (extra), Lieut. R. B. Croft; Commended, Mrs. West.

Class VI.—5l., Ed. A. Gollidge; Silver Medal, David R. Clark; Bronze Medal, H. Harvey-George; Commended, Messrs. H. J. Turney and Edward Pritchard.

Class VII.—5l., Miss C. Wrigley; Silver Medal, Miss Sullivan; Bronze Medal, Miss Florence Harvey; Commended, Miss Joyce Croft and Mrs. Edward Penton.

Class VIII.—10l., George Davison; Gold Medal (withheld); Silver Medal, C. S. Roe; Silver Medal, H. Tolly (for *On the Lonely Shore*); Silver Medal (extra), Miss Miles; Bronze Medal, H. Manfield; Bronze Medal, W. H. Banks; Bronze Medal, Rev. H. B. Hare; Commended, Messrs. A. Clarke, H. Harvey-George, and Mr. Brian Hodgson.

Class IX.—10l. (withheld); Silver Medal, Surgeon F. N. Puddicombe; Silver Medal (extra), Dr. Longfield; Bronze Medal, Col. L. D. Mackinnon; Bronze Medal, Col. Hooper; Bronze Medal (extra), Lieut. R. C. Tyllier-Blunt; Commended, Capt. W. A. Mess.

Class X.—Silver Medal, Cyril S. Cobb; Bronze Medal, G. Herklots Vos; Bronze Medal, C. C. Hughes D'Aeth.

Class XI.—Silver Medal, G. W. Catt; Silver Medal (withheld); Bronze Medal, Dr. W. Gray; Bronze Medal, F. L. Cox.

Class XII.—Silver Medal, W. L. Carpenter; Bronze Medal, S. F. Clarke; Bronze Medal (withheld).

Class XIII.—5l. (withheld); Silver Medal, W. L. Carpenter; Bronze Medal, Miss E. Graham Stone; Bronze Medal, A. J. Barnes.

Class XIV.—Gold Medal, J. T. Hopwood; Silver Medal, W. Adeock (for silver print); Bronze medal, H. Manfield; Bronze Medal, J. E. Dumont.

NOTES FROM ABROAD.

(From our Special Correspondent.)

II.

THE ROYAL OBSERVATORY AT BRUSSELS.

BEFORE leaving England on a few weeks' tour in Belgium, Germany, and Holland, I came upon some information collected for these pages during a previous visit to Belgium, and afterwards mislaid, so now clear out those particulars before dealing with more recent experiences.

Since the Royal Observatory at Brussels was erected, and fitted up for the most part with optical and chronometric apparatus bought in England, the then adjacent city has extended itself in all directions, until the Observatory now finds itself within town limits, an unfavourable position for any such establishment because of the unequal refraction of the atmosphere, due to hot air and gases rising from the chimneys of the houses, and because of the smoke. The latter, however, is not so thick as in England, because fuel on the Continent generally is burnt in a more scientific manner, and allowed but in a relatively small degree to escape as smoke to pollute the air, and to lengthen photographic exposures in the winter or other seasons. A new Observatory is in course of erection a few miles out of Brussels, and in due time to it the national astronomical work will be removed.

In the Brussels Observatory magnetic phenomena are recorded automatically by the aid of photography, as at Kew, so the method requires no description here. One of the officials has taken astronomical photographs by means of the great equatorial on the premises, and in this matter there is also nothing scientifically new. The recording of the readings of most of the meteorological instruments is not, as usual in England, done by photography, but by the celebrated meteorograph invented by Messrs. Van Rysselberghe and Schubart, by means of which the indications of the barometer, thermometer, and several other instruments are automatically recorded every ten minutes, in such a way, that after merely etching the record any number of copies can be printed off from it in the press. This is done by coating a thin sheet of brass or copper with a medium which resists the action of acids, and then fixing the prepared sheet round a drum, which gives one revolution every ten minutes. By means of an armature and electro-magnet, a diamond point is brought down upon the acid-resisting coating at intervals related to the indications of the various meteorological instruments, this being effected in them by means of make-and-break contacts; thus by means of a single frequently broken line upon the drum, the indications of all the instruments are recorded every ten minutes. When the metallic sheet is full of records it is taken off and etched, and a fresh sheet is put in its place.

In these operations are some which may be of practical use in photography, because in various photo-engraving processes it is necessary that the metal shall be covered with some tough acid-resisting medium, which shall not splinter under the action of the graver's tool, yet shall give clean lines. In Van Rysselberghe's meteorograph, it is necessary that this medium should as nearly as possible reach perfection, because any fault in it would cancel valuable records, so how it is made will now be set forth.

The metallic sheet is first well polished and cleaned, care being taken that its whole surface is free from the slightest defect. It is then covered with an engraver's varnish made in the following manner:—

Black pitch.....	1 part.
Burgundy pitch.....	1 „
Asphalte.....	2 parts.
Virgin wax.....	2½ „

The two kinds of pitch are first melted with the wax, then little by little, in very small portions at a time, the asphalte is added in exceedingly fine powder, with continued heating and stirring. When the mixing is thorough, withdraw the vessel from the fire, and before the varnish sets dissolve it in essence of turpentine, after which store it in vessels of white iron. Too much turpentine must not be added, it being necessary that the varnish should have a certain viscosity.

The following are the operations necessary in varnishing a plate:—

1. By the aid of a large brush, a thin cold coating of the varnish is distributed upon the metallic sheet; this coating must be of equal thickness throughout. If a bad coating be given, it must be removed, and the operation commenced afresh. The varnish can be wiped off by means of a ball of cotton wool dipped in essence of turpentine.

2. Slightly warm the varnished sheet above an alcohol flame, holding the sheet at about an angle of 45°, the non-varnished side of the sheet must be next to the flame.

3. Then slightly blacken the varnished side by moving it above a smoky flame. This flame may be produced by igniting a little ball of cotton wool soaked in a mixture of linseed oil and essence of turpentine.

4. Very slightly warm the sheet, while holding it, this time in a horizontal position, and with its non-varnished side turned towards the alcohol flame.

The heat should be sufficient to drive off the turpentine in the varnish, but too much heat must not be applied, or the varnish will be burnt. Engravers call it "burnt" when it splinters under the graver; it is necessary that when doing cross-hatching upon the varnish by means of a needle or other instrument, there shall be no splintering where the lines intersect each other.

A varnish may, however, become brittle under the graver owing to low temperature in the winter; in such case it contains too much pitch and asphalte, and the fault may be corrected by adding more wax. Too much wax makes it too soft. A good varnish does not splinter under the tool, and at the same time does not adhere to it; in the latter case, fragments stick to the point of the graver, and fall to powder when they are taken between the finger and the thumb. It is better that the plates should be varnished several days before they are required for use.

The lines made by the diamond point in the metal are visible when the sheet is taken from the drum, but they are not deep enough for engraving.

The sheet after removal is first coated on the back with a quick-drying black varnish of commerce, one which dries in half an hour at the outside; it is then placed in a large vessel containing a solution of one part of perchloride of iron in three parts of water. In about ten minutes the etching is sufficient; the plate is removed from the bath and washed instantly in a great quantity of water, then cleaned with cotton soaked in turpentine. Then it may be sent to a lithographer, who can take from it a thousand prints or more. When very long numbers are wanted, there is economy in not doing them all from the plate itself; one good copy should be taken from it in fatty ink, and this impression should be transferred to a lithographic stone, from which the actual printing can be done. Those prints I saw which had been taken by the latter method were inferior to those which had been taken direct from the metal. The same bath of perchloride of iron will do to etch fifty plates at least.

It has been said that ten minutes in the etching bath is sufficient, but if deeper lines are wanted, fifteen or twenty minutes may be allowed, but in this case it is well to watch the action. In general, when a plate is plunged in the bath, in one or two minutes the bright lines made by the diamond are equally tarnished throughout; if parts remain bright, they indicate that the diamond did not work with sufficient pressure, or that the plate had been unequally varnished. In the prolonged action of the bath, if points become exceptionally grey, the coating of varnish is too thin, and does not sufficiently resist the action of the liquid upon the metal. In this case the sheet must be immediately removed and washed in a great quantity of water. Then, if the general condition of the plate be satisfactory, do no more to it, but if the etching be not sufficiently deep, dry it and coat the parts which looked grey with a layer of varnish to preserve them from degradation, then etch the rest of the plate a little more in the bath.

The chief difficulty of the whole operation consists in getting an even coat of good varnish, and of the right thickness, upon the plate.

OPINION OF THE LONDON PRESS ON THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

[The Builder.]

THE Annual Exhibition of the Photographic Society of Great Britain, at present open in the rooms of the Society of Water Colours, contains a good many things that are really worth looking at for their success of execution or for the beauty of the objects which they represent; and though the interest which this exhibition excites is cold indeed compared with that aroused by the class of exhibitions which we are accustomed to see in these rooms, the very contrast of feeling naturally suggests some reflections as to the contrast between these two methods of representation, the chemical and manual, and what photography can and cannot accomplish.

The days are long past when photography offered to us as representations of landscape only some half-intelligible assortments of masses of dark and light. Comparatively speaking, the advance of late years is wonderful in this department of photographing, and a good many of the landscape photographs can be really enjoyed for their intrinsic beauty of representation. In almost all cases, indeed, it would seem that something is lost; one point is sacrificed to another, except where the scene offers special circumstances peculiarly suitable to be dealt with by photography. *A Frosty Walk* (31), for instance, by Mr. H. Tolley, represents a phase of nature, the ground whitened by hoar-frost, which falls in admirably with the special powers and the characteristic tone of photography. In *At Ilam, Derbyshire* (52), by the same exhibitor, the main point in the picture consists in the complex and delicate ramifications of the boughs and twigs of a bare tree, which form a network across nearly the whole surface of the picture, leaving the landscape to be seen through them. The anatomy of the tree, caught in every detail with the greatest sharpness, is an exquisite object in itself, and it is of real value in another sense, as a record of natural fact more elaborate than any painter could emulate by the labour of the eye and hand. *Falcon Crag, Derwentwater* (235), again, by Mr. T. A. Green, is composed in this way of a foreground tree—a noble tree—and a distance retiring behind it; the distance is beautifully soft, but we fancy something of it has been lost, and that the softness is really incompleteness; nevertheless, the result is beautiful in its way. Mr. Scamell's *Cottages at Steventon* (557), with the minute elaboration of the foliage and the broad mass of white light on the houses, is a most effective little bit, and here, it will be observed, there is no distance at all, and this is just one of the scenes in which photography succeeds best. Mr. Green's *Head of Buttermere* (236) is very soft and aerial in effect, but, as in many of these soft and rather misty views, the sky is lost, or only seen in faint and uncertain indications of cloud forms. One must except also the water from the foreground of *Cottages at Steventon*—water appears to be in every case and under all circumstances a failure in photography. We have not found one successful example in this collection. Smooth water, giving much reflected light, becomes woolly in texture and loses all hint of water; rough water looks only like a dry, wrinkled surface. Instantaneous renderings of breaking waves or surf, as in *A Ground Swell* (462), by Mr. W. P. Marsh, show the sensitiveness of the modern plate, which can catch a wave actually on the curl, but as a representation of water it is

valueless, almost disagreeable to look at, except solely as a business record of facts of form which a sea-painter may perhaps find useful to refer to. Among other landscape subjects which are successful may be mentioned the two platinotype photographs *On the Thames* (425), exhibited by the School of Military Engineering, the lower plate especially: two by Mr. F. M. Sutcliffe (548, 549), the first a fine little scene carefully chosen for effect—two trees on a ridge of down near the foreground, and a cloudy evening sky behind—a photograph into which something like poetic feeling has been conveyed; *View of Moel Wyn from Festiniog* (535), by Mr. C. E. Nesham, in which the large extent and aerial perspective of the hills is finely reproduced, though the sky seems to have been lost; *The Lea at Ware* (552), by Mr. Edgar Clifton, a carefully chosen subject, with an old barge in the foreground—artistic feeling is shown here in the choice of subject and point of view at all events; *Dunluce Castle* (219), by Mr. Vernon Heath, of which the same may be said; and *Carolling*, by Mr. H. P. Robinson (40), a landscape with two figures walking through fields, in which the landscape has really the softness and distance of a water-colour painting, but we imagine this has been touched upon and is not pure photographic work.

The figures in this last, however, jar upon the sentiment of the scene; they are supposed to be two rustic women singing as they go through the field. Mr. Thorne Waite or Mr. Tom Lloyd would have made a couple of expressive figures of them, in harmony with the feeling of the landscape; here we are brought down to the plain prose of commonplace everyday life, and the result is a total failure. The study of this and of a good many other photographic subjects compiled with similar aims is very instructive. It shows what we owe to art and artists in the production of the rustic idylls which form such a prominent and such a generally beautiful portion of our water-colour exhibitions. The photographers are very fond of trying to do the same thing, and the failure, in most instances, where the picture is simply a direct chemical transcript from nature, is complete, and in many cases almost ludicrous. A *Pretty Hop-picker* (63) seated on a stile is not pretty a bit; her face is a dead, dull blank. Mr. J. Gale shows some cottage or rural scenes with figures, the most successful being *Saturday Afternoon* (249), where he has been rather fortunate in his figures, and the broad mass of light on the white cottage is a good piece of effect. In others, such as *Too Wet for the Woods To-day* (245), the figures of an old woman leaning over the gate and a man coming up to it are simply vulgar. We can fancy what Mrs. Allingham would have made of them; and the same thought occurs in reference to *St. Catharine's Hill, Guildford* (61), a charming nook of landscape with a little girl seated in the midst of it just in the spot where "the figure" is wanted—it is all right so far, but the common, inexpressive countenance of the child spoils it; the artist's hand was wanting. So again in *The Secret* (553), by Mrs. Payne, a little girl and boy; a charming expression has been caught in the former, but the boy's face looks dull and sulky. Photography, in fact, gives in general the commonest and poorest expression of the countenance; the artist seeks out and gives the best expression; and there is a gulf between photography and art, or at least a part of it, for the still greater and essential distinction lies in the delight we all find in creating ourselves, or in studying the creations of others. Photography merely copies; the artist—even the most nominally realistic artist—does far more than copy, and nowhere can this distinction be more clearly seen or more strongly felt than in studying the efforts of photographers to produce pictures of human life. *Home, sweet Home* (41), an interior by Mr. Lyddell Sawyer, is another, we might almost say flagrant, example; the little bunched-up figure of the child held up in its father's arms is capital, and would be worth the attention of a painter, but the figures and physiognomies of the parents reduce the whole thing to sheer vulgarity.

Among really successful figure scenes we may, however, mention the little sleeping child, *Tired Out* (482), by Mr. R. W. Robinson, a perfect little picture just as it is.

In what has been with the public the great and popular function of photography, the taking of portraits pure and simple, there are some brilliant successes. Among these the three *Studies* by Mr. McLeish (292) are admirable; the photographer has been fortunate in his subjects, but he has also known how to light the profile portrait of the beautiful young girl on the right so as to give the most brilliant and striking effect to it. A medal has been awarded to another series of large portraits by Mr. W. J. Byrne (283), but from the artist's point of view these are not so good as No. 292, and in particular in the centre figure of the girl's head, nearly life-size, the modelling of the mouth has been quite lost.

As on former occasions, architecture, which of all classes of subject lends itself best to photography and loses least by any defects of the process, is the least represented of any class of subject. There is a fine and remarkably sharp view of *St. Paul's Cathedral* (20) by Mr. J. Braccbridge Hilditch, which, considering that it is an enlargement from the original negative, is a triumph of clear definition. It has been touched upon here and there with white for high lights, but so obviously as not to constitute any deception. Mr. Richard Keene shows some *Interiors of Osmaston Manor* (4); Mr. W. Webster some interiors of *Eaton Hall* (21). Mr. Salmon has some good photographs from *St. Bartholomew's* and other City churches, Mr. T. M. Browning gives a good view of the *Ponte Vecchio* at Florence, and Mr. Bedford Lemere has been successful in producing some very elaborate interior detail from rooms in *Beau Manor* (92).

Perhaps the most remarkable of all the architectural photographs for sharpness of definition are the two by Mr. Mold, of interiors of *St. Mary's Church, Raubury* (189 and 432), a classic interior which appears to have undergone recent decoration. Considering the difficulties in regard to light in interiors, these may be called extraordinarily successful. But we should recommend the Society to pay more attention to architectural photography, especially of ancient works, in their exhibitions: there is no class of subject in which their work can show to more advantage or be of more value.

Among the curiosities of the Exhibition is an architectural curiosity also, a photograph of a real contemporary series of lake dwellings, in full occupation, at *Tupuselai*, in New Guinea (404). Any architect visiting the exhibition would find it worth while to look at this. There are various photographs of flashes of lightning (but these are getting common now); photo-micrographs of minute objects from plant and insect life by Mr. F. H. Evans, for which the exhibitor has received a medal; the photograph of the claws of the house-spider, magnified 240 times, is one of the most remarkable and successful of these. Mr. G. W. Webster has somehow succeeded in photographing a couple of skylarks and their nest, the one bird on the ground, the other just hovering down: how he managed to get so close to the birds as to secure the photograph without frightening them away is the marvel; but the bird in flight illustrates one of the weak points of instantaneous photography: the bird's wings seem stationary, just as in the case of the instantaneous photograph of an express train which we noticed on another occasion: all idea of motion is taken away, wheels and wings alike are stopped dead. Mr. Sidney Tebbutt shows a photograph taken on a moonlight night in Saxony—"full moon and cloudless sky, exposure three hours, from ten p.m. to one a.m.;" but here again photography fails—it conveys no idea of moonlight; the lens, in fact, sees more than the human eye can, and as we mentally refer to our experience from actual vision, the photographic result appears false, though, in a scientific sense, it may be true enough. On the whole, the more we study photography, the more we feel how far removed is real art from mere imitation of nature; how much of the pleasure we derive from painting springs really, unknown perhaps either to spectator or artist, from the expression of the artist's own mental mood, and that sympathetic response to it in the mind of the spectator, which mere photographic reproduction is powerless either to express for the one or to awaken in the other.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

Last Tuesday night, at a meeting of the above Society, held at 5A, Pall Mall East, London, Mr. T. Sebastian Davis presided.

Various manufacturers explained the details of their apparatus on view at the Exhibition, many of which details would not be explicable in print without the aid of engravings.

Mr. T. SAMUELS demonstrated the working of his portable camera, as already described in these pages. It weighs four pounds thirteen ounces when charged with twelve 5×4 plates. He had not found any uncertainty in the action of changing the plates.

Mr. W. F. DOWKIN explained the action of an indicator he had attached to Mr. Samuels's camera. He had found that the indiarubber bag was not light-tight, neither was another bag which had been supplied to him, consequently the plates were fogged.

Mr. SAMUELS said that the latter experience was exceptional. He then exhibited his photographic tents.

Mr. W. H. WALKER described the new Eastman's roller slide. He had found that for English-made cameras a wooden was better than a metallic frame in the construction of the slide. The slide contained apparatus for keeping the paper in a state of definite tension, a principle which Messrs. Eastman were the first to introduce; otherwise at the points of suspension, when the paper expands and contracts with hygrometric changes, the paper will fog on development, though it may never have been exposed to light. This keeping the paper constantly in a state of equal tension is a most important thing in a roller slide. Out of sixty thousand amateurs in the United States he had never found one who preferred a hinged shutter to one which can be wholly withdrawn from the slide, though some objection to the latter was now and then expressed in England, perhaps from want of sufficiently long experience in the use of the American system. In some of their new slides enough paper for forty-eight exposures could be enclosed if the purchaser so desired. Perforators were not necessary; there was no safer method than to cut off by the aid of measurement each length exposed.

Mr. J. R. GOTZ exhibited his camera and view meter; the camera back had an improved swing motion, and the whole instrument was so made as to permit the obtaining of an extremely long or extremely short focus without any projecting parts being in the way. He also exhibited an improved shutter.

Mr. C. G. COLLINS exhibited a whole-plate camera with a novel front and a bellows which would rise and fall with the lens; he explained other points of detail. He also exhibited an adjustable bamboo stand and his detective camera.

Mr. HOWARD exhibited Mr. W. Tylar's double band shutter and explained its action. He also exhibited Messrs. Arundel & Marshall's plate boxes containing metal grooves covered with paper.

Mr. J. TRAILL TAYLOR asked what was the special point of novelty; plate boxes with metal grooves had been used years ago.

Mr. S. G. B. WOLLASTON had seen boxes with metal grooves covered with paper fourteen years ago.

Mr. A. MACKIE wished to know on what grounds a medal had been awarded for the boxes; the same firm had before exhibited much the same thing in public.

Mr. W. M. ASHMAN saw no points of novelty in the exhibit.

The CHAIRMAN said that the flap over the top and the interior ends of the box turning down to give power of greater grip of the plate were most useful.

Messrs. Watson & Sons' representative exhibited a detective camera, a translucent measuring glass, a cyclists' stand, and some metallic measuring dishes.

Mr. LEZARD exhibited his photochronoscopes for recording the times of exposures, the length of which could be indicated by means of the instrument and at the will of the operator.

Mr. Howard exhibited Mr. McKellen's camera.

General Preston complained that it was an injustice to country members who came up to town that apparatus announced to be described upon a particular night was not all described in consequence of other business earlier in the evening trenching upon the time of the meeting.

A vote of thanks was passed to those who had exhibited apparatus.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday night, October 20, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. A. Haddon presided.

Mr. H. W. G. FISHER exhibited the Welsbach light, which has already been fully described in these pages.

Mr. W. H. PRESTWICH had tried the light in his own home, and found the mantle to exhibit signs of decay four nights after purchase; in no very long time it was completely blown to pieces. He had been lighting the burner from the top of the lamp glass.

Mr. FISHER thought that by lighting the gas from the top of the glass instead of from the bottom Mr. Prestwich had produced small explosions of mixed air and gas which had blown the mantle to pieces. Mr. Winter, who was then present, had been using the light for three months, and could testify that the mantles were as good as at first. The gas consumed by each Welsbach burner averaged two and a half feet per hour, and was never more than two and three-quarter feet. The one on the table before them was then burning two feet per hour and giving the light of twenty candles. A Bray's burner, which he had selected haphazardly from those in use in the room, burnt exactly five feet per hour, as tested by the same gauge.

Mr. A. COWAN stated that he had brought some plates with him which at a distance of eight feet from a No. 4 Bray's burner, and with an exposure of sixty seconds, gave a faint twenty under Warnerke's sensitometer screen. He then made some experiments in the room with these plates at the same distance, first employing the Welsbach light, burning two feet per hour, and afterwards the Bray's burner light consuming five feet of gas per hour; the former gave twenty-three on the sensitometer and the latter nineteen.

Mr. J. B. B. WELLINGTON said that the experiment proved that the Welsbach light had two and a half times more photographic power than the flame of the Bray's burner.

The CHAIRMAN added that for equal consumption of gas the Welsbach light had five times more power.

Mr. SPINKS, of Brighton, exhibited a Sergeant's shutter which he said worked well.

The CHAIRMAN said that it and Grinston's shutter were made upon a principle introduced long ago from Russia by Mr. Warnerke.

Mr. A. L. HENDERSON had been testing the dry plates of the United Kingdom Company and found them to give sixteen on the sensitometer.

Mr. Fisher then sat for his portrait at a distance of about one yard from the single Welsbach light. Mr. Henderson exposed a half-plate in the camera for sixty seconds; the plate was one of a batch which gave twenty-two with Warnerke's sensitometer; on development Mr. Fisher's face came out pretty well, but not the dark parts of the subject. Several other plates were exposed upon the same sitter by various operators and the plates taken home to develop.

CAMERA CLUB.

THURSDAY, October 20, was the monthly lantern evening, and an excellent selection of slides was exhibited to a large company of members and friends numbering considerably over fifty.

The chief item of the evening consisted of a set of transparencies by Mr. W. Brooks, of Reigate, of interior and exterior views of Windsor Castle. Some of these were very fine both in tone, detail, and prospective effect.

Other slides were shown, including many from negatives taken on Club excursions by the Rev. — Fison, and Messrs. Barclay, Ferrero, and Howlett.

The lantern was worked by Messrs. Lyonel Clark and Gifford.

On Thursday, November 3, the subject is *Intensifying Gelatine Negatives with Mercury followed by Schlippe's Salt*, to be treated of and demonstrated by Mr. W. E. Debenham, at eight p.m.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

At the meeting held on Tuesday, October 18, at Myddelton Hall, Islington, N., Mr. J. Traill Taylor, President, in the chair, Messrs. F. Dunsterville and E. W. Parfitt were elected members of the Society.

Mr. A. MACKIE gave a demonstration of the method of preparing and developing collodio-bromide emulsion plates. In the course of his remarks he said the glass plates, after having been thoroughly cleaned, required some treatment to prevent the film slipping. A coating of thin indiarubber solution or even an edging of the same was effective, as was also a dusting of French chalk well polished off; but the method he recommended was a modification of that published by Mr. J. B. B. Wellington. It consisted simply in immersing the cleaned plates in a very hot solution of gelatine containing about twenty grains to the pint and drying with a clean cloth. The plates were coated with the emulsion by pouring it on exactly as, in the wet plate process, the plates were coated with collodion; but he advised that the surplus should not be returned to the stock, but should be received into a separate bottle, as by this plan spots in the plates due to dust were in a great measure avoided. The exposure for contact printing would be about twenty to forty seconds when a gas flame was used, but he preferred to use magnesium ribbon, a half-inch to one inch of which burned a foot from the negative would be found sufficient. The development was preferably by alkaline pyro, and either liquid ammonia or the carbonate of ammonia, potash, or soda, might be employed, the proportion being suitably adjusted. The following formulae would all be found to work well:—

Liquid ammonia	2 minims	} With 8 grains of pyro, 4 grains of bromide of ammonium, and with sulphite of soda, if preferred, to the ounce of developer.
or, Carbonate of ammonia.....	16 grains	
or, Carbonate of potash	24 „	
or, Carbonate of soda	40 „	

The colour of the image was somewhat dependent upon the alkali employed, but to a greater extent was controlled by the amount of the exposure, a full exposure being necessary to obtain a warm tone, and with a thin negative it was advisable to increase the pyro. Before development the plate should be flooded with methylated spirit and then washed until water would flow over its surface without streaky lines. A dish might be used for the development, but was not necessary, and the plate might be developed in the hand in the same manner as a wet plate. Speaking of the advantages of collodion over gelatine for transparencies, Mr. Mackie referred to the absence of any requirement for special apparatus for drying the plates, which would dry spontaneously in a few hours in an ordinary wood grooved plate box. By applying heat, however, the drying need not take more than a few minutes, and he claimed that it was quite possible to prepare a plate, expose, develop, fix, wash, dry, and bind it, so as to make a complete lantern slide, in a quarter of an hour. The whole of the operations were successfully performed at the table and the resulting slide afterwards passed through the lantern.

Mr. J. NESBIT then described the apparatus he used for reducing to lantern size from larger negatives, which was so arranged that the negative might be shifted so as to bring any part of it opposite the lens. The illumination was obtained by pointing the apparatus to the sky, but a reflector at an angle of forty-five degrees might also be used. In reply to a question, Mr. Nesbit said that no light except that passing through the negative should be allowed to reach the lens.

The nomination of officers for the ensuing year then took place, after which the lantern was set up and a large number of slides exhibited.

The next meeting will be on Tuesday, November 1, and will be the annual general meeting.

NORTH SURREY PHOTOGRAPHIC SOCIETY.

THE usual fortnightly meeting of this Society was held at the Greyhound Hotel, Dulwich, on Wednesday evening, October 19,—Mr. Yates in the chair.

Mr. W. H. Baldwin and D. Williams were elected members.

Mr. J. THOMSON, F.R.G.S., gave a lecture on *The Use and Abuse of Photographic Lenses*. Beginning with a general survey of the origin of lenses, Mr. Thomson described the properties of their various forms from the pinhole to the most recent patterns. When treating of wide-angle lenses the lecturer pointed out where this form could be used without destroying pictorial effect in the resulting picture. Mr. Thomson showed how the topographical value of pictures, especially of new countries, was entirely destroyed by the use of a lens of an angle widely differing from the human eye. The lecturer concluded by treating of the best form of lens for enlarging purposes.

A vote of thanks was accorded to Mr. Thomson for his lecture.

At the next meeting, on November 2, a paper will be read by Mr. Herbert Starnes on *The Permanence of Different Varieties of Photographic Prints*. Visitors desirous of being present will kindly communicate with the Hon. Secretary, Mr. Harold Senior, 88, Norwood-road, S.E.

BRISTOL CAMERA SOCIETY.

THE first meeting of the winter session of the above Society was held at the University College on Thursday, the 13th instant,—Dr. Arthur Richardson in the chair.

The first business of the evening was the election of the following members:—Mr. J. H. Brook, Rev. H. C. Coote, Mr. J. Carthage, Dr. D. S. Davies, Messrs. A. Keitel, Percy Lewis, J. W. Munro, R. C. Newick, and H. T. Rudge.

After which the CHAIRMAN proceeded to make some remarks in reference to the Society and photographic matters generally. He considered members of such a Society were placed in an advantageous position, having the opportunity of studying various subjects bearing upon the art in conjunction with their fellow members, by which means they were likely to gain more knowledge than by individual efforts and research. The aim of a photographic society, he maintained, should be to investigate, and he would remind his hearers of the ample field in which to labour. Chemists are at present undecided as to whether the image formed by the action of light is built up of particles of metallic silver or a subchloride of silver. Here was scope for investigation. He would also like to direct their attention to orthochromatic processes, which, when perfected, he considered would be a step in the right direction, inasmuch as it would give better proportion to various colours and enable us to form a more correct idea of their relative intensities. Our idea should be to have an intelligent understanding of the theory of different processes employed and a reason for results obtained. He should like to know if any of the members present had tried the experiment of exposing a piece of plain glass in the camera to an object and developing the image by means of breathing on the same, as in the case of exposed carbon tissue.

In compliance with the request of the Council, a large number of prints, the result of the summer's work, were handed round for inspection and criticism, and much useful information was elicited.

The meeting terminated with a vote of thanks to the Chairman.

BURY PHOTOGRAPHIC AND ARTS CLUB.

THE annual meeting of the above Club was held on Wednesday, October 19, at the Temperance Hall,—The President, Mr. F. W. Livsey, in the chair.

There was a large attendance of members, which proved the interest shown in the Club, and impressed upon the Council the necessity of providing larger rooms.

The following gentlemen were then elected as officers for the ensuing year:—President: Mr. F. Cooper.—Vice-Presidents: Messrs. W. S. Barlow and E. W. Mellor.—Council: Messrs. H. M. Dearden, C. H. Openshaw, R. Grundy, jun., A. Taylor, and W. Booth.—Hon. Secretary: Mr. F. W. Livsey.—Assistant Hon. Secretary and Treasurer: Mr. R. Grundy, sen.—Auditors: Messrs. J. Newbold and R. Wood.

Votes of thanks were passed to the retiring officers.

The members then resolved to hold an Exhibition and *soirée* in the early spring.

Correspondence.

THE PHOTOGRAPHIC EXHIBITION.

To the Editors.

GENTLEMEN,—Apropos of your reference in last week's issue to the *World's* critique on the present Exhibition in Pall Mall, I should like to ask, as a member of some years, how the Society came to accept and hang—to say nothing of giving them a medal—the pictures referred to by the *World* as having been for months used for advertising purposes?

I was under the impression that one condition of entry to the Pall Mall Exhibition was that the picture should never previously have been exhibited in London. At any rate, I know a few years ago that was the reason put forward semi-officially for not awarding a medal to a well-known professional exhibitor—one of the pictures in his frame had been exposed for sale at the art publishers'. What, then, has occurred to alter the minds of the erratic directors of the "poor old parent" sufficiently to induce them to admit and medal a series of pictures that have graced the Strand and other public-house windows for months past?—I am, yours, &c.,

A MEMBER.

PHOTO-MICROGRAPHS AT PALL MALL.

To the Editors.

GENTLEMEN,—There is no objection to Mr. Evans "cracking up" his own work, and pointing out the excellencies and difficulties which it appears critics have failed to observe in his exhibits at Pall Mall, so long as his modesty does not stand in his light and he can persuade you to print his letters. To all this there can be no objection, and I raise none. But surely it is unkind and unjust to belittle my poor productions by comparison with Mr. Evans's own feats, his "artistic and natural effects in illumination and great depth of focus, that elicited the very high praise" to which we are referred in the *Journal of the Royal Microscopical Society* and the *Photographic Year-book*, chapter and verse being freely quoted. Is it noble of Mr. Evans to allow his "extra deep objects, such as polycistina—opaque—taken with the one-inch O. G." to bully my miserable little organisms, some less than $\frac{1}{1000}$ th of an inch in diameter? It is all very fine to interlard criticisms with epithets such as "beautiful," "exquisite," and "artistic;" Mr. Evans's intention is plainly to make my work suffer by comparison not only with his own, but with that of Dr. Crookshank, who is, I understand, one of the most expert bacteriologists now alive, but who never within my knowledge showed any of his results

at any photographic exhibition, and so should not be brought into evidence to annihilate me or Mr. Evans's misguided critics. Does it not occur to Mr. Evans that his "faint praise," if not actual strictures, will tend seriously to discourage a struggling disciple who five months ago had never seen an O. G. of higher power than a quarter of an inch, and did not precisely know the meaning of homogeneous immersion, who never had heard of a paraboloid, nor ever attempted to use a polariser two months ago? I ask if most people in my present sad position would not be inclined to make a bonfire of the camera and send the objectives to the nearest pawnshop? As Mr. Evans is strong, oh, let him be merciful!

The worm, however, will turn sometimes, and, with your permission, I will attempt to palliate my offence in having dared to exhibit micro-organisms, in which Mr. Evans takes no interest, and which Mr. Evans considers to "have no structure to pay for care in delineation," and no value "therapeutically" or pathologically. Pasteur, *teste* Mr. Evans, is past his zenith (in the Evans I suppose), Klein is on the de-clein, Crookshank is a lean and slipped pantaloon, and should be written "Crook-ed-shanks," Maddox has been inoculated from a Mad-dog. "Theorists," says Mr. Evans, "are already decrying the value of Pasteur's processes and supposed results." If careful experiment and close reasoning can prove anything at all it is clearly proved that certain micro-organisms have pathological value, but, granting that Mr. Evans is right, and the men I have named all drivellers, what has this to do with my photographs? I have made no assertion about bacteria, I only exhibited my attempts to photograph certain objects, and I never asked any one to believe my photographs represented "the living originals." I have not examined Mr. Evans's wonderful exhibits, but I shall do so when I get a chance with immense interest now, as I am bound to infer, first, that they are truthful renderings of "the living originals," and, second, that Mr. Evans has overcome the great *crux* of "focussing all planes with equal sharpness, even in extra deep objects." This, he says, was his aim, and as he considers his critics unkind I suppose he claims to have overcome his *crux* as far as possible; how far it is possible to show "widely divergent planes in focus together" is a matter worthy of some consideration. Perhaps Mr. W. E. Dehenham will "favour the company with a sentiment."

Mr. Evans further seems inclined to cavil at my exhibits because "none but actual students and workers can at all appreciate (I don't mean enjoy) them at their real value." In the first place, I did not exhibit my micrographs with any expectation that persons ignorant of their nature would appreciate or enjoy them, nor do I see any necessity for any such consideration on exhibitors' part. In the second place, the same objection appears to hold equally good with Mr. Evans's own exhibits at Pall Mall; so far as we have any means of judging nobody except the jurors have either appreciated or enjoyed them. I do not venture to criticise Mr. Evans's exhibits, not having seen them except for a moment by chance but I hope in a short time to have the advantage of a close study of his photographs of "rare and beautiful objects." Mr. Evans makes great capital out of the difficulty and rarity of dark-ground illumination. I know nothing of its rarity, but I venture to deny the difficulty with a paraboloid or spot lens. I have done only a few dark grounds, but I found very little difficulty in producing what appeared to my untutored mind respectable representations of the objects I tackled. The use of polarised light I do find somewhat puzzling, but Mr. Evans has probably mastered that difficulty, as he does not mention it.

"Mr. Pringle's beautiful photographs charmed me most as specimens of exquisite decorative designs." In spite of the "beautiful" and "exquisite" this is evidently not intended as a compliment to what were shown as purely scientific photographs; in fact, it is pretty straight condemnation of my work as scientific or useful. But what a happy vein of thought it opens! Bacteria micrographs as decorative designs! My fortune is made! I shall at once call on Mr. Maple, the popular house decorator, and submit to him a selection of my designs for decorative purposes. A wall paper of *Cladothrix dichotoma* pattern, or of gold picked out with *Micrococcus tetragonus* would indeed be "exquisite" and original. *Micrococcus crepusculum* would be suitable for a dining room, and every aristocratic house would have, not its "red" or "blue" room, but its *Colmia rosco-persici*na chamber. Teacups might be adorned with a sprig of *Saccharomyces glutinis* and a neatly inserted *Bacterium lactis*, while the cosy would appropriately be sewed in zoogla of *Spirilla attenuata* (warming). Mr. Culleton might also secure my services for his search after armorial bearings. I could at least suggest some new es-cuteheons: "On argent field three *Spirilla undula* rampant, with the device, 'Thereby hangs a tail.'" As Mr. Evans does not believe in bacteria I cannot find bacteriological bearings for him, but I would suggest as a motto: "Wha daur medal wi' me?"

Enough, however, of this fooling. I do not see that Mr. Evans has in the very least exalted the public opinion of his exhibits by his depreciation of mine. Perhaps the reverse is the case. If I consider, after seeing Mr. Evans's work, that it calls for any special eulogy, I may ask you to publish my "coals of fire;" if not, the matter may be different. Meantime I protest against one thing which Mr. Evans does, viz., frightening people by bogus difficulties; and I guess your readers will join with me in deprecating another thing, viz., venting spleen in your columns against other journals and on unoffending persons.

My exhibited prints were among my earliest attempts in their line—in photo-micrography, indeed. I never expected an award for them, I do not

say they are the best ever done, and next year, in spite of Mr. Evans's discouragement and unbelief, I hope to show some bacteriographs both bigger and better.—I am, yours, &c.,

ANDREW PRINGLE, B.D. (Bacteriological Decorator).

ADHESION OF FILMS.

To the Editors.

GENTLEMEN,—In reference to the article on *Removing an adhering paper negative from its support*, perhaps the relation of my experience may be of service.

For a long time past I have used none but Eastman's paper negatives. I often, for the amusement of experimenting, do not follow—at least entirely—the directions given, and the following is my mode of procedure. After fixing, I thoroughly wash under a high-pressure tap, drain until water on negative ceases to drop, and then put it into methylated spirit. As I have written you before, this unmistakably clears the negative. After remaining in the spirit from three to five minutes, take it out and lay it at once down on a thin sheet of polished vulcanite. If the vulcanite has been used before, give it a rub with an old cambric handkerchief. When the negative is down on the vulcanite, put a double piece of blotting-paper over it, and roll it down with a common ruler. It will have a somewhat mottled appearance for a few moments, but rapidly get quite evenly white. Either let it stand against the wall till you want it, or at once, if you please, hold it over a paraffin lamp, first one side and then the other, and with some patience it will begin to loosen at one edge or corner and gradually come off, but don't pull it.

However, I find that all this can be saved, and after washing, by hanging the negative up by two pins—one in each corner—against a shelf, and letting it dry spontaneously, afterwards putting it under a lever copying press, you can get it quite flat after twelve hours' pressure, but you may print from it at once, and the pressure in the printing frame will go a long way to flatten it, especially if printed as I always print my paper negatives—in the sun.

While writing may I say I am glad to see in the "Answers to Correspondents" that there is to be an article on Hydrokinone in the ALMANAC? I hope to learn something from it, although, as I am very successful with my one solution developer—proportion one to sixteen—I don't know what I want more. Can you tell me the formula for meta-bisulphite potash?

I see in *Chambers's Journal* that the manufacture of soda and potash, especially the latter, is made much cheaper. If it reduces the price of hyposulphite potash to even double the price of hyposoda, photographers will not be long in finding out how much better the former is than the latter for fixing.—I am, yours, &c.,

W. T. F. M. INGALL.

Greenhithe, Kent, October 20, 1887.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED:—

A. Hill, Stonehouse, Devon.—Three photographs of Sir J. Puleston, M.P. for the Borough of Devonport.

J. SMITH (Burton-on-Trent).—Size the pictures.

C. BANYARD.—The Exhibition closes on November 14.

A. A. A.—All the lenses mentioned are constructed on the same principle.

HANLEY.—There is no work on the subject published. See leader in another column.

T.W.—Eau de Javelle is far preferable to the zinc salts, as it leaves no insoluble compound behind.

J. WORMALD.—Something is wrong either with the acid or the litmus paper—probably the former. Get a fresh supply.

T. E. WATSON.—Paper the side and front walls with a pale neutral-toned paper in preference to whitewashing them. An ordinary room paper with a neat pattern which is not too dark will answer the purpose.

AJAX.—For the purpose mentioned we, were we in your place, would select a single achromatic landscape lens of about thirty inches focus. If the lens be of a very pronounced meniscus type one of shorter focus will cover the plate quite well. Provision will have to be made in the camera for swinging back the top of the ground-glass else will not foreground objects be in focus.

A. COURTNEY.—In all probability the albumen on the paper you have employed was coagulated, hence the ink has adhered to all portions alike. For making transfers for photo-lithography the albumen must not be coagulated, otherwise, as in your case, the ink cannot be washed away from those parts upon which the light has not acted. It is not usual to coagulate the albumen on commercial papers nowadays.

C. H. L.—1. The only preparation the glass requires is to make it chemically clean. Nitric acid is very commonly used for the purpose. If you follow either of the receipts given in the ALMANAC you ought to succeed.—2. If the residues only contained sixpennyworth of silver no more could be recovered. "About three-quarters of a pound of paper cuttings" if reduced to ashes would not amount to much. The small amount charged by the refiner could not have paid him, we should think. In future it will be better to burn the paper yourself and assay the ashes before sending them away. This plan of proceeding will be more satisfactory to yourself and also to the refiner.

J. E. GOWER says: "I have used ordinary dry cake water colours for spotting some prints; will they stand burnishing without the spots being in any way moved? In the ordinary way I do not burnish my prints, so do not know anything about the proper sorts of paints to use."—The best plan will be to try the experiment. Some colours will adhere and others will not. If it be found that the colour comes off in the burnishing we should recommend our correspondent to mix them with albumen.

OLD PAPER writes: "I have recently had given to me a quantity of photographic material amongst which are several quires of albumenised paper. As I know this is very old (some of it probably twenty years, none less than ten), and as I wish to print a large number of negatives, will you kindly inform me if the resulting prints may be made better than they otherwise would be by any variation from the usual method of treatment in their production?"—If the paper has been kept in a dry place it will probably be none the worse for the keeping, but if it has been allowed to get damp it may be next to worthless. If the paper does not work properly our correspondent should send one or two prints for us to see. We may, however, mention that paper albumenised twenty years ago was usually more highly salted than modern ones, consequently a stronger sensitising bath will be required.

PERPLEXED writes: "My studio is blinded with white blinds, and I get very nice soft negatives, but I am very much troubled with the light in the eyes being all wrong and much too strong. I suspect it is owing to light coming through the blinds from a source different than through the open blinds. Can you tell me through your columns if this is so? also, what colour of blind you would recommend me to use, as I contemplate blinding my studio anew? Also, if you think green a suitable colour, as I think it would be pleasant to the eye. I find great difficulty in getting blind cloth to buy with a soft texture; I have written for samples to several firms, and they are all too hard for the purpose of running well."—We strongly suspect that the trouble arises not so much from the light coming through the white blinds as from too much front light being admitted into the studio. At this time of year, unless the sun shines direct on the studio, white blinds ought to be sufficient. Green is a very good colour for blinds, and a proper material for the purpose may be obtained at most upholsterers and blind makers.

RECEIVED.—Report of Manchester Photographic Society, and President's Address at Dundee Society. In our next.

PHOTOGRAPHIC CLUB.—The next meeting of this Club will be the annual general meeting for election of officers, &c., November 2, 1887.

We learn from the London Stereoscopic Company that their Third Annual Amateur Photographic Exhibition is likely to prove a great success. No less than 250 ladies and gentlemen from all parts of the world have entered for the fourteen classes, sending 2260 mounts, comprising some 4000 pictures. Due notice of the opening of the Exhibition will be given.

MESSRS. SMITH & PATTISON, Wabash Avenue, Chicago, in sending us some details relative to a new burnisher of alleged great merit which they are bringing out, and concerning which some particulars will be found in those pages of the forthcoming ALMANAC devoted to commerce, enclose a parcel of cabinet portraits burnished by this new candidate for popular favour. So perfect and bright is the finish that at first we thought they had been enamelled.

THE news of the death of Mr. Edgar Gould, of Elswick Lodge, Newcastle-on-Tyne, will be received with deep regret in many quarters. For a number of years Mr. Gould has managed the photographic business in the Elswick Works, and specimens of his skill in this connexion are distributed over all parts of the globe. The people of Newcastle and neighbourhood are, however, better acquainted with his merits as a photographer from the fine pictures which he has exhibited in the Art Gallery as a member of the Photographic Association. He was possessed of a nice artistic sense which, combined with the most skilful manipulation, enabled him to produce works of high excellence. In the various outdoor contests which the Society held he was often distinctly successful. A quiet, intelligent, kind-hearted man, he died at the early age of forty-seven, leaving behind nought but gracious memories.

ART PHOTOGRAPHS.—Although it may be the function of a Reynolds, Gainsborough, or Millais, to do full justice to the beauty of the living creature, and a Turner, Constable, or David Cox, to reproduce that of the mountain or plain, there is much to be done with the photographic lens which it would be folly to disparage, and infinitely more than it is ordinarily made to convey to us. A little happy touch of expression is a phenomenon one hardly ever remembers to have seen in a photographic portrait. The photographic artist who wishes to produce a really successful portrait studies the special defects as well as the special beauties of the sitter before him, and considers in what view the faults of such a physiognomy will assert themselves least strongly and the merits show the most. This is the function of an artist, of a man of considerable natural abilities and very great experience. Much might be written about the question of shadows and their value. Queen Elizabeth, in her ignorance, thought shadows unbefitting to the glory of her Majesty, and desired to be painted without any at all; and even at the present day there are ladies who think shade a smudge, dirty thing, the less of which comes on their countenances the better. But light cannot be thrown out in its full brilliance nor far as shown in their variety without shade.—*Liverpool Post*.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1435. VOL. XXXIV.—NOVEMBER 4, 1887.

THE GENESIS OF THE ROLLER SLIDE.

SOME mistaken ideas appearing to prevail with regard to the origin and nationality of the roller slide, we shall endeavour to place this matter on a solid foundation.

As will be seen, we shall not be stinted in our acknowledgments of what the mechanical genius of America has effected in the way of revolutionising and rendering practicable this increasingly popular piece of photographic apparatus, but its first inception is due to an Englishman, Mr. A. J. Melhuish, of London, at that time of Blackheath.

In the third volume of the *Journal of the Photographic Society*, and in the number issued under date of April 21, 1856, appears a description and drawing of a roller slide by the above-named gentleman. In this the sheets of paper were gummed together so as to form a long band, the ends of which were then gummed to pieces of paper always kept on the rollers. During exposure the sheet was pressed against a plate of glass by means of a board behind it. The time occupied in fixing thirty-six sheets to the holder was about an hour.

Working without a knowledge of what had been thus accomplished in the earlier days of the art, Mr. Leon Warnerke, in June, 1875 (see *THE BRITISH JOURNAL OF PHOTOGRAPHY*, vol. xxii., page 307), submitted to the South London Photographic Society a dark slide, in each end of which was fixed a roller on which to wind and unwind a sensitive film he had just previously introduced. It is perhaps difficult to say why the Warnerke slide did not attain popularity. The drawback which we experienced in using it arose from the trouble in affixing the film or paper to the roller and winding it upon it, operations which had to be conducted in the feeble light of the dark room. It fell into desuetude and became almost forgotten.

The next advance in the history of the roller slide was of quite a revolutionary nature, as an entirely new feature was introduced. It was the invention of Messrs. George Eastman and W. H. Walker, of Rochester, New York. The leading idea in the invention was the introduction of what we may term the spool system, that is to say, the films were supplied ready wound up upon spools or cores, which could be transferred in their wound up state from the long, light-proof cardboard cases in which they were supplied to the dark slide which was specially adapted for their reception; and by this ingenious contrivance the problem was solved.

Contrasting then and now,—the ancient and the modern, the *how* required by Mr. Melhuish to wind his paper upon his rollers, which were fixed in the slide, seems almost inconceivable when viewed in the light of modern improvements. No one who

was present at the last meeting of the Photographic Society and heard the lucid description by Mr. Walker of the construction of the elegant roller slide he then explained, could for a moment close their eyes to the great value of the underlying principle involved in the invention of a roller slide, and a spool or roll of sensitive flexible photographic material which could be used in conjunction.

Without dwelling upon other features of this roller slide, such as the method of retaining the paper under a definite tension under varying atmospheric conditions (which was undoubtedly as radical an improvement as the other feature before referred to), the automatic marking of the limitations of the several exposures, and numerous other points alluded to by Mr. Walker in the course of his remarks, we close by expressing our sense of the great practical ingenuity displayed in this invention by our transatlantic friends.

ILLUMINATING NEGATIVES FOR ENLARGEMENT OR REDUCTION.

At the close of the outdoor season and at the commencement of what, so far as the camera is concerned, may be considered "the recess," it is but natural that lantern matters should assume a greater degree of activity than prevails during the spring and summer months, though even during those seasons the interest is never entirely dormant. As a consequence, at this period of the year, and each recurring year, with greater force we are inundated with correspondence relating directly or indirectly to the optical lantern, to exhibitions, and to lantern slides. This year it would seem that amateurs are more than ever engaging in the practice of making their own slides, and with the facilities at present within their reach, and the fact that the practice keeps them in training during the "off season," it is not to be wondered at.

At the same time and directly, in consequence of the greater number interested, we find an increase in the difficulty, or rather of the numbers who experience the difficulty, of satisfactorily lighting the negative for reproduction in the camera. Many amateurs who make a practice of enlarging from their negatives, and compass the task successfully and to their satisfaction, imagine that the production of the diminutive lantern slide is a far easier matter, and are consequently the more surprised when on attempting it they find their arrangements are unsuitable. As a matter of fact, the requirements are very different in the two cases and in some points nearly opposite.

Thus, in ninety-nine cases out of a hundred, an enlargement is made from a very small negative; in the case of an amateur

nearly always a quarter-plate. If the picture be a portrait, especially if a bust or vignette, only a comparatively small portion of the plate is required to be illuminated evenly, and an ordinary three-and-a-half-inch condenser, as supplied with the cheapest lanterns, or obtainable separately for a few shillings, supplies all the optical arrangement needful. Even should the subject be a landscape, and the plate have to be reproduced to the edges, a five-inch condenser will scarcely fail to cover it to the corners, and the cost of the larger optical arrangement is still insignificant. Portrait enlargements from plates of larger dimensions than quarter size present the same advantage in requiring but a portion of the centre of the plate illuminated, but of course where the subject is a landscape, and has to be reproduced to the corners, the difficulty in illumination is greater.

But lantern slides, except when printed by contact, are almost invariably reduced from larger negatives, and in nine cases out of ten the subjects consist of landscapes or studies which require the whole, or at least the greater part, of the negative to be illuminated with a uniformity that is scarcely needful under any circumstances in the case of a portrait. Supposing even that the negative to be reproduced is of the actual size of the required slide, and that the portion to be illuminated is a *circle* of three inches diameter, the three-and-a-half-inch condenser will scarcely accomplish the task set it; but if the shape be square instead of circular a four-and-a-half-inch condenser will prove insufficient. If, then, the difficulties of illuminating the smallest size of negative in ordinary use by means of a condenser be so great, what will they be as the sizes increase? Condensers, of course, can be obtained suitable for any reasonable size of negative, but at a cost that entirely precludes their use by the amateur, while the professional would dispense altogether with their use by adopting daylight, which, as a rule, the amateur is not in a position to do. This, in fact, constitutes the chief difficulty with amateurs; their engagements do not permit them to utilise daylight, and being compelled to employ artificial light the problem is how to distribute it evenly.

Many plans have been devised for utilising gas or oil lamps, but these have been mostly defective either in necessitating a large number of flames and a great amount of heat, or else, on the other hand, imperfect distribution and great feebleness of light. Of the first class the principle is a translucent screen, illuminated by a series of separate flames placed at such intervals and at such a distance from the screen that their light is equalised over a large area, and the translucent surface then becomes a radiant; or the arrangement may be varied by allowing the light from two or more flames to fall upon a dead white surface from different directions, so as to equalise one another as far as possible, and the reflected light allowed to fall upon the negative. This answers tolerably well for small pictures when rapid plates are used, but the loss of light is very great.

Other methods consist of the use of a single flame with a sheet of ground-glass, or other suitable medium, interposed between it and the negative, the uniformity of the illumination depending upon the relative positions of the light and the screen. Here it becomes a matter of compromise between quality of illumination and length of exposure, for the greater the distance of the light the better its distribution but the less its power, and in practice it is found that to secure even tolerable uniformity of lighting entails an exposure too prolonged for any but very rapid plates.

These remarks refer to gas or oil flames, which are of a comparatively non-actinic character; the oxyhydrogen is better, but seldom available, while the electric light of suitable kind is still further out of the question. But since magnesium has at last come down to so moderate a price, there remains no valid reason why a cheap, convenient, and highly powerful light should not be available for the purpose we indicate wherever lantern slides or enlargements are made.

The simplest mode of using it scarcely requires any apparatus or preparation, all that is necessary being to ignite it at a sufficient distance from the negative with or without the intervention of a translucent screen; or the light may be allowed to fall upon a white sheet and passed, by reflection, through the negative to the camera, in which case the perfection of uniformity is secured. But though these makeshift methods may answer very well for lantern slide purposes where the sensitive plate is exposed in the camera, and thus protected from extraneous light, for enlarging they are wholly useless, since the sensitive surface is usually freely exposed, and it therefore becomes necessary to enclose the light in a suitable lantern. This is not a difficult task, and as, with the aid of magnesium, it removes all the difficulty of equal distribution of the light without inconveniently lengthening the exposure, no doubt many amateurs, in addition to those who have addressed us on the subject, will think it worth while to erect a simple lantern on the lines of the one we shall describe.

This consists roughly of a wooden body with ground-glass front, and acts at the same time as lantern and reflector combined, the ground-glass intercepting the whole of the light both direct and reflected, and becoming converted into a powerfully actinic radiant suitable for either enlarging or reducing purposes and for negatives of any size. The details of construction are so simple as to scarcely require a diagram, so we shall endeavour, by means of a verbal description, to make the arrangement clear.

We may premise that though the instrument we describe is constructed for use with negatives up to 12×10 , and is equally available for quarter-plates, it might be made of any smaller dimensions if preferred, though, as nothing is lost in the larger size, and little added to the cost, we should strongly recommend the twelve inch square front to be adhered to.

The shape of the lantern, or reflector, is a hollow pyramid, the base of which is twelve inches square, clear, and the sides slope at an angle of sixty degrees, which will make the height of the pyramid, roughly, between ten and eleven inches. Such are the interior shape and dimensions, but for convenience in construction, as well as in use, the structure may be built up in the following manner:—Cut two pieces of wood accurately to the shape and internal dimensions of the side of the reflector, and cut also two rectangular pieces of such size that, when placed together to form a V-shaped trough, the two triangular pieces will fit in at the proper angle to complete the reflector. The square ends of the two rectangular sides will then serve as feet, upon which the reflector will stand without further assistance. Before fastening the sides together, mark on each a line parallel with, and six or seven inches from, the front or base edge, and nail or glue on four fillets of wood to form a rebate or projection against which to fix a square of glass. In each of the triangular pieces which will form the top and bottom of the lantern when in use cut a hole an inch and a half, or two inches, in diameter for ventilating purposes, the upper one to be fitted with an external chimney to carry off the smoke.

When the frame is put together, let it be lined with white

paper or painted dead white; fit a square of clear glass into the rebate formed by the fillets already mentioned, and in the centre of this cement a disc of opal glass about an inch in diameter. The clear glass will convert the back portion into a separate lantern, and by reducing the space assist in carrying off the smoke, while the opal disc softens the intense brilliancy of the burning magnesium and helps to equalise the illumination. The front of the arrangement is provided with a frame into which a sheet of ground-glass slides, with a second groove at a distance of about an inch, into which carriers to hold different sized negatives can be inserted. So far as the lantern is concerned, nothing now remains but to supply the illuminating arrangement.

This is of the simplest. Procure two narrow brass tubes, five or six inches in length and an eighth of an inch in internal diameter. Saw off the apex of the pyramid and replace it with a flat piece of wood through which the two tubes are passed, one a quarter of an inch above, the other a quarter of an inch below, the centre and reaching to an inch or so of the clear glass screen, or eight inches from the ground-glass front. The upper tube serves as a guide for the magnesium wire and may be replaced, if it be at hand, by one of the simple little lamps supplied by Mr. F. W. Hart. The lower tube carries a strand of cotton wick kept saturated with spirit, and serves to light the magnesium as it is passed through the upper tube. If the outside end of the wick tube be bent at a right angle, it may be passed through a cork into a small bottle of methylated spirit and so converted into a permanent spirit lamp. A small aperture cut in one of the sides and glazed with blue glass will enable the operator to watch and regulate the supply of magnesium during use.

When required for work, all that is necessary is to light the spirit lamp by passing a taper through the air inlet at the bottom and to allow that to burn continuously. When an exposure is to be made a strand of magnesium ribbon is passed slowly, but regularly, through the upper tube, and being ignited by the spirit flame, continues to burn as long as the supply is kept up. If the reflector be constructed of the shape and angle given and the light arranged at a distance of eight inches from the front glass, the illumination over a surface of a foot square will be brilliant and uniform in the highest degree.

Not the least recommendation of this apparatus beyond its efficiency is its economy. It may be made by any one who can use tools at all, for a few shillings, and will serve a variety of purposes.

RESPONSIBILITIES OF PLATE MAKERS.

THE question has been raised by one of our correspondents as to whether an action could not be raised against a plate maker who supplies plates which in the hands of the purchaser and user turn out badly. Now, if one thing is, or ought to be, better understood than another it is this, that in the hands of one man a plate may often fail entirely in the production of a good negative, while one from the same packet will, when manipulated by another individual, prove to be all that can be desired. All depends upon the treatment. A plate maker, for his own sake not less than that of the user, will necessarily allow nothing except what he believes to be good and reliable to be issued with his insignia as an endorsement of such belief: it would prove fatal to his interests were it otherwise.

There is no one worthy of the name of a photographer who has not, at one period or other of his career, encountered failures which he afterwards realised were due to himself. We

quite grant that it is inexpressibly annoying and vexing to find, after returning from a long journey, that upon developing his plates, each, one after another, turns out to be weak, foggy, or otherwise bad. Of course the maker of the plates is blamed, and the question is ignored whether by the exercise of a little judgment in developing, in contradistinction to a blind mechanical adherence to formulæ, the result might not have been altogether different.

One instance, and it is an excellent one, illustrative of what we have said is to be found in a paper read by Mr. F. C. Beach at the last meeting of the Society of New York Amateurs. Mr. Beach read a letter from a correspondent, in the course of which he (the correspondent) cites things which would have borne very hard upon the maker of some plates he had used. The story is briefly thus: The gentleman in question had had a most untoward experience with his plates that were specially prepared for him. They turned out to be, he said, "a sad disappointment." The gelatine dissolved off in the developer in spite of ice. There was no frilling, but the film simply soaked off, leaving a large margin as clear glass. But he then put on his considering cap, and having left six of the quantity undeveloped he treated them with a developer differing from that hitherto employed. Although it does not bear upon the principle of the question now under discussion, we give his last thought of developer:

Ferrocyanide of potassium ...	1½ ounces avoirdupois.
Carbonate of potassium	1½ " "
Carbonate sodium (dry)	1 ounce "
Sulphite sodium crystals.....	2 ounces "
Hot distilled water to make...	10 " "

This proved very energetic in its action, half as much as the usual amount of potash solution being sufficient to easily develop the plate, while it was advisable also to employ a few drops of a ten per cent. solution of bromide of potassium to restrain.

With this modification he succeeded in obtaining from the six plates fine "snappy" negatives, free from the annoying fog that had spread over all the other deteriorated plates, with clear shadows and the high lights of that soft creamy grey that so delights the eye and prints so well in the wet-plate process. If potash and soda are alone used, the film seems to possess a cold, hard, grey colour, but the addition of ferrocyanide appears to give it a warmer, creamier grey. This formula, it seemed to the writer, should be further experimented with.

Now, this is a case that is directly to the point. The same plates which had produced fog and other evils, when thoughtfully treated yielded snappy negatives, having clear shadows and excellent high lights.

We might say much more relative to this, but it is not necessary. We know a good deal concerning the care exercised by plate makers both in this country and America to ensure the best possible class of production finding its way into the hands of the consumer; and, from what we know, we think it would be an exceedingly ill-judged action to hold them responsible in a court of law for deficiencies in plates which, if traced to their sources, would be found to be due to the operator.

SOME months ago, in our issue for April 29 of the present year, we called attention to a method of intensification by means of gallic acid and silver, introduced to the members of the Philadelphia Photographic Society. This process, which proved an absolute failure in our hands, presented certain anomalies which led us to believe that it had been incorrectly reported, or that some essential step in the

operations had been omitted. From a report of the last meeting of the Philadelphia Society, however, we see that the same process has been again on the *tapis*, and that it remains in a practically unaltered form. The strength of the stock solution of gallic acid is reduced one-third, and the composition of the preliminary acid bath is changed slightly, but for all practical purposes the process remains the same, and in the hands of some of the members of the Society is said to work well. We shall be glad to hear the experience of others on this side. Meanwhile we reiterate the doubts we previously expressed as to the practicability of the method. The strength of the gallic acid solution, even as reduced, and the quantity employed, are abnormal, while the acidification of the film itself instead of the gall-nitrate solution, seems to us scarcely conducive to clean and successful intensification.

Those who wish to secure autumnal effects in foliage should lose no time in obtaining them, or it will soon be too late. Although many of the trees in the immediate neighbourhood of London have lost their leaves, this as yet is not the case in country districts. If photography could but render the glorious tints now to be seen whenever the sun is shining on the trees, what magnificent effects might be secured. Orthochromatic plates will, however, aid considerably in rendering the delicate tints in their true relation. A few days back we were shown some views, taken in duplicate, on ordinary and on orthochromatic plates, and the distinction was very marked indeed. Those on the ordinary plates showed but very little difference, if any, in the variety of tints on the leaves, as, for the most part, they appeared of one uniform tone—the pale yellows and the darker colours being about equal. Not so, however, with the orthochromatic plates, for in these there was a well-marked distinction, and they depicted the varied tints in something like their proper relation. Even orthochromatic photography still leaves much to be desired in rendering the gorgeous autumnal effects, yet, on the whole, it cannot be denied that it is a vast improvement.

As the lantern season is now fast approaching, amateur photographers will be setting to work to prepare slides from the negatives taken during the past summer. Many are, doubtless, at the present time undecided as to the process they shall employ. Those desirous of avoiding all the trouble possible will probably adopt one or other of the commercial plates sold specially for the purpose. These will certainly—or at least such of them as we have tried—yield excellent results. Some, however, who do not mind a little extra trouble, will, perhaps, prefer collodio-bromide; and it must be admitted that, during the last few years, some of the best slides which have been shown on lantern nights at the Metropolitan societies and clubs have been by this process. Amongst amateurs, the wet collodion process, which, by the way, is capable of giving admirable results, now finds but little favour; and, except for making slides on a commercial scale, we suspect it will be but little used in the future for lantern pictures.

If it were not for the trouble involved in the preparation of the plates—after all, it is more imaginary than real—we suspect the albumen process would be more extensively employed than any other. It is the first process by which lantern slides were made, and for quality, and the variety of tones obtainable, it has never yet been surpassed. Compared with purchasing plates ready for use, of course, the albumen process does seem troublesome, as it involves several operations before the plate is ready for exposure. First there is the preparation of the albumen; but this a very simple matter, and sufficient may be prepared at a time to last many months. Then there is coating the plate with collodion, washing it, and then applying the albumen, and afterwards drying it. Next the plate has to be sensitised, washed, and again dried. The development differs somewhat from that of dry plates generally, although it involves but little more trouble, while, at the same time, it is more completely under control. The toning of the transparency does not differ materially from toning paper prints. The foregoing brief outline of the process may make it look complicated, but, as we have indicated before, it is not really so in practice, as all the work, up to the final sensitising, can be done in open daylight. If good albumen plates were, like gelatine ones, articles of commerce, we doubt not but that they would be

extensively employed by amateurs. Until they are, we surmise that only a very limited number will, as hitherto, go to the trouble of preparing them for themselves.

THERE are to be seen in many of the shop windows of those who make a speciality of the portraits of actresses some novel, unique, and somewhat eccentric examples of lighting the sitter. In some of these the model is lighted, for the most part, from behind, in others from the side and back, and in some from the top. In many of the pictures there is evidence of artistic treatment, but in others the reverse—novelty evidently being the end sought for rather than art. When the late Adam Salomon's work, which owed so much to the skilful lighting of the model, was first shown here, most of our older readers will remember the rush that was made for similar effects by some English operators—and the result. Again, when the so-called Rembrandt lighting was introduced, what libels on that famous artist's name were produced—and, for that matter, are still—by unskilled operators. It is to be hoped that the peculiar lighting to which allusion has been made will not be emulated, except by those who possess some artistic knowledge, otherwise it is impossible to speculate on the monstrosities in photography which we may ultimately have inflicted upon us.

It cannot be too strongly impressed upon all who aim at permanency in gelatino-bromide paper pictures the necessity of thoroughly freeing the prints from all traces of acid before they are immersed in the fixing bath. Unless this be done—and done completely, too—sulphur compounds will be formed in the picture, which no amount of after washing will eliminate, and which, of course, will considerably jeopardise their stability. We once more recur to this subject, as we recently saw some pictures being made in which this precaution was completely ignored. The prints, after development, were simply rinsed in the most careless manner possible, and then transferred direct into the hyposulphite of soda solution. Here they were allowed to remain for such a time as only sufficed to remove the bromide. If bromide pictures are made in this perfunctory manner, who can wonder if, after the lapse of a year or two, they show symptoms of evanescence? Most careful operators now consider that gelatine negatives should be left in the fixing bath for a much longer time than is actually required to dissolve out the unaltered bromide, in order to secure permanency. Surely, if this necessity exists in the case of negatives, it exists to the same extent in the case of paper pictures.

THE PHOTOGRAPHIC EXHIBITION.

V.

CAPTAIN ABNEY, R.E., F.R.S. (Nos. 307 to 312), *Merligen Thunersee*.—This is one of six exceedingly interesting views in Switzerland, because they show something else besides the tops of mountains, and help to convey a most satisfactory idea of the locality. In these pictures this seems to have been the intention, and well has it been carried out. Snowy distances have been contrasted by masses of near dark objects, and very beautiful and delicate work pervades the series, both photographic and pictorial.

T. M. Brownrigg (Nos. 316 to 322), *Goschenen*.—This picture of Swiss scenery contains some good points of treatment in development, although pictorially it is merely a transcript. No. 321, *A Bridge at Florence*, becomes another valuable record of the olden time when houses were built on bridges; it suggests a gloomy period of time, and has a "Canaletto" look about it. The other pictures are not quite up to that quality of work which this indefatigable exhibitor has of late years produced.

Robert Faulkner (Nos. 327, 328), *Portraits*.—Two frames of children, one with silver prints, the other with red. The same quality of work is here shown with which we have been familiar for many years past, soft and delicate in treatment; but the subjects are not so young as they hitherto have been.

G. Watmough Webster (No. 334), *Skylarks*.—We notice this picture simply to remark that photography, which attempts the copying of almost anything, is a little beyond the mark in attempting

to represent a scene which is not a fact. The picture, which is rather large, represents a skylark actually flying down from the sky to its mate in the nest. It is very cleverly arranged, but it would have been far more effective if a darker background had been introduced, otherwise the picture is very unique and attractive.

R. H. Lord (No. 338), *Osier Peeling*.—This is another direct large picture in platinotype, and technically is very good. It is simply a record of facts, a woman peeling an osier, and makes no pretensions on the art side. The whole work suggests how very useful photography can be in conveying correct notions of many industrial operations. We can imagine how deeply interesting a collection of such pictures would be, and it would be wise if photographers would assist in this direction.

W. Cobb (Nos. 339 to 346), *Views of London*.—These are most certainly the best instantaneous photographs ever produced by this exhibitor, who has made this work his speciality. Two points arrest our attention in these interesting views in London—one is that the point of view has been most carefully studied and selected, the other is the atmospheric condition, which has also been well chosen; the result is a series of very choice and effective bits of the Metropolis. There is one outcome of these instantaneous photographs which is curious, it is that moving figures seem as if they were suddenly arrested in the act of gliding, arising from the suspension of that undulatory movement which belongs almost exclusively to Man.

G. P. Cartland (No. 348), *Cattle*.—There are several photographs of bulls in this frame, which have been very well managed, being rather difficult subjects; and a matter which should be especially studied is the background where buildings are used, sometimes dark portions of which seem to belong to the animal.

Simeon Norman (No. 349), *Studies*.—The title is quite correct. These are pretty bits, not pictures. At the same time, the technical treatment is so perfect that we can only hope to see in the future the same good result in connexion with works of a much more ambitious character.

Seymour Conway (No. 350), *Views, North Wales*.—Here we undoubtedly have pictures, from the nature of the extent of subject matter included, and the points of view have been well chosen with regard to effective foregrounds. The outline of the distant mountains is rather hard; this detracts from their otherwise almost perfect rendering, and from the juxtaposition of each picture, there being four, they would have been increased in value if each had had its own frame. Why do not exhibitors consider this matter?

R. B. Berry (No. 351), *River and Waterfalls*.—Six small pictures exceedingly good in their technical treatment, considering the very short exposure each must have had to produce so free from white patches the various falls of water, both near and distant. If similar work could be obtained in photographs double the size some charming pictures would be the result.

J. Blain Scott (No. 353), *Miss Fales*.—Another large direct portrait, the pose and arrangement of lines of composition being very nice and satisfactory. It is printed in a very good black platinotype colour, but we fancy that the background is a second printing from the light halo which follows the outline of one side of the figure. This almost discounts the good there is in the picture.

Henry Aubrey (Nos. 355, 356), *Babies and Animals*.—Two frames of difficult subjects. In the instance of the "Babies" we notice that the pose has been very carefully adapted to the social individuality of each little one, with the result of pleasing naturalness. In the animals we particularly observe the standing out of the subjects from the backgrounds and the perception of the right moment of time when to photograph the object, which implies a quick artistic instinct.

Robinson & Thomson (No. 360), *Pisa*.—A frame of fourteen very small photographs of Pisa. There are also two other frames on the walls of views in Italy, containing forty-eight subjects. All these can only be regarded as very pleasant mementoes of deeply interesting places where photography by its realistic capability takes away much of that sentimental halo which artistic individuality has so often given to places of historical interest; yet at the same time these little pictures confer a vast amount of pleasure, because each observer can now exercise his own individuality of sentiment.

William England (No. 362), *Street Views of London*.—This frame and two others contain small photographs taken from a tricycle.

Here we have work by this well-known exhibitor which constitutes a departure from his usual Swiss scenes. The realistic part has been enriched by choosing moving objects, when they were in a position to add increased value to the streets and buildings depicted.

Benjamin Wyles (No. 369), *Sea Birds at Home*.—A frame of several photographs of sea gulls taken whilst flying. Really at this advanced stage of rapid dry plates and appliances there can be nothing very extraordinary in giving rapid exposures. Now if these birds could be taken with the light behind the camera with some dark clouds, causing them to be much lighter, then possibly something approaching the artistic might result; at present these birds are not of much value.

Dr. P. H. Emerson (No. 402), *The Poacher*.—There is a great amount of thought in this photograph. Just as the dawn is breaking a poacher stands, with hand on his dog, just ready to urge him on the instant the coveted object is visible. The poacher's head rises just above a very high horizon into the lighter sky, all the other parts of the picture being kept to one uniform tone, which is very low. All this suggests a kind of monotony which, however true in real life, is not very pleasant to contemplate; and, after all, the truth involved does not seem fitted for photographic production, because it is hardly possible that any photograph at all could be taken at that early time of day. However, let that pass. In all these attempts at low toned pictures we cannot but miss the suggestive influence of colour, and, therefore, we think that sentiment should be attempted more on the side of brightness rather than darkness. This picture, to which a medal has been awarded, has been printed in platinotype.

J. B. B. Wellington (No. 412), *Studies*.—Eleven small studies are comprised in this frame. They are all very well chosen; the size of the figures, to the amount of the surrounding objects, is exceedingly good. This is a matter which is not so much thought of as it ought to be, and, therefore, the more to be praised when we find it. Hence these photographs are real studies, because much thought has been given them. They are in platinotype, but the colour is not pleasant. Also if some of these pictures had been warmer in tone they would have been more artistic. A medal has been awarded these photographs.

Payne Jennings (No. 421), *On the Norfolk Broads*.—Another series of ten platinotypes. It is a long time since any work by this exhibitor has been seen at the Society's Exhibition. We welcome his return, but at the same time we feel that these pictures before us do not quite satisfy our expectations. The scenes chosen involve, in many of them, the leading line becoming almost a straight horizontal one, and as these ten pictures are mounted very close together, they run one into another. Photography this year has leaped up so much in its art side that these subsidiary (although at the same time powerful for good or evil) matters must have closer attention given them. We again think that the same colour is not appropriate for every picture.

School of Military Engineering (No. 425), *On the Thames*.—Three views in platinotype. The standpoint of view is not so good as it might have been, and we think that the charm of the original scenes is owing to their colour, which becomes lost when rendered in monotone, and that of a steely grey tint.

G. Renwick (No. 431), *Will it Bear?*—This is one of those wintry snow pictures which this exhibitor is making his special study. At all times they are very difficult to treat, and possibly when done are not always appreciated. Here we have an intention in relation to a wintry day which is appropriate. Distant trees in mist, a frozen river, two boys on a snowy foreground, suggest the title. Technically this has been well carried out, and appropriately printed on bromide paper.

Edmund Hyde (No. 437), *View on River Kid*.—Although this is an enlargement, yet we notice the picture on account of its evidencing some thought in selecting the point of view. The buildings and detail are commonplace, but a good effect has been obtained by bringing in a tree on one side which gracefully harmonises with the other parts and makes the distance retire.

Captain Abney (No. 439), *A Chill November Day*.—This is an English scene on a river, and the quietude of everything depicted makes it expressive, which is intensified by being in platinotype of a grey tone. But there is one drawback, and that is, some stems of a pollard-tree are all equally cut by the top line of the picture. This

might have been avoided by making the picture an upright one, where the stems naturally would get smaller in size.

J. Blain Scott (No. 451), *Study from Life*.—This is a very good attempt at making a picture out of a single figure, the pose, profile face, and nearly back view being very effective; but where the lines of the figure are equal in extent, then the background must be well arranged so as to carry out, harmonise, or contrast with the figure lines. Now this has not been attended to in this picture, and we therefore have three sections, viz., one central figure and two background bits. One single large leaf touches the figure. Why were not other large leaves introduced, which would have assisted the composition?

B. G. Wilkinson (No. 475), *Fishing Boats*.—Three very pretty small pictures, where selection of the position of the vessels has been very artistically studied. These photographs are very luminous. Indeed, it appears that all this class of subjects are well adapted for photographic purposes, owing to the reflective power of the water, which confers such a bright effect when technically well treated, as these pictures are. There is also another frame (No. 476) by the same exhibitor, containing four landscapes with figures. These are well selected, and remind us of the work of a well-known exhibitor.

John Terras (No. 492), *Darning*.—A photograph like all the work hitherto shown by this exhibitor, where everything has been sunned down to a very low scale of tone, except the face, upon which the eye always rests. This is very much after the style of the Dutch painters of *genre* pictures, but, as we have frequently observed, a great compensatory balance has been effected in painting by colour, which idealises the commonplace matter, but which is not realised in photography. There is much thought and skill involved in the picture before us, nevertheless it is rather gloomy in result.

THE APPARATUS.—IV.

A LARGE and imposing show-case of lenses on the table bear the names of T. S. & W. Taylor, Leicester (not Manchester, as wrongly given in the catalogue) as their makers and exhibitors. The casual visitor may look at but he cannot handle them, as a plate of glass intervenes between these optical treasures and meddling fingers. This is always a wise precaution to take where lenses are concerned, not alone because there may be an occasional visitor whose ideas of *meum* and *tuum* are loosely defined, but also because it is an almost invariable habit of the mere *dilettante* loungee at such an exhibition to rub his or her fingers over the surface of the polished glass with an admiring observation as to "how very smooth it is!" More fortunate than the class referred to, we have been afforded an opportunity of submitting these lenses, through the mediary of one of them, to any practical test we cared to apply. Our remarks at present apply to one of the rapid doublets of the Steinheil type. It is composed of two identical combinations, and thus being symmetrical with Waterhouse diaphragms midway between the two, it is rectilinear.

Having an equivalent focus of thirteen and a half inches, and working with the full aperture, and the lenses being one inch and three-quarters in diameter, it goes without saying that it is quite entitled to be termed "rapid," more especially as the glass of which the lenses are made is colourless, and the surfaces well polished. The diaphragms are stamped both with the "f" system, and with the Standard or U. S. System of the Photographic Society, and range from $f/4$ up to $f/256$. It needs only to add that the definition with full aperture is most excellent. It is for 10×8 plates.

The exhibits of Messrs. Watson & Son embrace a novelty for retaining the shutter of the dark slide closed. It consists of a brass spring lying across and outside of the part of the shutter which has to be laid hold of by finger and thumb. Now if we consider that it is impossible to grasp the projection without pressing upon the spring, and if we further consider that a projection on this spring, formed by lending it over at a right angle, catches underneath the shoulder of a screw in the slide, it will be readily conceived that the mere act of drawing out the shutter releases the catch by which it is otherwise retained in its place. All these being outside of the dark slide, no cutting into the latter is necessitated, and consequently no admission of light to the plate can take place.

This arrangement for securing the shutters is a great improvement, as regards convenience and security, on the pieces of bent wire

ordinarily used to prevent the shutters from unexpectedly sliding out, and cannot fail to recommend itself to all photographers. It is also a great advance on any other kind of spring hitherto made in this country, inasmuch as it does not require any portion of the frame of the slide to be cut away to attach it, but is fixed quite on the outside of the frame.

Another novelty of the Messrs. Watson consists of check pieces screwed on the shutter in such a way as to project in the groove in which the shutter slides and catch against pieces fixed in the groove. The effect of this is that there is no projection whatever on the face of the shutter, as in those in common use, and which necessitates this dark slide being a little more bulky than there is a real necessity for.

EVERY AMATEUR HIS OWN PRINTER.

AN old exhibitor at a certain Society which I will not specifically name, recently complained that the bad quality of his prints lost him a medal. How far correct the assumption was it is, of course, impossible to estimate; but one thing is very sure, namely, that if this gentleman, instead of "putting out" his printing as if it had been washing or mangling, had spared the time to do it himself, there would probably have been no excuse for grumbling at anybody's expense but his own. As we have again arrived at the period of the year that ushers in the time during which the greater number of photographic exhibitions take place, the occasion may perhaps serve for directing renewed attention to a subject of such supreme importance as the printing from amateurs' negatives.

It has been a reproach often enough levelled at non-professional workers that they are addicted to shirking what is, all things considered, the most difficult department of photography—the most difficult, that is, because it calls into exercise the utmost nicety of judgment and taste. That reproach undoubtedly has a respectable substratum of truth about it. The endeavour to set up a justification for it does not, however, fall within my present scope, unless I may premise with Mr. Dunmore, in his admirably digested article entitled *Photography and Photographers*, that this same department of printing is a succession of operations, the importance of which is not so generally appreciated as it should be; or with Mr. Bolton, when he truly remarks upon the scanty number of negatives that are worth printing from. Still, there is one point in this connexion to which I would, in passing, refer, and that is the extreme likelihood that with the majority of amateurs the labour and pains necessary to securing a passable negative are so exhausting, that they find it easier, cheaper, and occasionally more satisfactory—save in such instances as I have quoted—to delegate the printing to those who specially cater for that class of work. At the same time, while it is indubitable that it is only the few among amateurs who do their own printing in its entirety, it is just as certain that a large number of professionals habitually resort to the good offices of the trade printer, so that in reality the reproach covers a larger area than is generally admitted. There is, however, this difference in the end attained, although the means are coequal, that a professional photographer's negatives, being chiefly portraits, seldom, if ever, err greatly either on one side or the other of a certain fixed standard of printable quality, and that in the ordinary circumstances of commercial dealings with the trade printer, the photographer is not slow to reject prints that betray a lack of uniformity or any technical defect; whilst the amateur's negatives are, by comparison with the professional, few and intermittent, of variable density, and, in many cases, utterly worthless unless specially treated by the printer and given, what in the ordinary course of things they rarely receive, individual and particular attention.

With many amateurs it is customary to take prints from their negatives and get the printer to tone them. This class seems to be on the increase. Of course time and trouble are saved, but I maintain that such a method is opposed to the cultivation of just those qualities that go to form the finished photographer; for unless a man can print and tone, and, what is more, exercise at command the latitude of power contained in those operations, he can have little or no legitimate claim to the title. There is also another class which has been assumed by many to be nearly, if not quite, extinct, namely, amateurs who merely expose their plates, and get somebody else to develop the

negatives and print from them. This is photography made easy with a vengeance. One has no right to quarrel with amateurs of this kind, for this is a free country and it makes it good for trade, although any one such must have considerable applause and much faith in the credulity of his friends to dub himself an amateur photographer. The class of semi-photographers who avail themselves of other people's skill and abilities numerically the strongest, is that whose members do everything but the printing. Besides these there are others who make the reduction of labour a life study—in particular, those who never even fill their own slides when they can help it. A gentleman of this description (an eminent lawyer) was once going abroad, and, amongst other things, commissioned his dealer to fill his slides for him. The matter was overlooked, and the Q.C. did not find out the omission until he was seven thousand miles away. When he came home he wrote an indignant letter to the papers. This is one of those small things that are best done by one's self. And so it is with printing, although that is not a small thing—far from it.

Amateurs' negatives, as I have already said, are generally of variable qualities. As a rule, they require to be watched. Now, trade printers like watching negatives about as much as the small grocer likes selling you a pound of sugar without any tea—it doesn't pay. A man with a hundred and fifty frames to attend to isn't likely to neglect a hundred and forty-five of them containing good negatives on purpose to devote an unreasonable amount of attention to the remaining five. He lets them take their chance, I imagine, for photographs are not like the ninety-nine sheep—they won't stand still while search is being made for the stray. Some negatives are so dense that they want four or five days, say, in autumn, to give one print; others are so thin that they can only be printed in a certain light and behind screen of tissue paper; others have to be done sectionally, such, for instance, where there is plenty of detail in the middle distance whilst that in the foreground has not been developed out. To mention the broken negative from which a print *must* be got by hook or by crook is to raise dismal recollections in the mind of the trade printer, I'm afraid. There are also negatives from which not even the surface hypo has been removed; others that have markings and scratches which must upon no account appear in the print—finger marks, streaks of fog, stars, and all the rest of the long train of diseases to which many amateurs' negatives are subject, and from which those of professional men are, as a rule, entirely free. It will thus be seen that, although in the trade there are many printers who lay themselves open to print for amateurs, it is a department of photographic industry which is not so satisfactory as it might be—especially to the printer.

That amateurs are often dissatisfied with their prints as received from the trade printer is one of the most cogent arguments I could select in support of the advocacy that they should do their own printing, just as they select their own subjects, make their own exposures, and do their own developing. Of course there are occasions when it is imperative that they should seek outside assistance, as, for instance, when a large number of prints are required in a hurry for a bazaar or a presentation, &c., but even here, by the duplication and multiplication of the negative, it might be often found practicable to dispense with the aid of the professional printer. In general, however, it may be laid down that the more an amateur relies upon himself and his own powers, latent or otherwise, the less his ultimate dissatisfaction is likely to be. I do not say that he will prove, *pari passu*, one whit better or cleverer than the man who has to get his living by printing. What I do insist upon, however, is that he can afford to give the time, the attention, and the particular treatment demanded by them whilst his prints are in progress, which the professional man cannot. In the case of dense and thin negatives, such attention is vital to the success—the proximate success—of the print. The best and most accomplished amateurs amongst us—those whose names will readily occur to memory—would as soon think of turning over their printing to anybody else as they would of handing the keys of their dark rooms to a domestic with a request that she would step up and develop the plates exposed last month in Switzerland. It seems to me that not sufficient stress is laid upon this important branch of photography; that, in fact, we haggle so much over the quantitative constitution of a formula for development, &c., and are so prone to regard a good negative as the aim and end of all our efforts, that the after process of printing is left to

take care of itself, which, as it comes at the tail of a lot of other operations, is a very poor care indeed. That, by comparison with the number of even good negatives that are produced the number of prints is amazingly small, everybody knows. There is, none the less, obvious room for improvement in the prints we do permit ourselves to take, and the way to bring it about is not by placing the matter in the hands of a second person whose interest in the results is justly only gauged by a pecuniary measure, but by adopting the course of procedure most common in the cases where one wants a thing done well and doing it one's self. Printing from the negative is not easy if good results are sought for, and like everything else from which an ultimate measure of satisfaction is desired, it demands time, care, and attention. And as it is unreasonable of us to expect the trade printer to devote a larger *quantum* of these great qualities to us individually than is commensurate with the extent of the orders with which we favour him—which are generally ludicrously small—the readiest solution of this, an old difficulty, is to make up our minds to do our own printing—and to do it.

MARSTON MOORE.

THE GALLIC ACID AND SILVER NITRATE INTENSIFIER. —HYDROKINONE AS AN INTENSIFIER.

[A Communication to the Photographic Society of Philadelphia.]

THE best method of obtaining the proper density in a gelatine negative is undoubtedly proper exposure and development. But even the best manipulators will sometimes be deceived in the printing qualities of a negative, and I believe most all who have used the wet plate process have often longed for some intensifier like the old iron and silver, or pyro and silver, and no doubt many have tried to intensify gelatine negatives by the same method, but encountered the disagreeable foe, red stain, and abandoned its use.

Now I feel convinced, from a number of experiments made, that iron, pyro, or gallic acid and silver can be used without any danger of staining if the film is thoroughly washed and rendered slightly acid before attempting intensification. If the plate is bathed in the iron and acid, pyro and acid, or gallic acid and acid solution for a few minutes, and the solution then poured back into the graduate and the silver added and flowed back over the film, there will be very little danger of staining. Nitric, acetic, or citric acid can be used with either of the above reducing agents.

By this method a negative can be strengthened before fixing as well as after. In the first case the plate should be well freed from the developing solution, in the latter case thoroughly washed to remove all traces of hypo. To intensify a negative before fixing can only be necessary when handling plates extremely poor in silver, as otherwise the desirable strength can be obtained in the development.

Now to come to the gallic acid and silver intensifying process published by Mr. Bartlett and Dr. Wallace, I must say that after many experiments in this direction, I have adopted the same, as it has proven the best of all in my hands.

By using the preliminary bath of

Perechloride of iron	4 grains,
Chromic alum	2 "
Citric acid	4 "
Water	1 ounce,

we have at once a clearer, an acidifier, and a destroyer of the last traces of hypo.

The perechloride of iron (Mr. Bartlett's suggestion) has been added mainly for the last object, and also to improve the resulting colour of the negative. In ordinary temperature double the amount of citric acid can be used and the alum dispensed with. In extreme warm weather, and when dealing with plates inclined to frill or soften, it is best to pass them through an alum bath and to dry them before subjection to this process.

Attention should be paid not to carry the intensification too far, as the negative will gain intensity on drying. The negative should not remain too long in the preliminary bath, so as to allow it to bleach, unless handling a negative slightly fogged or over developed; in this case it is advisable to permit the plate to slightly bleach. The dish containing the solution should be gently rocked to prevent a net marking, which otherwise is apt to occur.

After taking the negative out of this bath, it should be well washed for several minutes under the tap, and the gallic acid and silver, as per formula, flowed over it:—

Gallic acid	80 grains.
Alcohol	1 ounce.

B.

Silver	40 grains.
Water	1 ounce.

One drachm of each to two to three ounces of water.

When the negative has been allowed to bleach, intensification will have to be carried further, as the underlying image has been converted into a chloride of silver, and consequently would dissolve in the subsequent hypo solution. By carrying the intensification just to the right point, the negative, after leaving the hypo, will prove free of fog, and have brilliant lights and clear shadows. Sometimes it will prove advantageous to flow the negative, when taken out of the fixing bath, with the clearing solution. It is needless to say that the plates should be well washed.

Recently I have made a few experiments with hydrokinone in place of gallic acid:—

Hydrokinone	60 grains.
Nitric acid	2 drops.
Water	6 ounces.

Half an ounce of this diluted with two ounces of water, and one drachm of silver solution added. Plate also previously acidified.

The action of this intensifier is somewhat slower, but the resulting colour of the negative is a rich black in the opaque parts, and even a plate, pyro stained to the colour of a lemon, was converted into one of a rich grey after subjection to this intensifier. I believe hydrokinone and silver will prove an excellent intensifier and toner for window transparencies.

JOHN G. CASSEBAUM.

THE AMERICAN ECLIPSE EXPEDITION IN JAPAN.

AFTER several weeks of travelling in the interior of Japan I find myself at Shirakawa, which is the station selected by the Americans for the eclipse expedition. I am not aware that any one is sending any account to the English photographic papers of the arrangements made here. I therefore write a few lines, although the prospect at present—about two hours before the time of totality—is very poor, the sky being completely overclouded.

The American expedition is under the direction of Professor D. P. Todd, of Amherst, who is assisted by Professor Hitchcock of the Smithsonian Institute, Dr. Holland the naturalist, Dr. King—a lady graduate of the New York Medical College for Women—and various others. It is by the kind invitation of Professor Hitchcock that I am here. As Mrs. Hitchcock and Mrs. Todd take part in the work, it will be seen that the Americans fully appreciate the assistance that can be rendered by ladies in scientific work. The site selected for the temporary observatory is an old Japanese fort or castle built on a piece of rising ground. It, as well as the whole country around, is remarkably picturesque, but as I shall have something to say of both in a general description of my travels through the interior of Japan, which I hope to have the pleasure of sending to England before very long, I give no description of them here.

The greater part of the energies of the expedition are concentrated on obtaining large photographs of the corona during totality. The members of the expedition have been fortunate enough to secure a lens of very great focal length. It is a single combination, presumably formed after a telescope formula. The diameter is very small comparatively, only about six inches, but the focal length is about forty feet. As every foot of focal length gives rather more than one-tenth of an inch diameter of an image, the subject got by this great lens will be rather more than four inches. The arrangement of the apparatus is as follows:—The lens is at one end of a horizontal tunnel, and at the other end is built the dark room. This is roomy, contains developing sink, &c., and a stand opposite the end of the tunnel for receiving the sensitive plates. This is, of course, capable of adjustment. There is an arrangement within the dark room for opening to make the exposure, so that everything except the heliostat which keeps the image of the sun directed on the lens is within control of the operator in the dark room. The stand for the plates being within the dark room there is no need to trouble with dark slides, &c. A plate is simply taken from the bath and is placed on the stand.

I should mention that Mr. Hitchcock has elected to use wet plates. He considers that even with the small aperture of lens he has (say $\frac{1}{16}$), the exposure on them will be ample.

I have seen images of the sun taken by the instrument. These are very good, but show a just perceptible falling off of sharpness at the edge of the disc. This, I was told, is due to want of perfect atmospheric clearness. Probably it is, but in Japan a factor must be reckoned with, which possibly is peculiar to the country. Professor John Milne, F.R.S., who has done more than any other to investigate the

subject of earthquakes in this country, has discovered that there is a variable but almost continual earth vibration quite strong enough to be recorded and measured by delicate instruments. Of course this must somewhat interfere with the definition given by the very best long-focus lens. I believe this remarkably interesting phenomenon has been investigated so far only in Japan, so that it is not yet possible to say whether it is of volcanic origin, or whether a vibration so great as to be readily recordable exists on all so-called "firm land." Professor Milne's own opinion is that it is due to wind—a vibration being first produced by wind on mountains, and afterwards conveyed through the earth. If this is the case the phenomenon will probably be found to be common to all mountainous countries. May it be that this factor, so far as I know not yet taken into consideration by astronomical photographers, accounts in whole or in part for the great rareness of a successful photograph of the moon on any large scale?

At the temporary observatory here, both the objective and the stand holding the plates are placed on solid foundations made of great blocks of granite, so that all possibility of vibration has been avoided so far as possible. Besides this forty-foot telescope, a smaller one of about ten or twelve feet focus is directed towards the position that the sun will occupy during the eclipse. It is proposed, with this, to make very short exposures, so as to show the phases before or after totality. Several appliances were fitted up to investigate the distribution of light in the outer corona. The smaller of the two telescopes was fitted with one of these. The arrangement is one whereby a plate is exposed with in front of it a sheet of tin perforated with a number of small holes, it being considered that the variation of density can better be judged of by observing the small spots thus produced, than by examining the gradation of density that would result were no perforated sheet interposed. There was, however, fitted up a pair of cameras side by side, one provided with the perforated sheet, the other without it, so that judgment might be made in either way as desired. In the case of these cameras, as no fine definition was required, single lenses somewhat after the nature of condensers were used.

One more observation was attempted. Its object was to decide the amount of light during totality. Two appliances were fitted to accomplish this. One consisted simply of a series of apertures of the same size arranged in front of a sensitive plate. These apertures were to screen exposures of different lengths by opening a shutter in front of them, withdrawing it so as to expose first one aperture, then, after a measured length of time, to withdraw a little more so as to expose two, and so on. Another appliance designed by Professor Hitchcock consisted in an arrangement not very unlike that of Mucklow and Spurge's sensitometer. A certain number of cells, each ending in an aperture, were made of wood, forming a sort of honey-comb structure, the apertures varying in area, and the whole arrangement of cells and apertures was placed in front of a sensitive plate. Of course the portion of the plate forming the end of one particular cell would receive an amount of light proportionate to the area of the opening at the other end. Whichever appliance was used the results would, of course, require to be compared with those got by exposing plates of the same sensitiveness at a measured distance from a standard light. For all the smaller instruments dry plates were to be used.

Taken altogether it is probable that no more complete arrangement was ever fitted out for the photographic observation of an eclipse, and after all, as will, long before the time this reaches England, have been well known, to no purpose. All the scientific experts mentioned came several thousand miles to this country and worked hard for a month in fitting up their elaborate appliances, and then, all through a cloudy afternoon nothing could be done, or next to nothing. No observation whatever could be made during totality, and only a very few imperfect ones before and afterwards.

In spite of the fact that the corona was not visible at all, the experience of the total eclipse was an interesting one. The light waned very perceptibly for long before totality began; but the darkening when the moon completely covered the sun's disc was far more sudden than I could have imagined possible. It was all but instantaneous, and the sensation produced was very curious. The darkness was by no means as great as that of a dark night. I could follow the hands of my watch during the whole time of totality, but it was only by close observation. Then, when totality was over, the bursting into light again was as sudden as the darkening had been before, and there was a feeling as of relief, as if some depressing influence had been removed. In a second or two after the light returned there was a sudden rift in the clouds, and we saw a thin half-circle of light like a bit of silver wire. It was only for a second or two, but the sight was a very beautiful one.

There is nothing to be done now but for the members of the expedition to "pack up" and return to America, bearing their disappointment as well as they can. Bitterly disappointed they all must be except Dr. Holland, who has captured I am afraid to say how many thousand insects, or "bugs," as the Americans all call them. Japan must be a paradise for naturalists; it positively swarms with life.

To-morrow I shall make a photograph of the arrangement of the instrument; it may perhaps be worth sending as far as England.

W. K. BURTON.

P.S. (written on the 22nd August).—The results of the observations have, after all, not been so completely *nil* as I at first imagined. No coronal observations were made, but by the great lens several phases of the eclipse were photographed of such a nature as to enable precise measurements of the angular distance of the centres of the earth and the moon for precise times to be made, a thing which, it seems, is desirable. Moreover, Mrs. Hitchcock obtained two very interesting photographs of the earth during the eclipse. One plate was exposed during the whole time of totality (three minutes), the other for twenty seconds, beginning thirty seconds after the termination of totality. The first photograph shows the landscape merely as a black mass against the sky, the second shows considerable detail. The lens used was one of the rapid landscape type, working at about $f/8$.

THE STANDARD OF DEVELOPER.

[A Communication to the Society of Amateur Photographers of New York.]

Nothing has stood more in the way of the amateur's acquisition of the best method of photographic manipulation than the confused and the confusing, muddled, misleading, and thoroughly unscientific way in which the formulae for developers have been made up. Whether these are to be found in the boxes of plates sold by the manufacturers, or on the pages of the works nominally intended for the instruction of the beginner, they are almost alike in their useless and senseless intricacy.

I brought the question of the possibility and advisability of our insisting upon a comprehensible and uniform method in the compounding of these formulae before a previous meeting of this Society, and having been placed on the Committee on Developers have given further attention to the matter.

A favourite plan of some reformers is the substitution of French for American weights and measures, and incidentally or independently, the use of ten per cent. solutions. These plans, one or both, have been pressed upon us as a correction of the difficulty, but they do not meet the case. We do not want a purely scientific manipulation, and the gramme will never be our Moses, nor foreign or unusual terms or scales guide us out of our wilderness. What we need is something for everyday use that the least experienced, equally with the most expert, can understand at a glance, employ with absolute certainty, and remember without difficulty. Talking in centimetres or multiplying by decimals is a useless confusion, and even when thoroughly mastered is only mere addition to the unnecessarily numerous differing tables which already bother the photographic mind. A percentage solution is not only an awkward combination to manage, but is so curiously inaccurate as to be nearly absurd. The percentage that a solid bears to a liquid is as droll as the view of the blind man who said that after much study he had discovered that the colour scarlet was very similar to the blast of a trumpet. A ten-grain solution, which is often mistaken for a ten per cent. one, would be entirely proper, but a percentage of hypo, or any other solid, to water is closely allied with the result of multiplying ten oranges by ten pears. Because there happens to be a fluid ounce as well as a solid ounce, it does not follow that there is a proportional relation between the two. Such a proportion if made should be by weight alone and accurately and not on the old cook's theory that a pint is necessarily a pound.

But what is needed in practical photography is a preparation which can be easily understood and quickly varied, while the proportions can be distinctly borne in the mind. Its constituent parts must be so separated that it can be strengthened or weakened from the point of view of effect on the latent image. The ordinarily accepted proportions of the materials of a pyrogallic developer are two grains of pyro to one ounce of water, combined with about eight grains of sulphite of soda, the latter being merely to keep the plate clear of stains. Both of these substances are perishable and deteriorate rapidly in water. To these are added about twelve grains of crystallised carbonate of soda or half the amount of potash for a working developer. Pyro has been used undissolved, but it was found that the same thing had to be done with the sulphite or that also would lose its power. The sulphite and the pyro go well together, but need a preservative. Amateurs are apt to keep their developers too long, and the best of preservatives lose their effects after a time. Nothing else is absolutely

needed in a developer except occasionally bromide as a restrainer, and this is to be added only by drops. Of the principal ingredients, however, the proportions have often to be greatly changed, and opinions differ widely as to the nature of this change. For instantaneous pictures some persons double the amount of pyro from the standard formula, while others reduce it, and for under-exposures one man wants a strong and another a weak developer.

Now my suggestion is that we should determine on a certain formula of a fixed strength according to fluid drachms. Say we accept two grains of pyro to eight grains of sulphite in each drachm of the pyro solution, with enough sulphurous or other acid to preserve it. Then for the accelerator let us determine on, say, six grains of potash or twelve of soda crystals to the drachm. We can then mix our developer intelligently without the study of French grammes or the complication of decimals. Say we need a normal compound, we pour out a certain number of drachms from each bottle and fill up to an equal number of ounces of water in our graduate, and we know exactly how many grains of each constituent we have. If we desire an increase of either we can get it exactly by half drachms or less. Thus the quantity of water and proportion of ingredients would be constant, or, in other words, the ingredients would be compounded by drachms containing a fixed number of grains. Then if one manufacturer or manipulator is of opinion that his plates or exposures need more pyro, he can simply use, or direct to be used, an additional amount of drachms of pyro solution; or, if he wants more potash or soda, or a combination of both, he has simply to say how much he wants to the ounce of developer, and those who use it will know what they are about and escape from the present darkness of mystery into the light of knowledge. Suppose, further, that other ingredients are found to be beneficial, for instance, yellow prussiate of potash, the substitution or addition is entirely simple, and the effect can be ascertained readily and certainly. In this way the developer can be varied indefinitely and intelligently, and progress gained where now there is little more than groping.

There is an incidental advantage in the use of a small proportion of fluid in the solutions, that in warm weather the addition of water will bring the developer to the temperature of the others. Of course to make this proposal effectual it will be necessary to get the manufacturers of plates and compounders of developers to consent to adopt it; but this, or some other equally practical plan must be followed if we are ever to settle the much disputed question, one that it is probable amateurs alone are competent to settle: Which is the best developer?

ROBERT B. ROOSEVELT.

SOME NOTES ON THE HISTORY OF THE DISCOVERY OF THE GELATINO-BROMIDE PROCESS.*

WISHING to know more of the steps which had led Dr. Maddox to his admirable researches in connexion with gelatine and silver bromide, I ventured to address him on the subject, and received from him the following note, which, although intended primarily as an appendix to *History of Photography* that I have written (and which will shortly appear in book-form), yet ought, I think, to be laid before the readers of that periodical in which Dr. Maddox's original paper appeared:—

"PORTSWOOD, SOUTHAMPTON, August 19, 1887.

"DEAR SIR,

"In your favour of August 17 you express a wish 'to know more how and why my attention was directed to gelatine and silver bromide.' If you find the answer rather a complex one you must excuse it upon its threefold character.

"Firstly, the cost of the collodion, with the troublesome manufacture of the cotton; secondly, health more or less affected by its constant use when working, as I was, in my camera, a dressing-room, often at a very high temperature in the summer months; and, thirdly, dissatisfaction with the dry methods for the photo-micrographic work upon which I was much engaged.

"The first reason may be dismissed as of little moment when there was an adequate return upon the work done, but not so when there was an absolute loss even in an amateur's point of view. The second reason was a more important one. Being often shut up for hours in the said camera, the temperature at full summer heat, I found the system completely saturated with the vapour of the collodion, so much so, that it could be tasted in the breath on awaking in the night, and sleep was generally much disturbed and unrefreshing, while it was much needed to restore the nervous energy wasted by constant suffering, often very severe in character; moreover, there was an outcry in the household that the collodion vapour unpleasantly pervaded every room in the house. The third reason was that I could find no satisfactory dry or sticky process that did not embrace the first two reasons, and add another of its own

* Concluded from page 603.

in the shape of additional time and trouble in the preparation of the plate.

"These reasons set me experimenting, sometimes on paper, sometimes on glass, with vegetable gummy matters, as lichen, linseed, quince-seed; and with starchy substances as rice, tapioca, sago, &c.; and with waxy material as Japanese vegetable wax. Often I fancied I was just within the doorway when the door closed, and other plans had to be tried. All the literature I could find bordering on the subject was searched, but it rather bewildered than enlightened.

"At last I turned to the animal series and wasted many eggs and some little silver; then I went to the finest isinglass at about twenty shillings the pound weight, and the very first experiment led me to hope I was on the right track, only something had to be altered as I was using iodo-bromide in varying collodion proportions, and the isinglass did not appear to yield a sufficiently even surface in spite of all kinds of filtering; yet confidence was felt that a vein had been struck.

"Search was now made in the house for a packet of Nelson's gelatine; this afforded a better surface, especially as the plates were dried generally on a hot one-inch thick iron slab, and tested at once. Then came the mixture of isinglass and gelatine, but the advantages pointed to gelatine. The little plates were tried under a negative, then on out-of-door objects, but it was impossible to get some laurels depicted in anything more than black and white. I remembered that some one had stated that the bromides were better suited than the iodides for foliage; now came the experiment of diminishing the iodide and increasing the bromide, until it settled into bromide alone.

"Yet I was not satisfied, but experimenting went on so rapidly that often I did not wait to filter the gelatine before mixing the bromide of silver in it. Before this period, that talented experimenter, Mr. Carey Lea, had spoken of the use of *aqua regia*, and my attention was turned to it, fancying that its use would decompose some of the gelatine and furnish the extra silver a chance of forming an organic salt of silver which might possibly improve the image. After working with this, and getting more satisfactory results, various substances were mixed with the gelatine as gum, sugar, glycerine, &c., which gave different tints to the developed negatives, and it was seen that it only required farther experimenting to put gelatine into use; for some of the negatives were fairly plucky and half tones beautifully rendered, but compared with collodion the gelatine was slower, although it stood its ground with some of the dry processes.

"Paper had not been neglected, for amongst the paper trials with the gelatine was one which I thought gave much promise, the tint on development equal to much of the kind at the present day. This was obtained by the addition of a small quantity of arsenite of silver.

"There was no thought of bringing the subject into notice until it had been lifted from the cradle. Soaking the plates before use, for of course I knew the useless salts were left in the gelatine, was noted down for trial; but at this stage, and while in the very heyday of experimenting, there came an urgent appeal from my kind friend Mr. J. Traill Taylor to assist him without delay by an article for THE BRITISH JOURNAL OF PHOTOGRAPHY, of which he was the editor, as he had been taken seriously ill.

"Without a moment's hesitation, and thinking it would give my friend pleasure, the hurriedly written and fragmentary article that appeared in the September JOURNAL of 1871 was forwarded to him, and proofs of sundry negatives were also sent, some of which, almost entirely defaced, my friend Mr. W. B. Bolton and I found three or four years since amongst the glass in the office at No. 2, York-street.

"Another pen had also come to the rescue, and my paper was deferred to the following weekly issue, when Mr. Taylor, with far-sighted judgment, noted the process had a future before it. Health had now fairly broken down, rest was needed, so that very little farther experimenting was done, and as there were other irons in the fire demanding attention, the process was offered to a firm in Southampton from whom I used to get my albumenised paper; but it was found there was no time to continue the necessary experiments to raise the rapidity and enhance its value. This was done at different stages by others, almost two years after I had freely given to the public what had cost me much time and labour.

"The world has been benefited, and I have been honoured with a gold medal and diploma by the Jurors' Committee of the Inventions Exhibition. Do not for one moment suppose I ignore the work of other hands in perfecting the gelatino-bromide process, and thus giving it its world-wide value in all departments of photography, especially that far reaching one of its adaptation to astronomical research. I am only too thankful to feel that I have been merely the stepping-stone upon which others have safely put their feet, though now and then there cropped up the old story of the prophet in his own country; let it pass—this is the Jubilee year. I am grateful to those abroad and at home, who, like yourself, have recognised the original claim of—

"Dear Sir, yours most truly,

"R. L. MADDOX.

"W. JEROME HARRISON, Esq., Birmingham."

There is less need to follow the steps by which Dr. Maddox's work was perfected. In the latter half of 1873, J. Burgess prepared and sold "gelatino-bromide dry plates"—the first ever placed on the market—at half-a-crown per dozen for quarter-plates; and later on

R. Kennett—1874-77—made similar plates, that even now would be called "rapid;" but neither Burgess nor Kennett could make the process a commercial success.

In 1874, the Belgian chemist, J. S. Stas, showed* the effect of heat in producing molecular modifications of silver bromide, and declared that certain of these were "the most sensitive substances to light with which I am acquainted."

When Bennett, in March, 1878, showed that great rapidity could be obtained by "stewing" for several days the gelatine emulsion, he was practically applying the researches of Stas; and the work was completed when Maunsfield, in August, 1879, obtained similar results by boiling the emulsion for a few minutes.

In view of the great development of the gelatino-bromide process, it is pleasant to think that we have still with us the man who sowed the first seed. Photography proper now rests, we may say, entirely upon the labours of three great Englishmen—Fox Talbot, calotype process, 1841; Scott Archer, collodion process, 1851; Dr. R. L. Maddox, gelatino-bromide, 1871. It is to be hoped that at some not distant date English photographers will acknowledge that it is their duty to commemorate in some lasting form the labours of this illustrious trio. France has set the example by raising statues to Niepce and to Daguerre; but Talbot and Archer—to speak only of those who have passed away—are still unhonoured and almost unknown. Who will lead the way in this matter? We have a Society, a Club, and a Convention, all aspiring to the title of "National." Could they not unite for so worthy an object? Again, I say that it is our duty to publicly honour the men to whom we owe so great a debt, and of whom as our countrymen we ought to be so proud.

W. JEROME HARRISON, F.G.S.

THE FIRST GELATINE EMULSION DRY PLATE.

THE circumstance that the first gelatine emulsion dry plate was made by myself, and, moreover, was developed with alkaline pyrogallol, has just been unearthed and published in these pages by Mr. Jerome Harrison. The question arises why no claim for priority in this matter has hitherto been made in the course of the various discussions upon the history of the subject in photographic journals and societies. The truth is that, having forgotten that the experiment had been published at the time, and as the scientific world is agreed that date of publication and nothing else gives claim to priority, the best plan seemed to be to hold my tongue, rather than to seek for the reputation of Oloffe, the dreamer. This Oloffe once wandered about the banks of the canals of Amsterdam; he was ever ready for a glass of schnapps, and his solitary garment was never washed except by the bounteous showers of heaven; but he was a marvellous man, because nothing remarkable ever happened in Amsterdam without his telling the people afterwards that he had dreamt of it two days before. He was therefore engaged as sailor on board the Dutch ship fitted out to discover the north-west passage to China, that he might aid the explorers by his valuable dreams, which subsequently had a share in founding the city of New York, saith Diedrich Kuickerbocker.

The plate I prepared was coated with a genuine unwashed, uncooked gelatine emulsion, containing bromide and iodide of silver, and was dried upon a levelling stand. Perhaps it may be as well to give the full text of the record, in place of the few lines quoted by my namesake, from my article on *The Philosophy of Dry Plates*, published in THE BRITISH JOURNAL OF PHOTOGRAPHY of January 17, 1868:—

"I dissolved a few grains of gelatine in some water, and diluted the mixture to such an extent that the liquid, when cold, was slightly viscous, like collodion. A little bromide and iodide of cadmium was then dissolved in the gelatinous liquid, after which some nitrate of silver was added in the dark. In fact, I wanted to have a solution which would give a good dry plate by simply coating a sheet of glass with it, and allowing it to dry on the levelling stand—thereby abolishing baths, washings, and the use of collodion in the process. After the nitrate of silver was added the scheme was killed, for the gelatinous character of the liquid was destroyed (possibly by the nitrate of cadmium formed), and the precipitate sank quickly to the bottom of the bottle. Nevertheless, I shook it up well and rapidly covered a plate with a layer of the solution, leaving it then on the levelling stand to dry."

It is evident now that the proportion of gelatine used as above stated was too small to hold the precipitate in suspension. The record continues:—

"The plate dried in a few hours. It had a granular and not very even film, which adhered well to the plate. It was exposed in the camera and then developed by the alkaline method. The picture came out very

* *Annales de Chimie*, Fifth Series, vol. iii., page 289.

rapidly, and was of great intensity; such depth of colour would, in fact, have required twenty or thirty times longer development on a collodionised plate.* I have never seen a picture on a dry plate coated with collodion come out so well, but the rough and uneven film made the picture worthless. Encouraged by the first trial, I added gelatine to the solution in the bottle to bring it to the consistency of collodion again, but had to use many scruples of it before the additions overcame the anti-gelatinising property imparted to the liquid by the added salts. When at last the liquid reassumed the consistency of collodion, and was slightly warmed, several plates were coated and left on the levelling stand, where the film soon began to 'set,' and the plates were then placed on end to dry. Irreproachably even films were obtained. The only fault to be found with them was, that expose or develop them in what way you would, not a trace of a picture would these plates give. The developers would bring out no more trace of a picture upon them than if they had been plates of plain glass."

The explanation of this I now suspect to be that it was a case of wholesale fog. The experiments extended over two days, during which the silver salt, while in the bottle and on the drying plates, was exposed more or less to such bright yellow light as was employed in developing rooms in the old collodion days. Apparently a peculiar sample of gelatine was used, as bought at a neighbouring shop; in those days gelatine specially prepared for photographic purposes did not exist. Mr. Jerome Harrison suggests that the absence of a developable image may have been due to the weakness of the alkaline developers in use in the olden times. Possibly, also, the youthful adventurer forgot to put the pyrogallol in the developer.

Mr. Jerome Harrison also calls attention to the previous work of Mr. W. H. Smith, whose patent may now be examined.

Patent No. 1174, April 26, 1865, is granted to "William Henry Smith, of 12, St. Ann's-gardens, Haverstock Hill, in the County of Middlesex, for the Invention of 'Improvements in Photographing upon Wood, and in the Preparation of Wood, Canvas, Silk, Glass, and other Substances for the Purpose of Receiving and Retaining Impressions.'"

The body of the patent chiefly speaks of photographing on wood, which is first coated with a specified solution, which when dry fills up its pores. The inventor thus describes the preparation of the film upon which he photographs:—

"I next prepare a receptive as above defined, being an aqueous solution, which for sake of reference I call solution No. 1, consisting of twelve parts of gelatine and five parts of honey in 250 parts of water, and I allow this to decompose, and when reduced to a liquid state by natural decomposition I take one ounce of this and dissolve in it a chloride or a bromide (if chloride of cadmium, two grains), one grain of the tincture of iodine and one grain of tartaric, citric, or any other acid of similar qualities. This mixture I call solution No. 2. I then take another ounce of the aqueous solution (before referred to as No. 1), and dissolve in it twelve grains of nitrate of silver, and add the solution to the before-named solution No. 2; this forms the receptive which I call receptive No. 1 for distinction, and this I apply to the wood either with a brush or by floating the wood on a bath of the said receptive No. 1 for five minutes, more or less, and afterwards allowing it to dry."

He then prints upon this surface either under a negative or in the solar camera. In fact it is a "printing-out" process, upon a film formed of an emulsion containing decomposed gelatine, chloride of silver, and a great excess of nitrate of silver.

One paragraph describes how he photographs upon "glass" as well as other substances than wood. He says:—

"I apply a receptive, which I call receptive No. 3, consisting of one ounce of receptive No. 2 as a chloride or bromide (if chloride of cadmium, four grains), three grains of tincture of iodine, and one grain of tartaric, citric, or any other acid of similar qualities until the object is coated. I then sensitise the said coating by immersing it in a nitrate of silver bath containing thirty-five grains of nitrate to the ounce of water. I then withdraw the said object from the bath, and while still wet I coat it with an aqueous solution, which I call solution No. 3 for distinction, composed of ten parts of gelatine and five parts of honey in 300 parts of water, and when dry I print, tone, and fix, as before described for wood."

Thus in photographing upon glass he used no ready-prepared emulsion, but dipped his plates in a nitrate of silver bath, thereby obtaining a sensitive surface with a large excess of nitrate of silver, upon which when dry he printed and toned positive pictures. The process is much like that of printing upon albumenised paper, except that other organic matter than albumen is used. There is nothing in the patent about taking negatives, or applying haloid emulsions to glass.

From what has already been said it appears to be conclusively established that the first negative upon a gelatine emulsion plate was taken in January, 1863; also that there was no excess of nitrate of silver, and that alkaline pyrogallol was used in development.

* This of course meant a collodionised dry plate, as intimated by the context.—W. H. H., November 2, 1887.

The necessity for a close examination of past records to compile accurate history is further illustrated by the circumstance that my record of 1868 was utterly forgotten by its own author until Mr. Jerome Harrison by careful reading brought it to light. I had often regretted that I had not, as I believed, recorded the experiment in print. A somewhat similar illustration of the value of referring always to original documents occurred to me recently while reading up in relation to the history of photography in natural colours. Niépce de St. Victor is habitually quoted in newspapers and books as a leading pioneer in this branch of research; as a matter of fact he was nothing of the kind. He merely adopted Becquerel's discoveries, and by dint of laborious practice turned out rather better pictures than Becquerel, who probably had not the necessary time to give to merely routine work. Truly Niépce enunciated the principle that the colours in such photographs bear relation to the colours the particular chlorides used, would give if ignited in an alcohol flame. If this be so, the credit of discovering the principle belongs to him, and that is all, but the principle is not sufficiently well proven as yet to have been either accepted or denied by the scientific world.

For years Becquerel took no notice of Niépce and his photographs in colour, but finally gave him a little footnote in vol. ii. page 231, of his book *La Lumière ses Causes et ses Effets*, Didot Freres, Paris, 1868. That footnote I now translate as follows:—

"M. Niépce de St. Victor has obtained upon silver plates since 1851 reproductions of coloured engravings and camera images by the first process which I discovered before 1848; but this method of preparation by immersion gives tints less vivid than are obtained when electrical currents have been used in the preparation. The results which he has obtained, and which bear relation to this subject, do not appear to me to differ notably from those which have been published previously and which I had obtained first, so it does not appear to me to be necessary to mention them."

He then gives references to the journals in which Niépce recorded his results, so that his readers might look into the matter for themselves. It must be remembered that Niépce de St. Victor was not the great founder of photography, Nicéphore Niépce, of Chalons-sur-Soane, but his nephew. A third Niépce, Isidore, is also sometimes mentioned in photographic literature; Nicéphore was his father.

Claude François Niépce de St. Victor was originally a lieutenant of dragoons, who afterwards entered the Municipal Guard of Paris. He was born in 1805. In 1850, Napoleon III. appointed him Commandant of the Louvre, to give him more leisure to prosecute his photographic researches.

PATENTS COMPLETED.

IMPROVEMENTS IN OR RELATING TO THE TREATMENT OF PHOTOGRAPHIC DRY PLATES OR FILMS.

No. 15,727. EDWARD WILLIAM FOXLEE, Acton, Middlesex.—*December 1, 1886.* This invention relates to the class of flexible film from which the paper or other backing is ultimately stripped. Films of this description vary in construction considerably; in some the stripping of the back is done in a wet state, and in others in a dry state. Some of the films are made with a paper backing, an insoluble gelatine film to receive the image, and a soluble gelatine layer interposed between the two; some makers do not use gelatine at all, but a gelatinous or mucilaginous compound instead. In all cases, however, the film is supported by a backing, generally of paper, which is subsequently stripped off; and to most, if not to all, of these the present invention is applicable. I will, however, describe it as applied to a plate made according to the Boulton (Eastman & Walker) patent, No. 13,596, of 1884, and consisting of the paper backing, the insoluble gelatine film, and the interposed layer of soluble gelatine. I shall use the word "negative" to indicate the insoluble film with the image in it, whether that image happen to be a negative or a positive picture, as it may be either.

An advantage of my invention is that whereas the "negatives" as ordinarily prepared are subject to the attacks of damp and other atmospheric influences, my improved negatives are, when required, coated on both sides with collodion or varnish, which is impervious to atmospheric influences.

In carrying out my invention, I take a plate of glass, or equivalent material, and coat it with plain or normal collodion, such as that employed by photographers but without being iodised. Before the collodion is poured upon the plate the latter is treated in the usual way with wax or indiarubber, dissolved in one of their solvents or powdered talc (French chalk), or some similar

material, to prevent the permanent adhesion of the collodion. When the collodion has set the plate is immersed in a dish of cold water until the ether and alcohol are washed out. This operation may be accelerated by washing under a tap. When the solvents have been removed from the collodion it is ready for the reception of the negative. This having been fixed and washed is laid faced downward upon the collodion. An indiarubber squeegee is now employed, with some pressure to ensure close contact and expel the superfluous water and air bubbles, but before the squeegee is applied a sheet of indiarubber or paper is laid on the paper and plate in order to prevent abrasion of any exposed portions of the collodion film. Blotting paper is now placed upon the paper backing of the negative, and put under light pressure and allowed to remain for a suitable time, rarely exceeding half an hour. The object of using the blotting paper is to further absorb the moisture and so secure a better contact between the glass and the film. Next the plate, with the adherent negative, is placed without previous drying in warm or hot water. In a short time the paper will be easily removed owing to the solution of the soluble substratum or interposed layer of gelatine, leaving the negative firmly attached to the collodion. The plate is now removed from the water, and a thin sheet or pellicle of gelatine, which has previously been thoroughly softened in water—or a mixture of water and glycerine—is laid upon the negative and pressed into close contact by a squeegee, a sheet of indiarubber being interposed to prevent abrasion. The whole is now allowed to dry; or, instead of applying this sheet in a firm state it may be run on in a liquid state. When the gelatine is dry it is coated with collodion or with a varnish. When this coating is dry the negative is stripped from the glass, when it will bring the collodion film, which was applied to the glass, away with it firmly attached, so that the negative and the gelatine are protected front and back with a film of collodion or with one of collodion and one of varnish.

To facilitate the stripping a sharp knife may be run round the negative, cutting the collodion to prevent tearing.

In some cases where it is not desired to remove the negative at all from the glass plate, as when an inverted or reversed negative is required, it is not necessary to prepare the surface of the glass with tale before running on the collodion; in these cases, when the negative has been attached to the glass and the backing stripped off, it is only necessary to coat the exposed surface with collodion or varnish.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—1. In the treatment of flexible films after exposure the method or process, consisting essentially in attaching the "negative" to a film of collodion spread upon prepared glass, or equivalent material, and stripping off the temporary backing from the said "negative" or image-bearing film, the whole substantially as specified. 2. In the treatment of flexible films after exposure the method or process, consisting essentially in attaching the "negative" to a film of collodion spread upon prepared glass or equivalent material, stripping off the temporary backing from the said "negative" or image-bearing film, and coating with collodion or varnish, and finally removing from the said glass or other plate the said "negative" or image-bearing film, so that the finished "negative" is enclosed between two coatings impervious to atmospheric influences, the whole substantially as specified. 3. In the treatment of flexible films after exposure, the method or process consisting essentially in attaching the "negative" to a film of collodion spread upon prepared glass or equivalent material, stripping off the temporary backing from the said "negative" or image-bearing film, applying a permanent backing of gelatine or equivalent material, and finally removing from the said glass or other plate the said "negative" or image-bearing film, the whole substantially as specified. 4. A finished "negative" consisting of an image-bearing film, having on each side a coating impervious to atmospheric influences, substantially as specified.

IMPROVEMENTS IN PHOTOGRAPHIC AND OTHER OPTICAL APPARATUS.

No. 15,873. ZACHARY HARRIS KINGDON, Old Charlton, Kent.—December 4, 1886.

MY invention relates to improvements in apparatus, such as cameras and lanterns, for photographic and other purposes, whereby such apparatus is rendered easily collapsible into a convenient form for carriage, and readily erected and adjusted for use.

My invention consists in connecting the parts of the apparatus which are to be closed together when out of use, and separated to a required distance or distances for use by links or levers, or links and levers either alone or in conjunction with flexible or other ties, or the ties may be replaced or assisted by causing certain or all of the links and levers to come in contact with fixed or movable stops or with one another when in certain relative positions, according to the requirements of any particular case.

To obtain rigidity of the structure with its parts in any particular relative positions, such as when opened to a required extent or when closed, I arrange springs so to act on any or all of the links or levers that they in conjunction with the ties or stops constrain the system as required, or I obtain rigidity by causing some or all of the links and levers or their joints to come on or slightly past their dead centres, or I apply spring or other catches or bolts of any form to effect the same end.

In one modification the system of links partakes of the form of the ordinary lazy tongs, whereby any required extension can be obtained by having a sufficient number of links suitably arranged which can be actuated and controlled either directly by hand or through any combination of links, levers, ties, stops, springs, joints, catches, and bolts, as aforesaid.

A final adjustment, when requisite, such, for example, as in the case of focussing the lens, is obtained in the following way:—The frame or setting which carries the lens, or similar part requiring adjustment, is arranged to slide in an outer tube or sheath, the sheath having in it one or more slots or grooves which engage with a stud or studs set in or affixed to the frame or setting. These grooves or slots may be straight, curved, stepped, notched, serrated, or of any other suitable form, and may be in any position and direction; and the studs may be of any suitable form, and may be rigid or otherwise,

as, for example, they, or a part of one or of any number of them, may be attached by a spring which will admit of a slight displacement and will bring them back again to their normal position. The relative positions of the studs and slots may be reversed, the studs being connected to the sheath and the slots or grooves being in the frame or setting.

The position of the frame or setting in the sheath may be indicated by an index and graduations upon any suitable part of either the frame or sheath, or both, or any other portion of the lens mount, or any extension thereof or attachment thereto; or it may be indicated and temporarily maintained by a stud, or catch, or similar appliance, engaging steps, notches, or serrations in the grooves or slots already described, or in any other part or extension of or any attachment to the lens mount. By these means the senses of touch and hearing, together or separately, are employed in focussing and adjusting; but I do not limit myself to these means, as I intend to include all suitable means by which the senses of touch or hearing may be used in obtaining the desired adjustment.

The claims are:—1. In cameras, lanterns, and similar apparatus for photographic and other optical purposes, the connecting of those parts which have to be closed together at one time and separated at another by systems of links and levers, and constraining the same by ties, stops, springs, catches, or bolts, or combinations of any or all of these. 2. The application to cameras, lanterns, &c., of the system of links used in the ordinary lazy tongs for the purpose of rendering them collapsible. 3. The combination of links, levers, ties, stops, and springs herein described and illustrated as applied to collapsible cameras. 4. The application to cameras, lanterns, &c., of jointed stretcher bars having a spring action similar to that of the blade of an ordinary pocket knife in its handle, substantially as herein set forth. 5. The application to cameras, lanterns, &c., of jointed stretcher bars having stops near their joints which prevent them from doubling backwards except a small amount past their dead centres, substantially as herein set forth. 6. All suitable means by which the senses of touch and hearing may be used for focussing and adjusting lenses and other similar parts of photographic apparatus. 7. The arrangements for focussing lenses herein described and illustrated.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday night, October 27, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. L. Medland presided.

Some prints from negatives, taken by Mr. A. L. Henderson and Mr. J. J. Briginshaw by the Welsbach light at the previous meeting, were exhibited. One by Mr. Henderson had ninety seconds exposure, with a Dallmeyer's 2½ portrait lens, No. 2 stop. The plate was one which gave twenty-two on the Warnerke scale, a single Welsbach light illuminated the sitter, the face came out well in the negative, and the remainder of the picture was somewhat under exposed.

Mr. F. W. Cox exhibited landscape prints.

The following question from the box was read:—"A negative of a public person was taken, and a promise made by the photographer at the time not to show or publish it during the lifetime of the sitter; the negative was copyrighted and not assigned by the sitter. After the death of the photographer was told that he might do what he liked with it. The death occurred, and the photograph was being published, when the publisher was requested by the executors to desist. Have they the power to stop publishing?"

Messrs. W. E. DEBENHAM and F. A. BRIDGE replied that if no money consideration was taken from the sitter the photographer had the right to publish.

Mr. J. B. B. WELLINGTON asked if anyone had the right to stop the publication of instantaneous photographs taken with detective cameras.

Mr. BRIDGE replied that if anyone were injured thereby, he had the right to stop publication.

Mr. W. M. AYRES believed it to be illegal for a photographer to exhibit the likeness of anyone in a show-case without permission.

Mr. SMITH said that he had taken photographs to be mounted, and was informed that the cost would be six or seven shillings; when a boy called for them the mounter refused to give them up unless he were paid nine shillings and sixpence, which the boy unfortunately paid because he had a half-sovereign. Had the mounter any right to the amount paid?

Mr. DEBENHAM replied that he had no right to more than seven shillings, which should have been tendered to him, and the matter then left for legal decision.

Mr. WELLINGTON stated that the hydrokinone developer gave a greenish black colour with a collodio-bromide plate.

The CHAIRMAN had obtained good black tones with it on lantern slides.

Mr. W. H. HARRISON said that Dr. Eder had recently published that hydroxylamine had come down so in price in Germany as to be practically cheaper in use than pyrogallol. Dr. Eder also said that as a developer it did not discolour in action, and did not stain the shadows of the negative, so must come largely into use.

Mr. WELLINGTON said that caustic potash had to be used with hydroxylamine, so raised blisters in the film.

Mr. HARRISON had forgotten what formula Dr. Eder recommended.

A question in the box asked, in relation to a statement that hypo could be squeezed from silver prints, how that could be done without tearing them.

Mr. AYRES said that they should be laid face downwards on a sheet of glass, and squeezed on the back.

Mr. W. WALLIS, when in haste for prints, had run them singly through an ordinary washing wringer; they were each passed through six or seven times, with ten minutes soaking in fresh water between each rolling. The size of the prints was $7\frac{1}{2} \times 5$.

Another question asked the best form of condenser for the optical lantern.

Mr. BRIDGE recommended a plano-convex lens mounted close to a double convex lens, both four and a half inches in diameter. A smaller size would not always well cover the cushion, and the greater the diameter the greater the loss of light.

Mr. W. M. ASHMAN remarked that Mr. Bridge was an authority, and what he had said as to diameter might be considered to settle the matter.

Mr. AYRES stated that once upon a Daguerreotype plate in his hands the sitter came out as usual, but a red book by his side came out on the plate as red as blood. He had been unable to repeat the experiment, not being able to again hit the exact and unknown conditions.

Mr. JACKSON after toning a collodio-bromide transparency had found local colouration to appear while fixing with cyanide of potassium; gold in various states of fine division seemed to have been thrown down in the film.

The HON. SECRETARY said that on the evening of Friday, the 11th, the proceeds of the meeting in the rooms of the Exhibition of the Photographic Society in Pall Mall would be given to the Photographers' Benevolent Association.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

A COMMITTEE meeting of the above Association was held on the 27th ultimo. The minutes of the previous meeting were read and passed. The election by the Sub-Committee of Messrs. R. H. Boodle, W. Lang, jun., W. J. Lancaster, J. M. Skinner, S. Bell, J. Stuart, J. Davie, H. J. Thorne, and W. Holt, was confirmed.

Photographic Exhibition.—On Friday, November 11, the Gallery at 5A, Pall Mall East will be open from seven to ten p.m. for the benefit of the Benevolent Association. Several well-known gentlemen have promised special selections of slides, which will be shown with the Photographic Society's lantern.

The SECRETARY reported that several members were seeking re-engagements. It was resolved that a general advertisement should be inserted, and it is earnestly desired that employers requiring assistants should communicate with the Secretary at 181, Aldersgate-street, E.C., or 83, Hawksley-road, Stoke Newington, N.

BRADFORD AMATEUR PHOTOGRAPHIC SOCIETY.

THE first monthly meeting of the new session was held at Bridges & Smith's studio on Thursday last.—The President, Mr. D. G. Law, in the chair.

After the minutes of the previous meeting had been read and confirmed, two new members were elected. Afterwards the officers of the previous year were re-elected.

Mr. G. D. SCORAH, the Secretary, introduced Mr. E. J. SMITH, the agent for Brin's Oxygen Company, who gave a demonstration with the lantern, using the new oxygen gas compressed into steel cylinders. This oxygen, being extracted from the air by a mechanical process, is perfectly free from chlorine, and fifty per cent. cheaper than it has been made before, and the bottles are much smaller. The gas is compressed to one thousand pounds to the square inch, and is easily regulated by a simple valve. The light was beautifully white and steady, and after one and a half hour's exhibition only three and a half cubic feet of oxygen and four and a half cubic feet of hydrogen had been used. A bottle of oxygen large enough for one night's lantern entertainment measures nine and a half inches long by three and a half inches thick, and weighs only eight pounds. It is therefore likely to cause a great change in the lantern and enlarging business this winter.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE annual meeting of this Society took place on Thursday, October 20, 1887, at the Rooms, 36, George-street.—Mr. Alan Garnett, Vice-President, in the chair.

The minutes of the September meeting were read and confirmed.

The minutes of a special general meeting held October 7, 1887, were read and passed.

The following gentlemen were admitted members of the Society:—Sir H. E. Roscoe, M.P., Messrs. John Macnamara, W. T. Cunliffe, James M. Kay, and C. H. Wolff.

The HON. SECRETARY (Mr. W. I. Chadwick) read the annual report as follows:—

Your Council have very great pleasure in presenting this annual report of the thirty-second year's proceedings of the Society, as probably not for many years have we had so successful a session. Our number of members have not increased to any considerable extent, nor is it necessary that they should, but it is gratifying to find that the average attendance at our monthly meetings has been greater than in any previous year in the history of the Society. During the past year we have elected twenty-seven new members, against which we have received nine resignations, six have been removed from us by death, and a few others have been struck off our list from other causes. The total number of members at the present time is one hundred and thirty-four against one hundred and thirty-two last year. The average attendance at our usual monthly meetings has been seventy-eight against forty-nine last year.

At the October meeting we had a very interesting paper by Mr. J. Stovold, subject, *Beer as a Retainer in developing gelatino-bromide plates*.

At the November meeting Mr. Sage gave a practical demonstration of the working and developing of Vergara film; and at the same meeting our President, Mr. Covey, exhibited his gelatino-bromide emulsion plate coating machine.

In December Mr. Sawyer read a paper on *Pigment Printing*, and gave a practical demonstration of the various processes used by the Autotype Company, and exhibited a large and fine collection of over one hundred specimens of various pigment printing processes.

At our January meeting Mr. Brothers gave an address on *Astronomical Photography*. At the same meeting Dr. Babin exhibited a number of specimens of Willodon paper, and explained its usefulness to the photographer in many ways; Mr. Edwards exhibited a novel roller slide for negative paper which he had made; and Mr. Whitfield showed a most ingenious camera and changing box of his own construction. We also had on that evening an exhibition of about thirty small cameras and tripods suitable for lantern work; these were sent down by their various manufacturers.

The February meeting was occupied with numerous short communications highly interesting to beginners.

In March we had an exhibition of members' work, and at this meeting a selection was made (by ballot) of a subject to form a presentation picture to each member of the Society.

At the April meeting Mr. Abel Heywood, jun., read a paper, subject, *Odors and Ends*, in which stereoscopic work and the development of gelatino-bromide plates was well gone into. Mr. Pollitt also read a paper on *Stereoscopic Photography*; and at the same meeting the Hon. Secretary (Mr. W. I. Chadwick) read a paper, subject, *Our Society*.

At our May meeting Mr. George Smith gave a lecture on *Photographic Apparatus and Landscape Photography*; and in September last Mr. J. Trill Taylor delivered a lecture on *Photographic Lenses*.

During the recess from May to September our outdoor meetings have not been perhaps so numerous as in past years, but they have certainly been very successful and well attended, and the Council desire to gracefully acknowledge the services of the Outdoor Meeting Committee and the leaders of those pleasure trips.

During the year our Lantern Section has been hard at work, and the popular evenings have been a thorough success, but, as the Hon. Secretary of that Section will read his report, we will conclude by a reference to the financial state of the Society.

From the Treasurer's balance sheet, which will be handed round, you will see that, notwithstanding the heavy calls made upon our exchequer during the last year, which include 50l. odd for presentation pictures, 16l. odd for lecturers' expenses, and 22l. incurred by the Lantern Section, we have still the substantial balance of 41l. odd in favour of the Society.

Trusting we have discharged our duties to your satisfaction, we respectfully beg to resign our various offices.

The Treasurer's accounts were passed and a balance sheet handed to each member present.

The HON. SECRETARY of the Lantern Section (Mr. W. Watts) read the annual report of that Section:—

In submitting the second annual report to the approval of the members, the Lantern Section Committee have reason to congratulate them upon the general success of the past session. There have been six nights devoted strictly to lantern matters, two popular exhibitions, two ordinary exhibitions, one technical meeting, chiefly discussion, and one night with the lantern microscope. The Committee have experienced some inconvenience since occupying the new quarters, partly through the unsuitability of the room for lantern meetings if well attended, and in having to find a large room for the popular exhibitions elsewhere, and thereby causing an increase in the expenditure. During the last session upwards of two thousand persons have been in attendance at the several meetings, which speaks well for the popularity of the Section. The Committee again regret to have to report that the invitation to form a Society stock of slides has still met with no response. The details of the six meetings are as follows:—

Wednesday, October 27, 1886, Mr. Schofield in the chair.—Mr. Grentorex gave an address of great technical interest, relating his experience with wet plates, ten process, collodio-albumen, collodio-bromide, Cowan, Edwards, Fry, and Vélér's chloride plates, Hutinet's plates, and gelatino-bromide plates. Upwards of sixty slides were shown by Mr. Grentorex, which were charming results of landscape composition and manipulative skill. The views were accompanied by a very careful paper giving formula and exposure. This was followed by thirty slides contributed by Messrs. R. Atherton, O. E. Taylor, and J. G. Jones, many of which were good examples of contact printing and reducing methods. The lantern was worked by the Hon. Secretary, Mr. W. I. Chadwick.

November 24, Mr. Muth in the chair.—This evening Dr. Sidebotham, of Hyde, demonstrated the application of the kaleidoscope and cycloidrope with the lantern, projecting upon the screen some very beautiful effects of colour and design. Upwards of one hundred slides were handed in for exhibition, from which a large number were selected for the popular exhibition in December. Mr. Grentorex assisted at the lantern.

December 22.—This evening was the first popular one of the session. The first portion of the exhibition consisted of sixty slides contributed by Mr. Heywood, taken by him during a tour in the Hardanger Fjord, Norway. The description which accompanied the views was exceedingly instructive and interesting. This was followed by an exhibition of the members' summer's work, and consisted of one hundred and fifty slides by the following members:—Messrs. Robinson, Muth, Farrow, Oram, Edwards, Cheetham, Stovold, Harrison, Smith, and Cooté. Mr. Cheetham, of Hyde, manipulated the lantern.

January 27, 1887, Mr. W. I. Chadwick in the chair.—This was the second popular meeting of the Section. Three hundred and fifty views out of five hundred contributed were shown on the screen and briefly described by Mr. W. I. Chadwick, and were contributed as follows:—Messrs. Gale, Brooks, Wilson, Fincham, Valentine, and York; also by the following members of the Society:—Messrs. Grentorex, Cooté, Burt, Muth, Whittaker, and Stovold. An important feature of this exhibition was the use of gas in bottles in comparison with gas in bags, the result in the first case being very good as concerned the light but wasteful as regards the cost, and not thoroughly satisfactory. Mr. Jones worked the lantern.

February 23.—Mr. Schofield presided at this meeting, which was announced to be devoted to the discussion of the important question to lanternists, *Baes versus Bottles*. The discussion, which was a lengthy one, emanated from the results gained at the previous exhibition test, was taken part in by the following members:—Messrs. Chadwick, Jones, Williams, Mellor, Furnival, and Okeel, the result being that the matter was not thoroughly thrashed out. A choice collection of slides by Mr. G. Smith, and a number of coloured slides by Messrs. Wilkinson, were shown in conclusion.

March 23.—This evening was devoted to the lantern microscope, Mr. Schofield in the chair. Mr. W. Leach gave an exceedingly interesting demonstration of the application of the microscope with the lantern and related many interesting details of his twenty years' experience with the combination of these instruments. Mr. Grentorex manipulated the lantern on this occasion.

In retiring from their term of office, the Committee cordially thank the members for their kind assistance, and hope that the Lantern Section will still continue to be an attractive and interesting source of recreation to the members of the Society.

Mr. WATTS proposed an addition to the rules, of which he had given due notice; this was seconded, and a discussion took place, the result being that the motion was withdrawn.

The election of officers for the ensuing year took place resulting as follows:—

President: Sir H. E. Roscoe, M.P.—*Vice-Presidents*: Canon Beechey, Messrs. A. Coventry, Abel Heywood, jun., Alan Garnett, and John S. Pollitt.—*Council*: Messrs. T. Chilton, J. R. Groatorex, J. G. Jones, S. D. McKellen, Otto Muth, S. Okel, John Schofield, H. Smith, W. Watts, and Leader E. Williams.—*Treasurer*: Mr. W. G. Coote.—*Librarian*: Mr. John Schofield.—*Hon. Secretary*: Mr. W. I. Chadwick.

During the time occupied in casting up the votes Mr. Alan Garnett exhibited a number of very excellent prints from stripping film negatives and also a number of film negatives. These were objects of great interest and considered quite equal to negatives upon glass plates.

Mr. H. Smith had similar exhibits.

Mr. W. Blakeley showed some very nice stereoscopic views.

Several other exhibits of members' work brought the meeting to a close at a late hour.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

THE usual fortnightly meeting of the above Society was held in the Technical Schools, Bridge-street, on the 27th ultimo.—The Vice-President (Mr. W. J. Harrison, F.G.S.) in the chair. There was a large attendance.

The minutes of the last meeting were read and confirmed.

Messrs. John Collier, D. Gwynne, C. J. Husband, James Harrison, G. C. Lloyd, J. H. Mackenzie, A. Pope, W. Walkington, and H. F. Woodward, were elected members of the Council.

THE HON. SECRETARY read a letter from the Camera Club asking for a member of this Society to join the Conference Committee for next year. This was referred to the Council, to nominate and elect a member for the same.

A letter was read from Mr. A. Constantine, offering five albums for presentation to the hospitals.

MR. PLACE, who was to read a paper on *Lantern and Slides*, kindly postponed the same for another evening, as the competition for the lantern slides shown at the late Exhibition had to be decided, and, in lieu of his paper, passed the different competing slides through the lantern. The judging was decided by the Lantern Committee, and the prize was awarded to Mr. W. Tylar (subject to the production of the original negative) for his picture *Whoa!* a team of horses and waggon in the hayfield. A picture of three geese, entitled *The Three Judges*, by Mr. E. H. Jaques, and *Fishing Boat*, by Mr. W. D. Welford, gaining honorary mention as second and third respectively.

The Judges had some difficulty in making the award, inasmuch as the good qualities of many of the pictures ran very close. Probably from a photographic view Mr. Jaques's picture was most perfect, but the composition and general effect placed Mr. Tylar's picture in the front.

After the competition Mr. Place showed on the screen lantern pictures of the prize and commended pictures at the late Exhibition, which Mr. Welford had not only suggested, but had taken himself, and kindly presented to add to the Society's stock of slides.

The meeting terminated with the announcement of the paper for November 10 next—*Collotype or Practical Lithography*, by Mr. E. C. Middleton.

HALIFAX PHOTOGRAPHIC CLUB.

THE annual meeting of the above Club was held on Friday evening last, October 28, in the Mechanics' Hall.—Mr. B. Rowley in the chair.

On the minutes being read, and the thanks of the Club unanimously given to the retiring officers, the election of officers for the ensuing session was proceeded with as follows:—*President*: Mr. B. Rowley.—*Vice-Presidents*: Messrs. T. Illingworth and J. E. Smith.—*Treasurer*: G. H. Jackson.—*Hon. Secretary*: W. Clement Williams.

The Hon. Secretary received instructions to conclude all arrangements for lectures and demonstrations, in order that interesting matter should be available for each meeting of the session.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting was held on Thursday, October 27.—The President, Mr. George H. Rutter, in the chair.

The minutes of the last meeting were read and confirmed.

The following were unanimously elected members of the Association:—Messrs. J. L. Mackrell, C. Oyler, and Joseph Walker.

THE HON. SECRETARY acknowledged with thanks the receipt from Messrs. Hliff & Son of a copy of Welford & Sturmy's *Photographers' Indispensable Handbook* for the library. He also read letters from the editors of the *Amateur Photographer* and *Camera Magazine*, placing their medals at the disposal of the Council for the forthcoming photographic exhibition.

THE SECRETARY of the Exhibition Sub-Committee (Mr. Mayne) read a report giving particulars of the proposed exhibition and *soirée*, from which it appeared that they proposed to hold the exhibition in March next for two weeks, commencing Monday, the 5th, in the Fountain Room of the Art Gallery, which had been granted for the purpose; also that about twenty medals, two of which were gold, seven silver, and the remainder bronze, would be offered for competition in various classes.

MR. RUTTER moved, and Mr. J. H. DAY seconded, "That the report of the Sub-Committee be accepted," which was carried unanimously; also a vote of thanks to the editors of the *Camera* and *Amateur Photographer*, for their generous offer, which was accepted; and particulars of the medals and the conditions on which they will be awarded will be added to the prospectus of classes and medals which will shortly be published for circulation.

A new Sub-Committee was appointed to carry out the details of the exhibition, consisting of Messrs. Atkins, Beer, Crowe, Day, Dearn, Gibbs, Lange, Lupton, Mayne, Riley, Rutter, Tomkinson, and the Hon. Treasurer and Secretary *ex officio*.

THE PRESIDENT announced that the Council had chosen Messrs. Boothroyd, Beadle, and Thompson, to act as Judges in the annual competition, for which that was the last day for entry of prints.

MR. H. N. ATKINS gave a hint in regard to film photography showing a

means of utilising ordinary double dark slides for films. He advised taking a piece of stout cardboard about one-eighth of an inch thick, the exact width and double the length of the glass plate; by partly dividing this at half its length it will fold over; a length of film is then taken from a roll an inch longer than the cardboard, this is folded tightly over the doubled cardboard and half an inch turned in at each end, which makes a compact parcel to fit the slide exactly. By placing half a dozen drawing pins into a slit cut at one end in the thickness of the cardboard, the points projecting inwards, when closed they will hold the paper quite firmly.

MR. G. E. THOMPSON then read a paper, which has already been printed in the journals, on *Picturesque Italy*, illustrated by about one hundred and sixty lantern slides projected by the limelight lantern, which was ably manipulated by Mr. Phillips. These slides, consisting of scenes from Genoa, Naples, Pompeii, Capri, Amalfi, and other places, were many of them of great beauty, and were received with much enthusiasm, bringing vividly before the stay-at-home members of the Association many of the beauties of "Picturesque Italy." Mr. Thompson's description of the scenes visited was followed with great interest, and a unanimous vote of thanks closed the proceedings.

Correspondence.

THE PHOTOGRAPHIC EXHIBITION.

To the EDITORS.

GENTLEMEN,—The Photographic Society of Great Britain have very kindly placed their Exhibition at the disposal of the Photographers' Benevolent Association on Friday, November 11, from seven to ten p.m. A charge of sixpence for admission will be made for the benefit of the funds. I should feel obliged if you will kindly find space for this announcement, as it will doubtless aid to ensure success.—I am, yours, &c.,

181, Aldersgate-street, E.C., Nov. 31, 1887. H. HARLAND, Secretary.

To the EDITORS.

GENTLEMEN,—Oh! why did the *Builder* not stick to its bricks and mortar, and leave we poor photographic minions to dream on in blissful ignorance of the manifold faults laid so cruelly bare in its Photographic Exhibition critique?

It makes one shudder at the unspanable gulf it discloses between photography and art. Among many other as able examples it proceeds to state: "Photography merely copies; the artist—even the most nominally realistic artist—does far more than copy, and nowhere can this distinction be more clearly seen or more strongly felt than in studying the efforts of photographers to produce pictures of human life. *Home, Sweet Home* (41), an interior by Mr. Lyddell Sawyer, is another, we might almost say flagrant, example; the little bunched-up figure of the child held up in its father's arms is capital, and would be worth the attention of a painter, but the figures and physiognomies of the parents reduce the whole thing to sheer vulgarity."

Here is evidenced a subtlety of keen art criticism which we, alas! must despair of ever attaining, and I sink abashed before this powerful discernment.

The only little consolation I find is that my ignorant lady acquaintances have, without a single dissentient voice, voted me a fraud for trying to palm off, in the picture in question, a palpable "bunch o' clouts" as a real baby! But now let them alter their blessed babies, for hath not the *Builder* spoken? *Dare*, dare I state that my sister and I proudly posed in that picture as the fond parents, whose "figures and physiognomies reduce the whole thing to sheer vulgarity?" In mad jealousy I have rent my too-gifted offspring in shreds, cast its fluttering remains to the relentless ragman, and now my sister and I occupy every spare moment hanging out on the clothes-line, hoping thereby to attain some of that enviable baby's pure æsthetic outlines. So far, alas! the results are only discouraging, but "hope springs eternal in the human breast." I am, yours, &c.,

LYD. SAWYER.

6, Novaire-row, Newcastle-on-Tyne.

TRAFALGAR-SQUARE MEETINGS.

To the EDITORS.

GENTLEMEN,—I beg to add my protest against the permission by the authorities of the holding of "Agitation Meetings" in Trafalgar-square, on the ground that the weekly takings for admission to the Exhibition of the Photographic Society of Great Britain are very seriously affected thereby. As a peaceful citizen, moreover, I have on two occasions been denied the right of crossing the Square, when pressed by time appointments on matters of business with gentlemen at the Gallery, 5A, Pall Mall East. I trust you will consider this letter sufficiently "photographic" to give it a place.—I am, yours, &c.,

S. G. BUCHANAN WOLLASTON.

Lennie, Chislehurst, Kent, November 1, 1887.

"CAROLLING."

To the EDITORS.

GENTLEMEN,—The curiosities of criticism are a mystery at which I often wondered, and usually enjoy in silence when my own works are concerned, but there is one remark in the notice of the Exhibition, reprinted by you from the *Builder*, which, as it pertains to a matter not

of taste but of fact, I should like to correct. The writer praises the landscape part of my picture—*Carolling*—which, he says, “has really the softness and distance of a water-colour painting,” and, he adds, “but we imagine this has been touched upon, and is not pure photographic work.” To this unwarranted statement I have to say most emphatically that this picture is absolutely free from any touching, or dodging, or falsifying, even to the innocent extent of the removal of a freckle, being in this respect, I fancy, purer than nine-tenths of the pictures exhibited, as you may yourself see in the unmounted print I have sent for your inspection.

Now I am on the subject, I may say that I am aware there has been a good deal of controversy about the truth of this picture. I know, also, that one good-natured critic neglected his legitimate business, both on the press day and at the *soirée*, that he might devote himself to the genial task (“picketing” I think it is called in the region from whence he comes) of pointing out to the members of the outside press and others that the figures are too tall, and their shadow too long, and other unpardonable artistic sins. But how can I help his ignorance? I am charitable to call it ignorance. My only reply is, that the figures were carefully sketched on the site they occupy, so that their proportions should be absolutely exact, and that the shadow is the work of nature. As Dryden tells us—

“Art may err, but nature cannot miss.”

It is a smaller argument, I suppose, to say that I was not likely to make a mistake of this simple kind after thirty years’ practice.

The picture is confessedly a combination print from several negatives, but the negatives were all taken at the same hour of the day, at the same time of year, and under similar circumstances. Nothing was altered but the focus of the lens to suit the different planes. I knew that the shadow to a superficial mind not accustomed to observing nature would look too long, but that effect is caused by the slope of the ground, and I could not alter the level of the land to aid the understanding of a superficial mind.

Now I may as well confess (for I have no secrets in my practice) a thing which would have rejoiced the heart of the kindly critic if he had found it out for himself, but which does not detract from the truth of the picture. Part of the picture was photographed as long ago as 1881. There was a want of balance which did not please me, so I preferred to wait for the two trees to the left, which had just been planted, to grow. I waited six years, and think the point they make was worth the patience, and a photographer who is not endowed with that quality must never expect to do good work.

Supposing—which is a large order—that the real object of our good friend was scientific accuracy, what would be the use of it in a picture intended to give delight to the eye only? Let us have truth by all means, or as near to it as we can go; but it is not a paradox to say that literal fact is often opposed to artistic truth. Painters seldom bother themselves about the trivialities of scientific fact; they never stoop to consider whether the wings of their angels would support them in the air, and I remember that Turner was much applauded for introducing two suns in one of his pictures, because the pictorial effect required some such device! And I may conclude by adding that, judging from the falsification of the report of a late exhibition, the critic I allude to is scarcely a trustworthy authority on a question of truth.—I am, yours, &c.,

Tunbridge Wells, October 29, 1887.

H. P. ROBINSON.

PHOTOGRAPHIC ACTION IN THE DARK.

To the Editors.

GENTLEMEN,—In your JOURNAL of October 7, page 628, Mr. D. Winstanley reports an experiment substantially the same as one reported by Charles Zenger a year or two ago, and arrives at the same conclusion, viz., that a piece of common white paper exposed to sunlight absorbs certain energy that is capable of producing photographic action when the paper is removed to a dark room.

Now, it is so easy to prove this to be untrue, that I am surprised to see such an assertion made by men who make a pretence to being scientific. The fact is, that the alleged “photographic” action will in most cases take place just as readily if the paper is not exposed to light at all, and is really nothing but a chemical discolouration, which a very slight cause is sufficient to bring about under certain conditions familiar to most photographers who have handled much silvered albumen paper in warm, moist weather.

The experiment with paper exposed under a negative, only proves that the prolonged action of intense sunlight produces some slight chemical change in the substance of the paper, which modifies its power to affect the sensitive paper when brought in contact with it. If the action were truly photographic, contact would not be necessary to secure an impression, and it would be unsafe to take a piece of white paper from under the skylight into a dark room, where plates are being handled that are a thousand times more sensitive to true photographic action than silvered albumen paper.

I have obtained very strong impressions of newspaper type matter on polished glass, by wrapping the glass in a newspaper, and allowing it to stand a few weeks in a room occupied every day by several persons. These impressions appeared to consist of a filmy deposit from the air, which is prevented from reaching the glass wherever it is covered by the printed characters. I would quite as soon think of calling these im-

pressions “photographs” as the discolourations produced on silvered albumen paper under somewhat similar conditions.—I am, yours, &c.,
Philadelphia, October 18, 1887.

FRED. E. IVES.

AMMONIA.

To the Editors.

GENTLEMEN,—The correspondence of Professor Donkin concerning the behaviour of ammonia on further solution in water has led me to look into the matter. The result is rather of physical than photographic interest; but as it seems to point a moral, I submit the following calculations:—

On page 331 of the last BRITISH JOURNAL PHOTOGRAPHIC ALMANAC is given a table of percentages of real ammonia in solutions of various specific gravities: I propose with its aid to calculate the s.g. of a “ten per cent.” solution of ammonia at 0.8844, on the hypothesis that no shrinkage takes place, and then to compare the result with the table, in order to see if this hypothesis be correct.

The table gives thirty-six per cent. real ammonia in the solution of s.g. 0.8844, therefore the weight of 100 volumes is 88.44. Of this the weight of ammonia is 31.84, and the weight of water is 56.60.

To make our ten per cent. solution, take ten volumes of the above (containing weight 3.184 of real ammonia) and weighing 8.844, and ninety volumes of water, weighing 90.000. Total weight of 100 volumes = 98.844. Therefore the s.g. (defined as the weight of a unit of volume) = 0.9884.

Again, we have 98.844 parts by weight contain 3.184 of real ammonia; what is that per cent.? Answer: $98.844 : 100 :: 3.184 : 3.221$, or ammonia of s.g. .9884 contains 3.221 per cent. of real ammonia, if no shrinkage take place.

Turning now to the table, and interpolating for the decimal, we find the actual s.g. of ammonia solution containing 3.221 per cent. of real ammonia is not .9884 but .9861—that is, an expansion has taken place; in other words, if we mix one fluid ounce of ammonia s.g. .8844 with nine ounces of water, the resulting bulk will be a trifle over ten fluid ounces.

One correction remains to be made:—The s.g. of water at 14° C. is not 1 but 0.999285; this reduces the calculated s.g. of the solution to .9877, still in excess of the actual, as found from the table.

The result is what might have been expected; if solution is accompanied by shrinkage, dilution will be accompanied by expansion.

Thus it appears to me that while Professor Donkin rightly contended that no shrinkage occurred in the experiment described by the Editor, and rightly interpreted the phenomenon, he overlooked an accompanying phenomenon which really supports the Editor’s (and my) contention, that shrinkage occurs in many cases when solids (or liquids) are dissolved in water.—I am, yours, &c.,

R. C. PHILLIPS.

4, Camp-street, Lower Broughton, Manchester, Nov. 1, 1887.

THE LATE I. H. JENNINGS.—AN APPEAL.

To the Editors.

GENTLEMEN,—In an obscure cottage in the little village of Bulcote, near Nottingham, has just passed away at the early age of thirty-seven, a gentleman who, amongst his other pursuits, had made photo-micrography one of his serious studies. The benefit of his knowledge he gave to amateurs in a little work entitled, *How to Photograph Microscopic Objects*, by I. H. Jennings, and published by Messrs. Carter & Piper, and which he begged to dedicate to myself as a token of a kindred aim and valued friendship.

This gentleman, Mr. I. H. Jennings, was finishing the term of thirteen years as one of the assistant masters at the High School of Nottingham, when a new head-master was appointed and Mr. Jennings was informed his services were no longer required. Sadly depressed, misfortune followed him—he lost his little boy, his wife had a serious illness, and he had to remove to a miserable cottage. At my suggestion, and much against his wish, a public appeal was made for him, but with very feeble response, the small sum ending in the miserable dole of twelve shillings a-week to pay rent, taxes, food, coals, and clothing for himself, wife, and little baby. This was a pitiable condition and deep distress for one in sad ill-health, endowed with high intellectual powers, and most capable of writing upon any of the topics he had studied, especially on photography, natural history, and country pursuits of shooting, angling, and gardening. A good microscopist and geologist, he had formerly turned his attention to rock sections; but now the dark cloud of semi-starvation canopied his home, and it was only by the timely help of three or four correspondents, whom he had never seen, that this impending cloud was prevented from earlier breaking up the home.

Mr. Jennings was a terse writer, and his pen has furnished valuable contributions at various times to some of the journals, at home and abroad. He has left a widow, herself sadly broken down by want, and one infant. It has greatly pained me to give this brief notice of one for many years my valued correspondent. The case is well known to my friend Mr. A. Pringle, and I trust this may, with your permission, be the means of calling attention to the pressing needs of the widow and fatherless child.—I am, yours, &c.,
October 31, 1887.

R. L. MADDOX.

MERCHANDISE MARKS ACT, 1887.

To the Editors.

GENTLEMEN,—So far as I am aware there have not yet been any prosecutions under this Act. But some of its provisions are so far-reaching that

its possible effects upon one branch at least of photographic business may be well deserving of a little consideration. I will first give a few extracts.

Clause 2.—"Every person who . . . applies any false trade descriptions to goods, &c., shall be guilty of an offence against this Act. (2.) Every person who sells or has in his possession for sale, or any purpose of trade, or manufacture, any goods to which any false trade description is applied shall be guilty," &c.

Clause 3.—(1.) The expression "trade description" means any description, statement, or other indication direct or indirect. "(b) As to any place or country in which any goods were made or produced, or (c) as to any goods being the subject of an existing patent, privilege, or copyright." The expression "goods" means anything which is the subject of trade, manufacture, or merchandise. (2.) "The provisions of this Act respecting the application of a false trade description to goods shall extend to the application to goods of any such figures, words, or marks, or arrangements or combinations thereof . . . as are reasonably calculated to lead persons to believe that the goods are the manufacture or merchandise of some person other than the person whose manufacture or merchandise they really are."

Clause 5.—"A person shall be deemed to apply a trade mark or trade description to goods who (a) applies it to the goods themselves, or . . ."

There are very many other clauses deserving attention, but for my present purpose the above will suffice. On this occasion I confine my remarks to the possible bearing of this Act upon the photographic lens trade. I conceive that any person who imports and sells or exposes for sale any photographic lens manufactured abroad, and issued by the manufacturer without name or address, and who subsequently engraves or in any manner affixes the name of any person or company in this country to a foreign lens without intimating that the lens is of foreign manufacture, is guilty of an offence under this Act.

In Clause 3, Sub-section (b), it is quite clear that to mark any lens "Patent" when no patent, privilege, or copyright is still existing, is an offence under this Act.

I may possibly have some further remarks to submit next week.—I am, yours, &c.,

C. W.

November 1, 1887.

Exchange Column.

Four Victoria lenses and camera offered for whole-plate camera and double backs.—Address, C. BANYARD, Yoxford, Suffolk.

Bigelow's *Album of Lighting and Posing*, with Key, for 12x10 or 10x8 view lens.—Address, W. W. EVERS, Waltham, Rotherham.

Wanted, good half-plate printing frames in exchange for Seavey's profile stile and fence.—Address, COLES, Photographer, Watford.

I will exchange whole-plate portrait lens for modern camera with latest improvements.—Address, W. W., 156, Noel-street, Nottingham.

Will exchange 12x10 portrait lens, equal to new (Leicheston), for rectilinear lens, 12x10, good.—Address, GUTHRIE, Photographer, Dundee.

I will exchange a twelve-inch roller for background, and Rouch's 12x10 dark tent for chair.—Address, C. EASTMENT & SON, Photographers, Ebbw Vale, Monmouthshire.

Will exchange Rhumkorff coil and batteries, also microscope and objects, for good magic lantern with four-inch condensers.—Address, THOMAS J. McCANN, 24, Kirkpatrick-street, Bridgeton, Glasgow.

I will exchange a pair of oxycaesium jets and sheet four yards square, also block of lanterns for advertising, for half-plate camera and lens or a good camera with more than one dark slide.—Address, C. CHAMBERS, 18, Tipping-street, Stafford.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED:—

H. Wray, Wigan.—Four photographs of late W. Pickard, Esq., J.P., of Wigan.

T. P. Graham, Bedford.—Photograph, "Where's your License, Major?"

W. C.—The matter will receive consideration.

T. B.—Any gasfitter in your neighbourhood will procure the burner for you.

REV. B. P.—Mr. Redmond Barrett is one of our best and most intelligent retouchers.

J. E. M.—The *Chemical News* is published in Boy-court, Ludgate-hill, London, E.C.

WILL.—1. Yes.—2. We are uncertain; but you might try Schianschiff.—3. We use the Pamphengos lamp.

W. PHILLIPS.—Try a different sample of gelatine. The gelatine is, no doubt, the primary cause of the trouble.

SILVER IODIDE.—The colour of the print appears to be all right. What is the fault you find with it? Does it not tone properly?

H. W. B.—1. It is usual to consider the effective to be the actual aperture.—2. Yes, the stop should be situated proportionate to the focus of the lenses.

S. N. (Lansame).—1 and 2. Yes, if the solutions be saturated at the temperature stated; but you must bear in mind that temperature is an important factor in the case. A solution that may be saturated at one temperature may be very far from it at another. The best plan is to prepare the solution of a definite strength.

A. H. HALL.—1. The amount of emulsion to be put upon a plate depends very much upon how it is prepared. If it be rich in silver bromide a much smaller quantity will suffice than if it contains a large amount of gelatine in proportion to the silver. Better coat a few plates with different quantities of that you propose to use, and when they are dry compare them for opacity with good commercial plates.—2. Citric acid is preferable.

R. RESTALL.—From your description we surmise that your collotype plates have been over exposed as they take too much ink. Try the effect of less exposure.

J. B.—Marine glue or shellac dissolved in methylated alcohol will do quite well for cementing in the piece of glass; but, unless the bath is a large and expensive one, it may probably be cheaper in the long run to get a new one. Mended vessels which are to contain silver solutions are seldom satisfactory.

LIGHT writes: "Will you tell me if I can make use of pyrotechnic powders, such as nitre, sulphur, and orpiment, for the production of photographs without being sued for an infringement of any patent? or, if so, what light can I use?"—There is no patent which will prevent our correspondent from employing pyrotechnic compounds for taking photographs.

AN ANXIOUS INQUIRER.—Assuming that your studio is lighted only from one side, more shadow and greater rotundity can be obtained by drawing down the roof blinds so as to cover up about half the glass, and at the same time taking away the tissue paper at the side. If, however, the studio has glass on both sides, cover up one side and proceed as just recommended.

COL. HERBERT.—We do not know of any such photographically illustrated work on the Norfolk Broads as that of which you speak. The only work of this nature of which we are aware is one entitled *Three Weeks in Norfolk*, by J. F. Mostyn Clarke. It, we know, contains many attractive illustrations, and is, without doubt, the work to which reference is made. It may be obtained from Wyman & Sons, London. Mr. Emerson's work is entitled *Pictures from Life in Field and Fen*.

3. ST. JAMES'S-TERRACE, NOTTINGHAM.—We cannot decipher your signature, although aided by all the powers at our command. Certainly you were answered, but we answer again. An article on photo-lithography appears in the last edition of *Hardwick's Manual* (Messrs. Churchill). Probably you will find something in the forthcoming ALMANAC that will supplement what is written in the manual referred to. Kindly write your signature plainly; and this applies to many others of our friends.

H. B. A.—1. If the dish be mended it will do quite well for an alum bath. As the size is so small it will probably be cheaper in the end to get a new one.—2. It will depend upon the value an amateur puts on his time and the price at which he can purchase the frames as to whether it will be cheaper for him "to frame his own pictures or not."—3. Forms for patents can be procured from any Post Office, for which no charge is made. The cost of a Provisional Specification is 1*l.*, and for a complete one 3*l.*; total, 4*l.* for four years.

J. W. L. asks: "What is the cause of the markings on the portion of a negative which I send you? Lately I find it impossible to intensify the plates with bichloride of mercury without staining, and the stains show more in the prints than in the negative. I use one part of a saturated solution of the bichloride to four parts water, and half a drachm of ammonia to a pint of water. The markings extend nearly over the whole of the plate."—The cause of the stains is that the plates have been imperfectly washed between the operations. The make of the plate has nothing to do with it. More complete washing will entirely obviate the evil.

S. M. writes: "1. Would you recommend me to add gold to a toning bath when it has got very weak or make fresh? If it should be added, how long before use? I mean an acetate bath.—2. What kind of lens is best for enlarging up to 15x12, to make the best of work?—3. For carte work in the studio would you use a lens advertised as a card lens or a cabinet?"—In reply: 1. Fresh chloride of gold may be added, but the addition should be made twenty-four hours before the bath has to be used. A little fresh acetate will be required from time to time.—2. A lens of the "rapid" type or a portrait lens is as good as any.—3. Either will do.

W. D. writes: "I have unfortunately broken one of my whole-plate negatives of a group of cows which I prize very much. I find the glass support is broken but the film remains uninjured (at least as far as I can ascertain). Would you kindly give me the necessary instructions for floating off the film on to another sheet of glass?"—Our correspondent's best plan, if the film itself is not injured, will be to alum the negative, to prevent expansion, and then immerse it in a very dilute solution of fluoric acid—about one drachm of acid in ten ounces of water. This will detach the film, which can then be floated on to a fresh piece of glass. It will be well to give the new glass a preliminary coating of gelatine. The deposit is no doubt oxalate of lime unless, indeed, the solution was put into a dirty bottle.

THE FORTHCOMING ALMANAC.—Those friends who purpose sending contributions to the ALMANAC will oblige by doing so under such circumstances as to reach the Editor not later than Tuesday morning next.—THE EDITOR, 2, York-street, Covent Garden, London, W.C.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, November 9, 1887, will be *Instantaneous Snappers*.

UNDER the designation "R. W. Thomas & Co., Limited," it is proposed to convert the long favourably known firm of R. W. Thomas into a limited company. The capital is 20,000*l.*, in 20,000 shares of 1*l.* each. Among the Directors are the names of J. L. Lyell, Frederick York, Herbert R. Barrand, H. Manfield, Wm. F. Donkin, A. E. Brooke-Hunt. The General Manager is Mr. J. T. Sandell, Mr. Andrew Pringle being Consulting Experimentalist.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1436. Vol. XXXIV.—NOVEMBER 11, 1887.

VEILED SHADOWS.

We have arrived at a season of the year when, if we may judge from murmurings that have come within our own purview, the dry plate manufacturer must be receiving such frequent complaints of "foggy plates" as to cause considerable disquietude, to use the mildest term. The time is gone by when the silver bath was credited with all the fogs that collodion negatives were heir to; the careless, the ignorant, the incompetent, could once lay all their sins on the vagaries of their baths, but now there is no middle way betwixt the faults in the plate and faults in the user. Yet, as a matter of fact, so far as the manufacture of plates is concerned, the makers at the present time enjoy excellent weather for their purpose, and there is every reason for their plates to be good instead of bad. There is no fear of intense heat interfering with emulsion, and the trials brought about by extreme hygrometric conditions of the atmosphere have scarcely yet made themselves felt, as they shortly will do.

The trouble is mainly in portraiture; the landscapist does not make much use of his camera in the month of November, while the portraitist just now is only beginning to feel the decline of the season rush. And the cause is not defective plates (we do not of course suggest that all plates must be perfect at this time), but atmospheric fog increased to vicious proportions by the insinuating presence of smoke. We have heard a well-known photographer state that there ought not to be such a fog trap as an open fireplace in any part of the premises connected with a portrait studio. Heating appliances, it goes without saying, have to be provided—as who with cold, pinched features can be properly represented in the camera?—but the suggestion is that gas or hot water should be the medium for the introduction of heat. To those who have not observed this closely it is surprising how great an effect may be produced by a trifling whiff of smoke; a sudden closing of a reception-room door or the quick brush past of a lady's dress may cause a slight puff of smoke to dart out, and a few minutes only will then be needed for it to permeate in some remarkable manner every room in the building. In early autumn, before fogs set in, this would soon subside, but when, almost every morning, daylight is ushered in by an atmosphere of fog, there ensues such an intimate combination between the smoke and the water particles that a considerable period of time must elapse before deposition can take place.

We are well acquainted with a gentleman holding these views about fireplaces whose extensive premises receive their chief heating through hot-water pipes, but who was recently at his wits' end how to get negatives with non-veiled shadows. He was experienced enough to know that it was the atmosphere,

and not the plates, that was at fault (and we may say *en passant* that it needs some experience to detect an atmosphere with translucency very slightly injured by the presence of foggy or hazy matter); yet, after going so far as to watch the actual lighting of the only fire that could possibly do any harm, and seeing that no smoke whatever came from it, while the haze was still perceptible, he came to the conclusion that it was the early morning fog that had gained an entrance and not been entirely eliminated. Furious firing of the hot-water-pipe furnace did not appear to remedy the matter in the slightest degree. By chance the cause was revealed. A little-used room on the first floor had its fireplace covered over with brown paper, to keep the dust and soot from falling down into the room, and this paper, which was found to be slightly torn into one or two insignificant holes, allowed the exit of a continuous almost imperceptible fine discharge of coal smoke. And this smoke came from a neighbour's chimney stack. The one open fire and the furnace fire in the photographer's premises required a good supply of air to feed them, and as, on these cold autumn mornings, all outer doors and windows were naturally kept well closed, the readiest mode of access for fresh air was down the chimney. On its way it carried with it the smoke from the neighbouring chimney, and the riddle was solved.

The cause of the baneful effects of an unclear atmosphere scarcely need explaining. In landscape work a little "atmosphere" is desirable: in photographic portraiture it is not. The faintest trace of haze will impress itself before the delicate half tones that constitute so large a portion of the charms of a good photographic portrait are duly secured, and the consequence is that between lights and darks there is little gradation, and at the same time the darks are greatly degraded by the interposition of a thin light veil.

One obvious mode of getting rid of the effect is to have as little atmosphere as possible between sitter and lens, which may be achieved either by using shorter focus lenses, or by inducing the sitter to have a style of picture—such as a vignette bust—as against a three-quarter length.

Again, we know of the plan adopted by one photographer when he finds himself troubled by ineradicable haze is to lessen the amount of illumination in his studio by contracting the area of the illuminating aperture controlled by his screens; he thus, it is true, by robbing his model of light increases the exposure required, but not in anything like the proportion in which the illumination of the atmosphere itself is reduced: hence the veil on the shadows is considerably reduced.

It is, however, quite certain that if the plan of entirely preventing the entry of any light whatever, except that

which falls upon the sitter and his immediate surroundings were to be adopted, fog and haze might be laughed at. Such a tunnel idea, as we have before suggested, might be carried out with little outlay and vast advantage. We fear that the time is far distant when electricity as an atmosphere clearer will be put to practical use, though every one is familiar with the lecture experiment of almost instantly depositing a dense smoke in a bell-glass by submitting it to the discharge from a frictional electrical machine. On the other hand, the electric light, though not illuminating any large proportion of the atmosphere between lens and sitter, enables the operator to produce splendidly clear negatives, though the air be most hazy or foggy.

We will conclude our remarks by drawing attention to a little-noticed cause of haze which recently caused the rejection of a large number of negatives at the hands of a well-known professional, and which may prevail in many a studio without being noticed. The photographic sufferer in this case always employed a pneumatic shutter for making his exposures, and the flap working inside the camera, the outer lens of the combination was constantly exposed to the air. The photographer we allude to is one who greatly deprecates the continual rubbing or polishing of lenses so much in favour with some of the fraternity; but in this case he had carried his objections too far. The anterior surface of his lens had received from the atmosphere a most distinct deposit, semi-milky in appearance, which the exposure of months to the atmosphere had imparted to it, and this film was the means of producing a more or less veiled shadow in his negatives. The moral from this story is that lenses should be kept covered when not actually in use, and that even then their surfaces should be occasionally scrutinised, to observe if there be any need for polishing operations.

WITH reference to an appeal in our last issue by Dr. R. L. Maddox on behalf of the widow and child of the late Mr. I. H. Jennings, we would gladly say a few words. Mr. Jennings was, after many years of public service, thrown, by no fault of his own, into circumstances of the greatest difficulty—into poverty, and even to starvation, as we are informed on excellent authority. He died lately, leaving a widow and child entirely destitute, and on their behalf we venture to press upon our readers the touching appeal of Dr. Maddox. Mr. Jennings's book on *How to Photograph Microscopic Objects* is one of the best text-books on the subject, if not the very best; and the author was to the very end, and even when almost helpless from disease and hunger, a true and ardent scientist. We commend the case to our generous readers as one deserving their notice, and we shall be most happy to receive any sums of money that may be sent to us with a view to forming a fund for the use of the widow and the infant. Dr. R. L. Maddox (Greenbank, Park-road, Portswood, Southampton) and Mr. Andrew Pringle (Baxley Heath, Kent), to both of whom the merits of the case are known, will also be happy to receive gifts for this humane object.

THE reversing prism employed in taking reversed negatives for carbon printing and many other purposes is too expensive for practical use except with lenses of very small diameter. Silvered glass, however, answers every purpose, and we have occasionally described methods of performing the operation of imparting a coating of pure silver to a piece of plate glass by which these mirrors are made. An American correspondent, writing to a contemporary recently, gave a formula for silvering small discs of glass such as those used in mounting microscopic objects, which would be useful for the larger surfaces we speak of also. He adds two grains of nitrate of silver dissolved in a drachm of water to a boiling solution of twelve grains of Rochelle salts in an ounce of water, and after boiling a few minutes filter and makes the bulk up to an ounce and a half. This

forms a reducing solution, the silver solution being made by dissolving forty-five grains of nitrate of silver in an ounce of water, and adding strong ammonia solution till the precipitate first formed is nearly, but not quite, dissolved. To use these solutions, equal parts are mixed together and filtered, and the glass to be silvered placed so as to touch the upper surface of the fluid, the whole arrangement being then placed in the sun or in a warm place. From 100° to 130° Fahr. is the best temperature.

THERE is no patent for the above useful employment of a familiar photographic chemical; but we note, that the use of a combination of some other substances familiar to photographers—cyanide of platinum and magnesium—has been patented for purposes that will be of no doubted use to him, that is to say, for indicating the state of the atmosphere as regards moisture. The above salt in solution, in combination with gum, gelatine, &c., is painted upon any desired substance, and when dry remains white; but under the influence of moisture turns to a pink or red, more or less deep according to the amount of moisture present. It is stated that for a repetition of the action the platinum-painted object must be heated after each reddening, so that each time the photographer had benefited by its warning the tablet or other object would have to be "set" again. This adds another to the list of ingenious hygrometers; but be the instrument selected what it may, there is no doubt that an hygrometer of some sort is of very considerable service as regards the state of silvered paper, or the exposure of negatives to the atmosphere, or, again, as a weather indicator for the outdoor operator.

It will be remembered that at the International Congress of Astronomers held in Paris last April, it was determined to construct a chart of the heavens by a concerted system of working. The chief map was to include stars down to the fourteenth magnitude, and for the thorough obtaining of uniformity each telescope was to be of the same aperture, about thirteen inches, which will give a scale of a millimetre to each minute of arc. The work is being carried on apace, and such progress has been made with the optical instruments that it is expected that ten of them will be ready for use and forwarded to their destinations by the end of next year. It is anticipated in consequence, according to Admiral Mouchez, that the charts will all be completed within the specified time.

THOSE who are familiar with the use of sulphate of mercury as an exciting salt in a galvanic battery have often queried why same salt should not be made which would not give the well-known yellow deposit on the addition of water—why, in fact, the soluble matter extracted, so to speak, should not be an article purchaseable separately. Recently Mr. Schanschiff has patented a salt which is practically the substance in question; he refers to it as "a novel saline preparation." We need not here enter into the exact mode of manufacture, but as it will probably be an article of sale, our readers will have an opportunity of utilising, without loss by precipitation, one of the handiest of all exciting liquids for batteries.

THE remarkable manner in which in many instances photography has, by reason of the non-actinic colour of the writing, rendered plainly legible faded manuscripts, the handwriting of which was almost undecipherable from its paleness, is well known; nevertheless, in any case of copying it is clearly evident that it is desirable to have as dark a colour as possible, hence we may place on record the plan adopted at the Bodleian Library at Oxford for a long time past for restoring faded ink on parchment, &c. It consists simply in painting the faded ink-marks with a solution of hydrosulphide of ammonium with a camel-hair pencil. This is the same solution which some photographers employ as an intensifier, its action following upon the soaking in bichloride of mercury.

SOME time ago we described the performance of an electric lamp of the incandescence pattern, which, instead of succumbing after reaching the maximum time of burning—six hundred hours—which is commonly allotted to a good lamp, had long passed its four thousandth hour, and was as good at the time of writing as when new. The

filament was one of Edison's make, and it is well known that the life of a lamp depends greatly upon the character of the filament whose incandescence is the cause of the light. There can be no doubt that for dark-room work, for example, the longer a lamp will work without requiring changing the more useful it must be, so that every improvement in this direction is worthy of note for the photographer. We observe that a patent has been taken out for an entirely new form of filament, which the inventor has styled *ordite*. Instead of seeking for the most homogeneous form of organic structure, which, when carbonised, would be stable and regular in electrical conducting power, he breaks ground in an entirely new direction. He makes the filament of any one of a number of common organic substances, preferring to select a material with porous texture, or one having interstitial spaces—thus common slack twisted cotton yarn or thread answers his purpose. It is prepared by soaking in a solution of an aluminous salt, the base of which is then thrown down by ammonia, and the soluble product removed by soaking in water. The whole is then, after drying, carbonised in one of the many accustomed modes. He also makes the thread by mixing an organic salt of alumina with carbon, and a little dextrine to hold all together, the whole being then dried and exposed to a white heat after being pressed through a syringe in the style familiar to the old emulsion experimenter. Every form of improvement in connexion with electrical lighting is to be welcomed, for we are well assured that the use of electrical lighting is increasing, and will continue to increase, in the *atelier* of the enterprising photographer.

THE PHOTOGRAPHIC EXHIBITION.

VI.

FRANK M. SUTCLIFFE (No. 512), *Study*.—One of a group of seven small pictures, all evidencing a keen perception of artistic composition and effect. In this particular photograph of three sailors grouped on and around a capstan, it will be evident that the pose of the three figures has received much thought, and the result is an artistic study. Captain Abney, R.E., F.R.S. (No. 519), *Ulrich Kaufmann*.—One of four small portraits of Swiss guides. A departure from the usual landscape work of this exhibitor, but valuable as giving us the actual presentment of men upon whose experience the lives of many mountain climbers depend. Photography, when properly used, is here seen in its capacity to give character and individuality, which is something. G. B. Wood (No. 524), *Chain Gang*.—This title is given to five large puppies chained together. The technical part is good, they having been taken in bright sunshine; but we notice this photograph for the purpose of stating that this American amateur is not so strong in artistic results as he was last year. Few photographers seem to be able to sustain a reputation year after year, and quantity will never compensate for quality. Geo. Scamell (No. 539), *At Pungbourne*.—A small study evidenced by placing two figures in a boat, who do not look at the camera. This picture would have gained if the sky had been toned down so as to lessen the contrast between that and the dark foliage. It is also an excellent example of a good result taken on negative paper.

Ralph W. Robinson (No. 540), *Out of her Reach*.—An old woman about to cross a stream. Well placed in a rather nice bit of scenery, but still that objectionable cutting off the bare tree-stem at the top of the picture is again seen. Robinson & Thomson (No. 543), *Capri*.—A most excellent photograph, toned to a warm brick-dust colour; very unpleasant, because it cannot be like or suggest the natural colour, and where distances are concerned still more out of place. Photographs like this one and No. 544, although very artistic in selection, seem to take away all poetry from preconceived notions of such well-known spots, whose beauty consists in rich colour, which monochrome, and especially this tone, does not realise. Frank M. Sutcliffe (No. 546), *Study*.—This is one of five small studies, where this exhibitor shows how to convert commonplace subjects into something attractive entirely by artistic treatment, and the matter of this particular picture becomes another thing altogether by first of all mentally seeing the result, and then by combining well-chosen contrasted clouds with a number of upright lines arising from buildings and boats, and waiting (ah, there is the mental design!) for a vessel with dark sails

to come into close proximity with the highest lights. Then follows an artistic picture, which is looked upon with intense pleasure both by the painter and the public. A medal has been awarded this picture. C. T. Mallin (No. 551), *Sea Gulls*.—This is the original picture which caused a sensation some little time since. There is absolutely nothing to criticise in it, being the result of chemical work and mechanical appliances which might go on repeating similar facts day by day. Edgar Clifton (No. 552), *The Lea*.—Here we have a picture made out of ordinary matter, where judicious advantage has been taken of a barge on a river to emphasise the leading lines of the subject. Mrs. S. G. Payne (No. 553), *The Secret*.—This is a small picture of a boy and girl walking along a country lane. The girl is speaking to the boy, hence the title, which is not a good subject for children to pose for. The exhibitor is not so happy this year in her pictorial work, the titles of which seem to have been thought of after the photographs had been taken. Ralph W. Robinson (No. 558), *Frost and Mist*.—This is another small photograph, where the mist is indicated by distant trees (a second printing). The two sections of this picture want something to unite them. The mist might have been brought nearer, the front portion being too crisp, but the idea is good.

Underwood French (No. 559), *Promontory of Monaco*.—This is a very soft photograph of a celebrated place. It would be a difficult matter to get anything pictorial out of such materials, and therefore the simple facts are alone interesting. Fred Hollyer (No. 569), *Miss Ellen Terry*.—We are so accustomed to reproductions by this exhibitor that an original study from life comes upon us with pleasure. This is but a small picture, with the face in profile, but the pose and especially the hands are admirable, and whilst intended as a portrait it has been made into an artistic study. Mrs. Brian Hodgson (No. 570), *Living Flowers*.—Two heads of young girls, where original drapery has been entirely concealed by some sheet-like material, the folds of which have received much attention, suggesting antique study; and although the result is not quite satisfactory, yet it indicates an artistic perception. J. Milman Brown (No. 571), *View, Isle of Wight*.—This is from a very pretty bit of nature, and yet this photograph does not quite realise the scene; it looks as if it was made up of thousands of similar sized bits, like mosaic. Possibly another time of day might have given breadth, which we recollect at one time characterised the very good work shown by this exhibitor.

J. B. B. Wellington (No. 576), *Studies*.—Here we have twenty small platinotype photographs taken with a detective camera held in the hand. The subject-matter of each has been well chosen; but why a detective camera was used upon sailing vessels and other subjects we fail to understand. Nevertheless these little pictures are very good, and it would seem that artistic photography at the present moment finds its outcome in extreme opposite sizes. G. W. Tyser (No. 585), *Old Street, Mentone*.—This is a good photograph of old buildings and streets, very picturesque and singular, and reminds one of a bit of Prout, the painter's work. George Hadley (No. 590), *A Connoisseur*.—We notice this picture merely to remark that, although the photographic part may be good, a curious effect is produced by the old antique vases being placed so much apart that with the head of the connoisseur they form six unconnected objects to be considered, which is wrong. Mrs. Brian Hodgson (No. 610), *In an Orange Garden*.—We find in this small photograph a female figure with classical drapery well arranged, but so out of harmony with the rest of the picture that we wonder how she got there, especially as the technical work is not equal to her presence. Benque & Co. (No. 615), *Portraits*.—These consist chiefly of standing figures, in platinotype, on large paper and white backgrounds. They are exceedingly clever in pose and most artistic in the delicate brush work, which has been added as necessary backgrounds to the photographic work. Leonard Blake (No. 618), *Children*.—This frame contains a quantity of portraits by one who last year had a medal awarded to him, but who is now no more. They are very original and artistic in pose.

Rev. H. B. Hare (No. 427), *The Gloucester on the Usk*.—This picture has been taken at a time when very little foliage was on the trees; it may look very well in nature, but the composition formed by the stems does not produce such a pleasing result as full foliage would have done. This exhibitor is noted for his extreme delicacy of foliage in gradation, which we do not see here, and, in fact, we think that the possible beauty of the original may arise from its local colour,

which photography, alas, gives us faint idea of. The water (on the Usk) has been very well rendered.

Miss E. D. Anderson (No. 618A), *Studies*.—Two frames of some very good photographs, where artistic instinct is evidently struggling to do something. Experience and study will enable this exhibitor to produce far better work in the future. Miss Georgina French (No. 620), *Studies in Venice*.—A frame of six bits of Venice. There is very good work in these studies, which appear to have received much thought and attention, and they convey a better idea of the buildings and the water highways than many other Venetian pictures have done. Teich Hanfstaengl (No. 633), *Portraits*.—Another sample of foreign work from Dresden. There is very little that is good in this "board" of photographs; one large panel portrait in the centre being very nice in pose, profile, face, slightly back view, and arms straight down to hands on knee. Much is due to the picturesque costume and the flowing down of some very long back hair, but its value is spoiled by having other photographs pinned on to it, a foreign idea which had better not be imitated.

W. H. Hyslop (No. 635), *Yachting Studies*.—To this picture a medal has been awarded, and it is most certainly the very best photograph that has been taken of vessels in motion. How many times did the photographer beat about in his vessel before he saw these two racing yachts in good position? And what a position! Both being broadside to the camera, and almost under our feet, implies a quick perception of the picture, and a nervous letting go the exposure, the result being a photograph full of life and most exquisite detail. No. 636, by the same exhibitor, is also a very good photograph, but it would appear in this case he had only to wait for the yachts passing round the turning point, and his work was done. This is a singular instance of objects forming themselves into a picture, and the result is very pretty and most interesting.

We now consider enlarged works and reproductions. Morgan & Kidd (No. 34), *Portrait*.—This is a very fair specimen of argentic gelatino-bromide paper enlargements, the colour being much better than usual. We might take exception to the vignetting, which should not look as if the lower part had been moulded in a basin; but this requires such special capabilities that do not always go with technical excellence. Robinson & Thomson (No. 71), *The Last Load*.—This is a very good enlargement, and the original photograph has been well put together, the white horses coming along with the last load being very strongly contrasted, and thereby made very effective. This picture of English country life should hang upon the walls of many an old farmhouse, it being so pleasant and genial. G. Watmough Webster (No. 90), *Miss Coplestone*.—This is an autotype enlargement, and it does full justice to the original negative, which, although giving delicate detail on white objects, has not increased the depth of shadows and parts in shade. Samuel Fry & Company (No. 161), *Bromide Enlargement*.—This is a tolerably fair example of work which after all must depend upon the original negative. On the taste displayed we are not called upon to make any remark. In connexion with all bromide enlargements it is a great pity that so much brush work, which is far from being artistic, should be found necessary. Marsh Bros. (No. 201), *Horse's Head*.—This is a very good work, and the head is very lifelike in detail; but its pictorial value would have been increased if it had been put into an oval mount. Autotype Company (No. 282), *Tree House, New Guinea*.—This is undoubtedly one of the very finest specimens of autotype enlargements we have ever seen; apart from its very unique subject this work is full of most exquisite detail and soft half tone, the original negative only representing a fact, yet makes up into a very pleasing artistic picture. H. S. Mendelssohn (No. 304), *Grand Duchess Serge*.—Here we have a comparatively small enlargement of a high personage, who ought to make a good picture. There are some strong contrasts in this work which are produced by the brush, and, as we are getting almost tired of stating, are very far from being technically artistic in touch. Eastman Company (Nos. 366 and 418).—Two monster enlargements on bromide paper, which only serve to show what can be done in size by this process, and so far answer a definite purpose in pointing to possibilities for better work in this direction in the future. One thing is right to notice: no attempt has been made to "brush" them up; but why was not better subjects utilised? Autotype Company (Nos. 384 and 403).—These

are two frames of collotypes from negatives by J. W. Lindt, and are exceedingly good specimens of the process; but these pictures possess an unusual interest from their being almost the first contact of photography with mankind in its barbaric state. Boussod, Valadon, & Co. (No. 394), *The Welcome*.—This is a very large and fine example of photogravure to which a medal has been awarded, and where the original intention of the painter seems possible to be reproduced in monotone without the individuality of a translator. There are many other large works by these exhibitors, all very good.

Annan & Swan (No. 410), *Dr. Bonar*.—This is another specimen of photogravure, to which a medal has been awarded. There is also a large work by these well-known exhibitors from a painting by Sir Noel Paton, *Oberon and Titania*, which is very good. Autotype Company (No. 390), *Idyls of the Norfolk Broads*.—These are autogravures, and are more like hand engravings than any other photogravure process; but then they are done from Dr. Emerson's negatives. These exhibitors have also other fine specimens of work done from paintings. Henry Dixon & Son (No. 447), *Orthochromatic Photographs*.—These are copies from oil paintings, and most certainly are very fine examples of the process. These exhibitors have a large variety of other copies on the walls, which all point to success in that work. Andrew Pringle (Nos. 389 and 398), *Micro-organisms*.—A medal has been awarded these exhibits, which are wonderful examples of patience and skill in utilising modern advances in relation to micro-work. F. H. Evans (Nos. 452 and 453), *Photo-micrographs*.—A medal has also been awarded to these frames for photographic work in connexion with photography.

We congratulate the photographic world upon the display of good work which the Photographic Society of Great Britain has been enabled to hang on its Gallery, which, whilst showing much of what the past has done, most assuredly holds out a great promise of better work in the future.

Remarks on Apparatus next week.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

In working up enlargements in colour (be it monochrome or natural colours) the features just treated are not the only ones demanding our most careful attention. No doubt the face and all its component parts are not only the most difficult to master, but they are naturally the most essential portions of a portrait; still there are many other points which must be treated with skill and judgment in order to make the *portrait a pleasing picture*.

The *hair and beard*, which we will treat of first, may be considered as part of the face, they are so closely allied to it, but the *draperies, ornaments, and backgrounds* must be most skilfully treated (especially when worked in natural colours) in order to harmonise with and generally add to, the beauty of the subject. There are many artists who hold the opinion that there is much more skill and judgment required in painting a really successful background than in painting the portrait itself. There is one thing sure, that a background can make or mar a portrait however good it may be, and we should, therefore, spare no pains in mastering all the details necessary to ensure success in this quarter.

Hair when smooth will appear most glossy, and this glossiness will be rendered in the photograph by a patch of white, in many cases unduly large and shapeless, not in the least preserving the natural characteristics of hair. There are several causes for this, but all turning upon the disposition of the light. If too great an amount of light be used in lighting the sitter this defect will be very palpable, and more than ordinarily so in the cases where the sitters have very dark hair. Now the white patches thus produced will require toning down, and in many instances will lack the character of hair at all, and, therefore, we are called upon to impart this appearance to it. In doing so we must be careful to preserve broadness of effect combined with a certain looseness, as any approach to solidity would mar the effect we are, or ought to be, so anxious to produce. In most cases a broad but thin wash of colour will be found advantageous, and upon this a few effective touches to give character, but never try to represent the individual hairs or we may have the doubtful success

* Continued from page 680.

of procuring *wiriness*, a characteristic than which nothing can be more objectionable.

The shadows, too, will require strengthening with a few forcible and vigorous touches, always trying to keep our effects as broad as possible. Sometimes when the print is very deep and powerful, *glazing* will be almost sufficient. That is, instead of making our vigorous touches with a more or less deep colour we simply make them with gum water in such places as will throw up and give effect to the other portions of the hair or beard.

As we treat the hair so we must treat the beard. The latter is naturally more coarse than the former, and must, therefore, be treated with greater freedom. All the light patches must be toned down, and a general effort made to gain the appearance of softness. This may be done by a judicious mixing of the treatments—washing, stippling, and hatching. As in the treatment of the hair, do not strive to particularise too much, but rather to gain the effect of a whole which will more or less truthfully represent nature. In many enlargements the photograph is so coarse that the beard very often is more like twine than hair. Needless to say this must be altered and all made to, as closely as possible, resemble nature. I think there is little more to be said about the hair and beard, so we can pass on to the *draperies*, &c.

Under the heading of *draperies* may be classed not only the certain accessories in a picture but also the dresses, coats, &c., to which we may now direct our attention. In cases where the enlargements are from copies there will be a great deal of work before these parts of your picture will present a satisfactory appearance. They very often, if not always, lack strength and brilliancy. It is, therefore, best to give a general *wash*, and then even up such places as still require it by a broad system of stippling. It is absolutely necessary that the *tone* of the colour used for this purpose should be made to exactly match that of the photograph, otherwise a very unsatisfactory effect is sure to result. Now having matched the colour you are going to *wash on*, to the tone of the photograph, you proceed to work. This wash should be put on with rather a large brush; one made of camel-hair will be found to be the best adapted for this purpose. It will naturally hold a lot of colour, and is so soft that it will not touch any under tone or wash that might have been already put on. The *lights* in all these cases, when occasion requires, should be produced by an eraser. The effect is always soft, and the operation lends itself to the treatment of passing a uniform tint over the enlargement, with the intention of strengthening or giving depth to the plain enlargement. This done, it will be found often that the folds will require emphasising or intensifying. For this purpose the colour should not be too moist nor yet too dry, and the original form should be strictly adhered to. The brush must be used very lightly, or else we will disturb the original wash—a result that would give very considerable labour to put right.

In a good photograph it will be observed these defects will never present themselves. On the contrary, it is little short of wonderful the extreme truthfulness with which the various characteristics of the different materials are reproduced. This texture must on no account be lost sight of, but rather helped out with the greatest care. There is a certain freedom in the treatment of the *draperies*, &c., which is quite legitimate and just. It is left to the judgment of the artist to alter or tone down any objectionable folds, lights or shadows; of course this must never be done at random, but always with the gaining of some artistic purpose in view.

It may not be altogether useless to note a few of the characteristics of the various materials, which may help us as a guide where the photograph may be deficient in detail.

In *cloth* materials the folds are always broad and soft, and, as a natural consequence, the lights and shadows are also broad and soft, with reflected lights between the folds. These lights when necessary can be heightened by rubbing with an eraser, and the shadows deepened in the usual way.

In *silks* and *satins* the character of the folds and the lights are quite different. The folds are somewhat angular, the lights much more brilliant and well defined, the shadows dark and rich with strong reflected light. These features are especially remarkable in satin. Where the lights are not sufficiently strong in the original the use of the eraser will be quite equal to the task of making the necessary alteration.

In photography, *velvet* is somewhat liable to be represented too dark in tone and lacking in detail, and will therefore require some shape and drawing put into it. The highest lights (which are sometimes very strong indeed) will be found on the extreme edges of the folds. Some suggest the putting in of these lights with the aid of Chinese white, but personally I do not hold with this treatment. I do not wish to interdict the use of Chinese white altogether, but I certainly think the less it is used in these cases the better. A touch here and there will give a very great effect, but this will be lost if a general use is made of it. Judiciously used, I think the eraser and the knife will be found sufficient for nearly all the necessary effects. As I always say regarding these matters, it is very difficult, indeed, to lay down hard-and-fast rules, and I can almost say it would be loss of time to try and do so, as so much must always be left to the judgment and skill of the artist. I have known good men who could not use the knife, others who were perfect marvels with it, and both secured splendid results in their own particular way. I think, therefore, it is somewhat wrong to try and force any particular style as being the only and absolutely correct. One can only express their preference for one or other style as it may please them best. The effect of the more intense shadows may be strengthened and enhanced by the use of gum water, or, better still, by a weak or well diluted wash of Newman's "Sizing Preparation," when you have finished your work and it is dry. This latter has an advantage over the gum water, inasmuch as it has not such an objectionable gloss, but harmonizes more completely with the general quality of the photograph.

For all *white draperies* the eraser and knife will be your best friends, with here and there a touch of Chinese white. By a skilful combination of the three, beautiful effects may be realised. Too much of one will spoil, while the introduction of one or other of the others would tend to relieve and heighten the effect.

It will invariably be found best to paint in the *draperies* with repetitions of washes of different strength, reserving your stippling and hatching for the finishing up. By this means it is more easy to secure softness and harmony. The use of too decided dashes of colour may often lead to *hardness*.

In working up *jewellery*, the use of Chinese white is not only admissible but advisable, as you will get minute sharp details with it that the eraser will not give, and for which the use of the knife would be very troublesome, and perhaps unsuccessful. As all articles such as jewellery partake more or less of the nature of a polished surface, the photograph will make the high lights much broader and out of proportion than is consistent with nature. It is one of the cases where photography exaggerates. Of course I am speaking generally, and of work taken in the ordinary way. It will therefore require toning down, and then "picking out" with sharp and decided touches of Chinese white.

The foregoing naturally bears most upon monochrome. In natural colours the same remarks apply as regards light and shade, but there is naturally greater scope for effect than in the very limited lines of monochrome work. Still, the practice of the latter will be of great help when the student enters on the more extended, I might almost say limitless, area of painting in natural colours. The study of nature never becomes monotonous. Why? Simply because it is so vast. We never feel cramped, new experiences crop up at every turn, and even if we live to a ripe old age, we will find something new to finish up with. One day I was admiring a number of sketches from nature, and made some remarks regarding their freshness, when my artist friend said, "Oh, yes, they are all from nature! But do you know I will lose much of that same freshness when I paint my picture from these sketches; there is no inspiration apart from nature." These were landscapes, and the remarks applied mostly to colour, but in portraiture there is also an endless study.

REDMOND BARNETT.

(To be continued.)

HYDROKINONE.—LANTERN SLIDES.—THE CARRIER.—THE LANTERN.

In last week's JOURNAL I saw hydrokinone mentioned in America as an intensifier. I am glad to see my old friend H. K. coming more to the front, and I hold still the opinion that it will ultimately

supersede pyro. Let your readers try the following formula, which, after making up and trying various modifications, I find the best.

Soft water	10 ounces.
Chloride of potash	$\frac{1}{2}$ drachm.
Sulphite of potash (not meta-bisulphite)	1 ounce.
Tartrate of potash	1 drachm.
Commercial carbonate of potash	3 ounces.

Thoroughly dissolve all this, and after filtering it through a plug of cotton pushed well down into the neck of a funnel, add hydrokinone two drachms, and filter once more. Proportion to soft water for use for ordinary negatives one to sixteen, and patience *quant. suff.*, as in this proportion it is a slow developer, but I think gives best results. After development has proceeded some time, you may with advantage pour it off, and pour on a fresh quantity. For lantern slides, giving black tones and clear glass, one to eight. Two ounces of soft water, and two drachms of the developer will develop quickly and well three lantern slides, one after the other.

Lantern Slides.—Having to give a local exhibition at a schoolroom, and wanting a few slides as an interlude for the children of a more amusing than instructive character, I bethought me of trying if I could not make them sufficiently good for the immediate purpose from some paper stereograms I have. I selected a dozen and proceeded, but found a difficulty from my camera—nothing long enough to produce them lantern size; but an idea struck me, which answered admirably. I screwed the lens I was working with—viz., a Dallmeyer's wide-angle doublet, $7\frac{1}{2} \times 4\frac{1}{2}$ —inside my camera instead of outside, using it really, I suppose, as an enlarging lens (?), and then my subject seven and a half to eight inches from the lens, on a rough miniature easel I knocked up, and the camera drawn out to about the same. I got capital results, even making allowance for copying from paper.

The Carrier.—I have altered that to enter the slides from the side instead of above, and can use one half of some good glass stereos. The best results are obtained by taking off the ground-glass and replacing it with plain. They are just as good for the stereoscope by having a loose piece of ground-glass to put in with them to the stereoscope, and when used for the lantern the half holds quite firmly in the carrier—of course the other half projects into the room.

Finally, the Lantern.—"Ament the lantern's murky smell" which everyone complains of. Mine, do what I would, was nearly useless in the drawing-room, but in a lucky hour I had recommended to me by a tradesman in the neighbouring town a substance without a name to put into the domestic duplex lamp. I said I would try its virtues, one of which was the removal of smell, so I thought the most severe test would be my Sciopticon, three wick. It answers beyond all expectation. Clean the lantern thoroughly—as ought always to be done with all lamps, we know—put half the sixpenny packet into the reservoir and shake it up; let it stand about six hours before use, and if every one succeeds as well as I have done, they will think it a boon indeed. The name of the maker on the packet is Lynch & Co., 8, Carpenter's-lane, Manchester, and it is "originated by Professor Beck."

Greenhithe, Kent.

W. T. F. M. INGALL.

ORTHOCHROMATIC PHOTOGRAPHY.

[A Communication to the Photographic Club.]

NOTWITHSTANDING the many statements that have been made with regard to the use of orthochromatic plates for outdoor work, that they were bound to be far superior to the ordinary plate, I think sufficient time has elapsed to have enabled photographers to have fairly tested them for that purpose; and what has been the result the present Exhibition will show, with one exception, that orthochromatic plates have not superseded others as yet. And why is this? In many cases they have found but little difference between them and the ordinary plate, and, again, many have found that the use of them entails much greater care in manipulation that they are not worth the extra trouble and cost in using them.

One great advantage of orthochromatic plates (in conjunction with a yellow screen) is photographing outdoor subjects on a slightly foggy day; the result on an ordinary plate being flat and foggy, on the orthochromatic, crisp and brilliant. But for landscapes with distance, if used with a yellow screen (especially on a clear day), the charm of distance is gone by losing what we call atmosphere and bringing it sharp and clear; and, again, with shadows which are usually of a bluish grey nature, are rendered much darker than they appear, so that if used at all for landscape a great amount of judgment and experience are necessary. But I admit in some cases it is an advantage to render distance clearer, especially on those occasions when there is too much atmosphere. I think I may fairly state that this is the most difficult branch of anything connected with photography. But when we come

to photographing flowers or other close studies in colour, as well as copying paintings, then, to get the best results, their use is absolutely necessary.

We are now approaching the season when, if orthochromatic plates are to prove of any use at all for landscape work, their value will become apparent. I refer to the beautiful tints of yellows, browns, and shades of red, which we see on the foliage at this time of the year, one tree with its sere and yellow leaf standing out in bold relief against some darker green tree which has not yet begun to put on its autumnal robe. I know many have been waiting to try the effect of this latest discovery in photography for this purpose, and I have taken this opportunity of bringing before you two new formulæ which will enable you to try for yourselves whether there is any real value in the process for outdoor work. I think it would prove interesting if members were to bring the results of their trials in this direction before the Club; an ordinary plate should be exposed at the same time.

What I specially claim at present is the use of quinine in conjunction with the dyes for the purpose of prolonging the keeping qualities of the stained plates, and also treating the dye itself with chloral hydrate. In fact, quinine has many other advantages in connexion with photography, and no doubt before another year has elapsed we shall have many uses to which quinine will be put. One little use, or novelty I perhaps should say, I discovered only a few weeks ago, and which will serve as a short paragraph for the coming ALMANAC.

My formula, although working satisfactory, might, with advantage, be made less complicated, at least for those who wish to make it up; but I hardly see my way of doing so at present so as to keep all the existing good qualities in it, and I thought it would be a pity to wait till all further experiments were completed, as every one knows that experiments create experiments, and so we may go on almost for ever.

The two dyes which I propose to bring before you are cyanine, which is well known, and methyl violet. Cyanine, in my opinion, has a greater range of colour sensitiveness than almost any other dye, and is most useful in copying paintings, where, as a rule, a large amount of red is to be found. This dye is particularly sensitive to red, and sufficiently so to green (I am referring to copying, and not to the spectrum), which is not the case with erythrosine, which barely extends beyond the yellow, being quite insensitive to red; and, moreover, this dye (cyanine) has no action on the gelatine like some other dyes, but develops clear and brilliant as any ordinary plate.

Between cyanine and methyl violet there appears to be but little difference in colour sensitiveness. The cyanine is a trifle the more sensitive to red. On the whole, perhaps, methyl violet is preferable to use, not only on account of its price (which is one-fortieth that of cyanine), but it appears to me that when it has commenced to develop the sensitiveness to yellow is somewhat destroyed, and more yellow light can be used in developing than is the case with cyanine. But great care must be taken when dipping the plates, placing them in the dark slides and again into the developing dish, which should be done in almost total darkness. This applies more forcibly when using cyanine.

Now to come to the formula of cyanine. I find by treating it with chloral hydrate and again separating by means of ammonia it is much improved, and does not precipitate when added to an aqueous solution, which untreated cyanine does, as many no doubt know who have tried it. Take—

Chloral hydrate.....	1 ounce.
Cyanine	10 grains.
Water.....	4 ounces.

Boil together in a water bath, when the cyanine will be found to be dissolved. Keep stewing for twenty minutes, then add one ounce of liquor ammonia carefully; ebullition takes place, and chloroform is liberated, therefore it is advisable to do this in the open air. After a few minutes the cyanine will be found adhering to the sides of the vessel, the supernatant liquor being carefully decanted away, the residue being rinsed one or twice with water. Eight ounces of methylated spirit is now added to dissolve the cyanine, together with 120 grains of soluble sulphate of quinine. Dissolve the latter by heat in a small portion of the spirit first. Finally, filter through a small filter paper. The solution will keep as long as a dipped plate, namely, about four to six weeks.

For dipping take of the above—

Cyanine solution	1 drachm.
Liquor ammonia	1 "
Water, distilled	20 ounces.

A weaker or stronger solution may be used to suit various plates. The weaker it is the longer will the plates keep. As a rule a plate

of medium rapidity will be found easier to work than one of extreme rapidity. The cyanine is added to the water, the drachm measure washed out, the drachm of ammonia next measured out and added to the cyanine and water, with stirring. If the ammonia is poured into the same measure which contained the cyanine, a precipitate of quinine takes place, which does not happen if in a diluted form, thus the reason of adding the cyanine to the twenty ounces of water first, and finally the ammonia.

For a half-plate take two ounces of the above diluted solution and flow over the plate, and keep rocking for two minutes, after which throw the solution away. On no account must the same be used for another plate, as great irregularity will result in the rapidity and colour sensitiveness of the next plate. This applies to all dipping operations. The plate now dipped is to be dried in total darkness.

For methyl violet the treatment required is somewhat different. The dye used by itself produces fog, which baffled me for some time to get rid of, but finally I succeeded by treating it with an oxidiser, such as bichromate of potash, and then proceeding as with cyanine, viz., by treating it with chloral hydrate. But this latter treatment is not absolutely necessary; in fact there is so little difference worth speaking of that you may as well disregard this latter treatment. Take—

Methyl violet.....	10 grains.
Water.....	4 ounces.
Bichromate of potash	$\frac{1}{2}$ ounce.
Water.....	2 ounces.

Raise both as near boiling as possible, and mix. Keep in the water for half an hour, collect the precipitate by filtration, and wash by passing water through the filter. By this treatment it is no longer soluble in water, as was the original. Dissolve the filtrate in methylated spirit containing 120 grains of the soluble quinine sulphate and filter.

For bath take—

Methyl violet solution	1 drachm.
Ammonia	1 "
Water, distilled	20 ounces.

To get any decided effect at all on orthochromatic plates, a yellow screen is necessary, but many people imagine they will show correct rendering of colour without any screen at all. I have not yet seen the gelatine plate that will do so. Almost any yellow dye will answer, some better than others. I have a liking for turmeric, which I prepare as follows:—

Turmeric	1 ounce.
Methylated spirit.....	7 ounces.

Digest on a water bath for twenty minutes, and allow to stand a day or two to settle, then decant the clear solution off, about four ounces, and add to this four ounces of methylated ether and fifty grains of pyroxyline. This will make the stained collodion. Coat a piece of patent plate $3\frac{1}{2} \times 3\frac{1}{2}$ —ordinary glass should not be used owing to its want of flatness, and with which it is difficult to get a sharp image—take another similar piece of glass and cement the two together by means of Canada balsam, the glass being slightly warm. I have to thank Mr. Debenham for the suggestion of Canada balsam. It not only reduces the reflecting surfaces, but it also renders the film more transparent as well as protecting the film from injury. Clean away the balsam that oozes out, and mount as an ordinary lantern slide. This should be kept in the dark when not in use, as turmeric is bleached by the action of light. I prefer to use it behind the lens, as then it is protected from the light, and the folds of the bellows will prevent it from falling down. With this screen the exposure will be increased about ten times.

Any of the usual modes of development will suit, but I must again caution you to expose the plate as little as possible to the light of the developing room. With these precautions I can ensure success to any who may try it. J. B. B. WELLINGTON.

THE PERMANENCE OF PHOTOGRAPHIC PRINTS.

[A Communication to the North Surrey Photographic Society.]

I HAVE received several very kind invitations from our friend Mr. Senior to attend one of your meetings and have a chat with you on some photographic subject. I was afraid that none of the subjects that I have been working at lately would be of much general interest, but he thought that the question of the probable permanence of photographic prints done by the various printing processes in common use at the present day, would be interesting. Anyhow, I hope it will lead to a useful discussion afterwards.

The position of the photographic amateur of the present day about to decide upon the best printing process for him to use, is something like that of a young man I met the other day in a photographic

dealer's shop. He had come up from the country to get all the necessaries to set up as an amateur photographer. In his bag he had got catalogues and price lists from, I should think, every dealer in London. The poor fellow had spent hours in studying those books, and was evidently fast qualifying for the post of inmate to a lunatic asylum, when, as he told me, "his mamma suggested that he should come up to London and see the cameras, &c., and he would be able to judge, then, which was best." He had come up, and when I met him he had been to three or four shops, the owners of which had each explained the advantages of using the only perfect camera in the world, and had advised him (as a disinterested friend) not to have anything to do with any of the rubbish generally met with. Need I say that the poor fellow was in a bigger fog than ever. So it is if an amateur seeks advice as to what printing process to use. An old photographer would probably tell him that if he wants quality he must print on albumenised paper, that he himself had been working at it for the past thirty years, and ought to know something about it by this time. So he ought, but somehow some of them do not. The Platinotype Company's people would not be able to understand how any one but a born idiot could think for one moment of printing in anything but platinum.

If the said amateur were to wander into Soho-square, at No. 13 he would be informed that if he wanted anything simple, effective, and profitable he must use the Eastman permanent bromide paper; whereas if he called on Messrs. Marion, at No. 23, they would advise him to use the Britannia—no, I beg pardon, they might think they had got a better brand than that in stock now, or at least something they would prefer to recommend; then, if he got down as far as Richmond or Kingston, he might almost get to think that those London fellows had been trying to take advantage of his innocence.

Well, gentlemen, I will now tell you, as a photographic amateur, and I believe unprejudiced on the subject, how to my mind the rival claims of these different processes appear to stand as regards their practical use to the professional as well as the amateur photographer, and then we will go into the question of probable comparative permanence. First, as to ease of working. With the professional a printing-out process is probably as expeditious as any other, because a large number of negatives can be printed from at one time. Platinum prints more rapidly, but then one cannot attend to so many frames at once; besides, with the less exposure required (especially with the ever changing strength of daylight) the more the prints are liable to get over printed. But with most amateurs the trouble of printing is due to its having to be done in the daytime. For such the bromide paper is just the thing, because it can not only be done of an evening, but there is the interest attaching to the development, which I consider the most interesting part of photography.

The next subject is, "Certainty of Result," and I must say that I do not believe that any process will displace the albumenised paper print in the professional's printing room unless it enables him to see the result during the printing. With his work there must be no uncertainty or waste. With the amateur, however, the question is rather different, because he has not the experience of the professional printer to enable him to take advantage of the means of dodging a negative, which a printing-out process allows.

If you will allow me I will just show some of the amateurs present a few methods how a print can be improved after being taken from a printing frame. First as to printing in clouds. The greatest mistake photographers as a rule make, is to over cloud their prints, and so detract from the interest in the landscape; if you have large masses of white clouds in your picture with well defined forms, they will attract the eye more than anything. All that is required is a suggestion of clouds to act as a background to the landscape, and to carry a scale of tones through the picture.

Other ways of improving a print are when there are two subjects of equal brightness, or if there is any bright light near the edges of the picture, such as a pathway, by just tinting it the picture will be much improved. With the aid of a clean duster to screen parts of the print from the light, a picture can be worked up by tinting the lights and deepening the half tones and shadows, which would have been quite useless as it left the printing frame, and it is as interesting as working up a picture with a brush. It is the inability to do this that to my mind is the great drawback to platinum printing; indeed, I think it is almost safer to trust to time exposures by an artificial light of known power with the bromide papers than to have to depend on a chance exposure to varying daylight with platinum. I think you will agree with me that the charm of a picture depends very much on these delicate half tints. Understand me, I am quite aware that platinum is capable of producing these tints in a most marvellous manner—the present Pall Mall Exhibition proves this most conclusively—but how often do we see a print which would have been

improved by a little dodging if one could only have seen what was necessary during printing.

As to printing on bromide paper, I am inclined to think that in time it will take the place of the platinum, because it has not the curse of the latter in having to be so carefully kept from the damp; besides, I am in hopes that soon we shall be able to so control the action of the developer as to be able to build up the picture to what we require during the development. There is a good deal of experimental work to be done in this direction. Only last week I coated some paper for the purpose of taking this subject up again.

I will tell you what I am driving at. I want to be able to take a fully exposed bromide print and do with my developer something like what an artist does with his colours, viz., build up the picture to my own liking, and be able to stop the action of development at any part of the picture—while a shadow requires to be deepened on, more detail brought out in another. I do not think this is a wild, idle dream. Some time ago I was working in this direction, with, I think, some hopes of success. On these plates you will see that although the whole of the plate had the same exposure I controlled the action of the developer over the different portions, and in one case prevented the action of the developer at all on the darkest part of the picture. I hope soon to have time to work at this subject again, and if we can control the development of our prints we shall then be able to dispense with the advantages at present given us by the prolonged exposures of the printing-out processes.

And now for the question of permanence. But mind you, if we could not get good results with platinum or bromide of silver, I would prefer to keep to our old friend albumenised paper. I would rather have a print I could admire for a few years than be troubled with an eyesore for a lifetime. Some time ago you may remember a discussion took place in the columns of THE BRITISH JOURNAL OF PHOTOGRAPHY as to the correctness of the manufacturers of the Eastman bromide papers in calling it permanent, and as I was trying experiments with different formulae of bromide of silver for paper work, I thought I would put prints by the different processes to the same test. I first thought of getting samples of the different papers and printing all from one negative, but then I decided that it would not be fair to judge any process with which I had had no experience by prints of my own preparation. I therefore obtained prints on Alpha, argentotype, Eastman, and platinum papers, done either by the manufacturers or their acknowledged agents. I also obtained a number of prints on fresh and ready sensitised albumenised paper, and some bromide of silver prints of my own preparation with different proportions of silver bromide and gelatine. These were all put in a sealed bottle with a sponge filled with water, and sulphuretted hydrogen was passed into it for nine days. I am very sorry now I did not keep them all, but as I only did it for my own information, I have only a few of the pieces on this card which I kept for references, but there are enough for you to see the characteristic result from each process. There are other destructive tests besides sulphuretting compounds which I have applied to these prints—oxidising agents, such as permanganate of potash, the effect of which you will see. Of course with such a test as chromic acid, platinum was the only one which could stand it.

And now, to conclude, I must say that I was thoroughly staggered with the Eastman paper prints. When we think that they had been subjected for nine days to a humid atmosphere of sulphuretted hydrogen, which practically destroyed the albumen prints, yellowed the whites of the platinum prints, and changed the bromide and others as you see, I am sure that you will agree with me that the colour of the image on the Eastman paper has actually improved, without any loss of density, and the whites have not yellowed. These two latter points are most surprising. Some of Monckhoven's "enamelled double transfer paper" was tested at the same time, and had yellowed slightly.

I feel convinced that there is some secret in the preparation of the Eastman paper that gives it a permanence which I, for one, cannot obtain with bromide of silver alone, to say nothing of the beautiful rich black image so characteristic of an untouched Eastman print. I need hardly say that I have no interest whatever in any of these processes. I simply show you these results of my experiments, and leave you to judge for yourselves.

HERBERT S. STARNES.

THE GENESIS OF GELATINE EMULSION DRY PLATES.

THE ABOLITION OF WASHING SHREDDED EMULSIONS.

IN those particulars, recently published in these pages, about the first gelatine emulsion dry plate for alkaline development, prepared by me in January, 1868, it may have been noticed that the decomposition of

the nitrate of silver was effected in a cold instead of a warm gelatine solution, to meet the requirements of certain hypothetical speculations which led to the performance of the experiment. This trial revealed the fact, that when chloride of cadmium was so used to effect the precipitation, the gelatinous quality of the liquid was destroyed, whether it be so or not with other chlorides. The suggestion was published in 1868 that perhaps the nitrate of cadmium formed destroyed the glutinosity. Another explanation may be that the precipitate carried down with it the small proportion of cold gelatine present, for we have it on the authority of Herr Plener, in about the most philosophical paper on emulsions read of late years before any English photographic society, that in emulsion processes a small proportion of gelatine enters into adhesion or combination with the precipitate, and is afterwards inseparable by the centrifugal machine or any other appliances. These various facts derived from different sources raise the question to my mind, whether by effecting the precipitation in a cold solution of gelatine of proper strength enough gelatine may not be carried down to permit good re-emulsification with additional plain gelatine, or, in other words, whether gelatine emulsion may not be washed quickly by precipitation in the form of damp powder, instead of being washed in shreds, to the great saving of time and trouble in preparing dry plates. Therefore, as my experiment in preparing the first gelatine emulsion dry plate for alkaline development contains evidence in favour of this idea, the present lines are written to invite the attention of dry-plate makers to the present suggestion, for I have not leisure just now to devote personally to experiments with emulsions.

The observation of 1868 as to the destruction of some of the qualities of gelatine by nitrates and by alkaline chlorides has since been confirmed by the high authority of Mr. Wilson, in his memoir to the Photographic Society upon the process which won the Paget prize for the best dry plate at the public competition of 1880. He said:—

"The addition of the gelatine after boiling should be made when the boiled emulsion and the dissolved gelatine are both at as low a temperature as possible, and between the time of this addition and that of washing the emulsion it should be kept as cold as possible. The reason of this appears to be that the excess of alkaline bromide has a most destructive effect on the new gelatine, and therefore the lower the temperature and shorter the time during which the two are in contact the better. . . . A plain solution of gelatine in pure water is very little injured by prolonged boiling; but if an alkaline bromide (or chloride) be added it is speedily decomposed. Probably the alkaline nitrate, which is present in the emulsion in large quantity, may be even more effective."

From the foregoing statement it appears that there would be great advantages if the soluble chlorides and nitrates, and decomposed organic matter, could be poured off before adding the fresh complement of pure gelatine. The principle I have hereby suggested for trial may reduce the time and expense of making dry plates.

M. GAUDIN'S EARLY EMULSION PLATES.

Mr. Jerome Harrison recently pointed out that M. Gaudin, of Paris, devised a gelatine emulsion in 1861, but he did not give an exact reference to the original record, which I have found and examined since writing my previous article. It is pleasing to hear of such early researches originating in France, the birthplace of photography, the home of elegance, refinement, and the highest civilisation in the world—"The chosen home of chivalry, the garden of romance."

Mons. M. A. Gaudin was the editor of a journal entitled *La Lumière*, published twice a month at 9, Rue de la Perle, Paris; the periodical was regularly on sale in London at 5, Doctors' Commons, St. Paul's Churchyard. In its issue of April 15, 1861, M. Gaudin published therein an article entitled *Photogène à la Gelatine*, which I translate as follows:—

"I give the name of *photogène* to a mixture sensitive to light, which contains at the same time nitrate of silver in excess and iodide of silver in suspension. Gelatine, which can be mixed with nitrate of silver in all proportions without being altered, is the substance most suitable for making a *photogène*.

"To prepare the composition, melt at a gentle heat in a deep glass vessel, ten grammes of white gelatine in one hundred grammes of common water. When all the gelatine is dissolved, add five grammes of crystallised nitrate of silver. On the other hand dissolve two grammes of nitrate of silver and precipitate it as iodide of silver by the addition of a soluble iodide; the precipitate is thrown upon a paper filter, and washed with water for some time; the washed iodide of silver is then added to the argentiferous solution of gelatine, and is beaten up therein for a certain time until it forms a homogeneous liquid which, when spread upon glass, gives a film having the appearance of sensitised collodion.

"Before using the *photogène* it is filtered warm through a glass funnel with the bottom lightly plugged with a tuft of cotton wool,

Medal.

CAROLLING.

"This Carol they began that hour,
How that a Life was but a flower
In Spring-time."

[H. P. ROBINSON.]

through which alcohol has been passed to remove grease, and afterwards water to wet it.

"The opalescent filtered liquid is distributed while warm on plates with an albumen substratum, as I have directed for collodion.

"Photogene prepared in these proportions is very fluid and sets upon the glass as readily as collodion. Its great fluidity, favoured by its temperature, leaves upon the plate an infinitely thin film, as uniform as that of the glass itself. After the plate is coated, it is placed vertically to dry, resting upon blotting-paper.

"If the proportions of gelatine and iodide of silver be increased, it is necessary to apply photogene at a higher temperature, for the film must be as thin as possible.

"When the photogene becomes cold, it sets and can be placed in the camera, only the development cannot be commenced until it is sufficiently dry not to be injured by contact with the finger.

"The image is developed by covering the plate with a concentrated solution of filtered tannin; it comes out in general without the addition of silver, but it is better to add several drops of nitrate of silver a little after the immersion of the plate in the tannin bath.

"By this method the image appears exactly like one upon plates prepared with albumen; but if the gelatine expands, and if the sensitive film be not extremely thin, its surface will become frilled, and the finer details will be destroyed.

"The image comes out at first a somewhat red colour, and changes gradually to a very intense bistre.

"Photogene is slow in receiving impressions, almost like albumen; the image is also very long in appearing.

"The mixture should be prepared and applied by candlelight, and kept from the light of day, under the influence of which photogene turns brown and becomes useless without being revived; it can be restored by the addition of a few drops of bromine water, which, after agitation therewith, restore its clear yellow colour.

"Photogene distributed upon a glass and allowed to dry spontaneously, serves, like albumen, for the taking of positive transparencies.

"The hyposulphite fixing solution must be very weak, of the strength of five per cent., for it tends still more than tannin to make the film frill. After abundant washing, the plate is dried again by artificial heat, then varnished in the ordinary way."

From the records so far examined, it seems that before 1868 the few negative gelatine plates tried contained an excess of nitrate of silver, and received acid development in the attempt to substitute gelatine for pyroxyline, and to leave the rest of the process like that in common use with wet collodion. M. Gaudin, however, knew that his plates, with excess of nitrate of silver, could be dried, and with tannic acid development could be used for the printing of transparencies. M. Gaudin has certainly published the earliest information about the frilling of gelatine plates.

In his opening article about *The Discovery of the Gelatino-Bromide Process*, Mr. Jerome Harrison mentions still other pioneers, without giving references to their channels of publication; Gaudin's foregoing article I searched out, but Mr. Harrison would oblige me by telling me exactly where to find the original memoirs of Gustave le Gray and of Dr. Halleur.

PATENTS COMPLETED.

A NEW OR IMPROVED ADJUSTABLE DIAPHRAGM FOR PHOTOGRAPHIC CAMERAS.

No. 3879*. WILLIAM JAMES LANCASTER, Colmore-row, Birmingham.—*March 19, 1886.*

My invention relates to photographic lens diaphragms, employed in photographic operations to determine and regulate the amount of light that shall be admitted into a camera; thus the time of exposure in photographic operations depends upon the light upon an object about to be taken and the size of the aperture of the diaphragm used with the lens.

Usually a series of various sized diaphragms are employed, or rather a series of diaphragms with various sized holes. This is objectionable, inasmuch as there is no means of varying the difference between the size of one aperture and the size of one above or below it, so as to give a mean difference.

By my invention the diaphragm is made adjustable, so as to be able to control the size of the aperture according to the varying requirements and will of the operator; thus the aperture in the diaphragm is expanded or enlarged in such a manner that an infinite variety of apertures can be readily obtained.

The diaphragms, or series of plates which constitute the diaphragm, form a part of the mount of the lens, thereby avoiding any loose diaphragms or parts whatsoever; and further, the aperture necessary for certain conditions of light can be predetermined by an index finger, before the former of which the latter travels.

The adjustable diaphragm is constructed as follows:—

Within the inside, and crossing the lens tube, is a circular plate or disc with a hole in its middle of the full size which the aperture in the diaphragm can acquire. The diaphragm is a compound or segmental one, made up of a series of thin plates overlapping each other, but so disposed or arranged with respect to each other that their radial curved inside ends or parts enclose a circular, or nearly circular, space or opening; so that on the concave or curved inside edges of the ends of these plates being moved or made to approach each other, a greater or less aperture or hole is thereby produced.

The parts constituting the diaphragm, and the manner in which the curved or crescent inside edges of the plates are made to approach and recede from each other, is as follows:—

Each plate of the series of plates consists of a plate concave at one end to the radius or about the radius of the larger sized aperture which the plates will make when fully opened out or expanded. This curved part forms the inside end of the plate; the other or outside end is pivoted or hung eccentrically upon the inside of the disc, with a hole in its middle as before described. The said pivot forms a centre upon which the plate turns inwards or outwards, in approaching or receding from the centre of the lens tube; and situated below, and somewhat in a line with the said centre, is a stud or pin upon the face on the side of the plate, which engages and works within one of a series of radial tangential slots cut within a plate or disc with a hole in its middle which works or is moved in front of the series of plates by a protruding arm or finger working through a slot cut in the outside tube of the lens.

Each of the said plates constituting the diaphragm are pivoted, and have studs like the one described, and each of the said studs of the series work within the slots as described; and, further, each of the plates overlap each other, so that the edges of the one extend over the edges of the other, so as to form, as it were, a solid plate, but with an aperture that is able to be increased or decreased in size at pleasure.

Upon the top outside of the lens tube, and in front or surrounding the slit through which the finger works, is an index or graduated scale before which the finger is moved, so that a person can, by moving the finger in front of one or other of the numbers or figures upon the scale, have the size of aperture required. Thus the top scale may be 4, 6, 8, 10, 12, onwards, and bottom or second line "speed" 1, 2, 3, 4, &c.

The moving of the index finger or arm through a quadrant of a circle for closing, or for obtaining a smaller aperture, the studs on the plate of the series of plates, which may be six, eight, or any other suitable number, are made to travel down the tangential slots or slits, and each plate is at the same time turned inwardly upon the pivots upon which they are hung, thereby causing the curved inside ends to collectively approach each other, and make a contracted aperture. When a larger aperture is required, the arm or finger is only required to be turned in the reverse direction, when the plates are collectively made to slide over each other, and recede from the middle or axis of the lens, by turning eccentrically upon the pivot upon which they are hung, and by the studs on their sides travelling up the slits on the disc or plate wherein they are formed being partially rotated.

A supplementary disc, with a hole in its middle, comes in front of the plate with the tangential or inclined slits, in order to preserve or protect the same from injury or otherwise.

The claim as amended is:—Combining with a lens tube an adjustable diaphragm, in a photographic camera substantially as and for the purpose herein described. Also providing combined lens tubes and adjustable diaphragms with graduated scales or equivalents thereof, for the purpose substantially as described and set forth.

IMPROVEMENTS IN AND CONNECTED WITH PHOTOGRAPHY AND THE TREATMENT OF PHOTOGRAPHIC PRINTS OR PICTURES.

No. 16,327. JOHN URIE, Senior, and JOHN URIE, Junior, 83, Jamaica-street, Glasgow, Lanarkshire.—*December 13, 1886.*

OUR invention has reference to and comprises a new or improved mode and means or arrangement of mechanism for developing, clearing, toning, fixing, or other ordinary chemical treatment or washing of photographs, which have been previously exposed and printed, by artificial or other light, in long lengths, bands, or webs of sensitised paper or fine-surface cloth, or other web fabric, all by and while traversing the said webs or bands at a constant, regulated speed, simultaneously through the required well-known chemical and other liquid baths required for the various purposes stated; which improvements will produce work of more uniform excellence, and save much time and labour, as compared with the modes and means heretofore in use for treating said photographic prints, singly or in short lengths containing a few prints, in the various baths at different times.

The improvements of our said invention consist all as follows:—According to one arrangement and adaptation suitable for treating the photographic printed bands of paper for book illustrations up to twelve inches or so broad, we take the photographic bands, as printed in the photographic printing machine or otherwise, and wind them on to rollers to be put into journal bearings in a dark box, and fed forward to and through the new developing and treating process and arrangement of mechanism; or when the printed bands are delivered loose into dark boxes, these may be removed to, and passed through, a pair of feeding-in rollers at the entering end of the new arrangement of mechanism. The web or band of printed paper from the said dark boxes and supply-rolls or feed-rollers, is led over guide and reversing rollers placed over and within the said developing and other treating baths, ranged in their proper sequential order in advance of each other, as required to be used, on a table or platform, which would preferably be in the form of a tray to receive and convey away any liquid that may be spilt. The baths would preferably be constructed in a deep narrow form for getting the greatest and best action of

the chemicals with economy of materials, and so that the deposit would settle to the bottom and not pervade the whole bath; while the traversing of the paper would always cause a motion of the liquid, which would also aid in maintaining the liquids in the baths in a uniform state throughout for action. The web of photographs would in this way be led over the said upper guide rollers and down under the rollers in the lower part of the baths, and may be thus undulated up and down one, two, or more times within the bath to give a longer or shorter time of treatment within the bath, as within the first or toning bath, which takes longer than either the second or clearing bath, or the after-toning or fixing baths, or the intermediate washing baths. Beyond the fixing bath the drawing and delivery drum or roller would be mounted by its central shaft in journal bearings in side frames, preferably mounted in a portable form over a cistern of washing water, so that the web of photographs would be led over the sides and upper surface in a moist state from the fixing bath, and be delivered down into the water-washing cistern on the front side. The drawing drum would be considerably larger than the width of the widest paper to be treated, and preferably large enough in diameter to give sufficient circumferential surface that it could draw the web paper over the guide and immersed rollers and through the several baths by the gripping action of the wet paper on its surface, and deliver it into the washing bath below. But for large machines and wide webs of paper, weighted drawing rollers might be laid on top of paper and drum to assist the gripping action. This drawing and delivery drum, which pulls the paper through the machine, would be driven either by motive-power machinery, or it might be by clockwork, or other gearing actuated by weights or springs at a uniform time speed, regulated as desired by the driving cone pulleys, when motive bands are used, or by small oscillating fan blades; or, it might be, a brake on the high-speed gearing of the weight or spring clockwork mechanism when that is employed; or a shifting pendulum might be used on an escapement motion, or other equivalent governor which would regulate the velocity of the gearing to actuate the drawing and delivery drum at the desired speed, the paper was wished to be drawn through the baths for the time being. To further regulate the time, the paper web and prints would be under treatment in the several baths to perform their respective operations, the undulating and guide rollers immersing the paper within the baths may be mounted on portable frames, which can be raised and lowered into the baths to give a longer or shorter time traverse of the material through the baths; or the baths might be fitted with movable siphons, which would regulate the height of the liquid within the baths higher or lower, to act on the paper for the greater time length of the traverse of the paper through them. Or by another arrangement—in some cases the paper on leaving one bath might be passed over a movable raising and lowering guide roller before allowing it to enter the next bath; or by an equivalent arrangement the baths might be removed further from each other, and in either case allow the paper photographs to be under the action of the chemicals in the last bath for a longer period, after leaving one bath before entering the next.

Any of these arrangements might give a nice adjustment as to seconds of time under which the photographic prints might each be under treatment within the respective baths; while the speed at which the drawing and delivery drum actuated the paper might regulate a mean speed of the traverse of the paper, which would suit the treatment in the baths generally for being otherwise regulated, as stated, within the individual baths.

Although deep, narrow baths have been described as being generally preferable, for giving longer chemical action or treatment with the least amount and waste of the mixtures or liquid employed; yet many other forms of baths might be employed to give the same effect, as by making a wide, broad bath, and immersing an inverted close hollow vessel within it, with the guide rollers at its under edges or angles to keep the paper immersed and clear of either the lower or upper vessel, the immersion of this upper vessel, which might be hung by cords, and counterweights, and pulleys, so as to immerse it to any desired depth with the bath, raises the liquid higher or lower within the narrow side spaces through which the web was made to travel, thus giving a longer or shorter action of the chemicals on the paper. For giving a more uniform strength of the chemicals and action in each bath, a cistern of the mixture would preferably be mounted a few feet or so above the top level of their respective baths, and a rubber or other pipe led down to each bath from its cistern above, controlled by a small tap to regulate the supply of liquid to the bath and keep a motion of liquid through the bath. A lower cistern would also be fitted below each bath for allowing the overflow liquid from each bath to pass down to the lower cistern, the liquid from which might be occasionally removed, or forced up by air pressure into the upper cistern to keep up the constant current through the bath, the drawing-off pipe or siphon regulating the height of the liquid within the bath.

Although only one drawing and delivery drum or rollers has been described, other intermediate drawing rollers might be employed to lessen the strain on the web of paper, these secondary drawing rollers being driven at the same speed as the others by bands and pulley, which bands might be tightened by a movable spring pulley, to regulate the driving tension and allow the bands to slip on their pulleys when the strain on the paper became too great; and tension cords or friction levers might be employed on the spindles of the supply rolls or rollers to keep the web tight.

The claims are:—1. The construction of a machine or general arrangement and combination of the parts, of mechanism for mechanism for chemically treating, or developing, clearing, toning, fixing and washing photographic prints or pictures traversed at a regulated speed continuously in a web or band of paper or other web fabric, all substantially, as herein described, in reference to and shown in accompanying drawings. 2. For the chemically treating and washing of photographs in a continuous web or roll, the use of drawing and delivery drums, driven at a regulated speed, for carrying forward the web of paper, either with or without spray jets of water for removing and delivering the paper from the surface of the drawing drums, substantially, as herein described, in reference to and shown in accompanying drawings. 3. For the chemically treating of photographs in a continuous web or roll, the traversing of the web through deep or other baths, which would regulate the duration of time the web was under treatment, substantially, as herein described, in reference to and shown in accompanying drawings.

IMPROVEMENTS IN PHOTOGRAPHIC PRINTING.

No. 16,356. GEORGE JOSEPH SERSHALL, 371, Lodge-road, Hockley, Birmingham.—December 14, 1886.

THE object of this invention is to produce finished photographs in such a manner as to represent portraits or views apparently laid or placed in certain positions upon the face of larger photographic views, landscapes, or floral scenes, all forming one photographic combination picture on the same sheet of sensitised paper.

For this purpose, in accordance with this invention, if two views, portrait and view, or two portraits, are required to be represented as lying upon parts of a larger view, or if it be required to represent a view portrait or scene as lying upon part of a larger view, and this latter view as lying upon a still larger view and forming together one combined and complete photograph, the process for its production consists of two or more stages, each stage being in itself a separate and distinct operation in photographic printing. For each of these two or more operations a separate and distinct mat or mask, having a part or parts of its surface sufficiently transparent to transmit light, with the other remaining portion or portions of its surface rendered opaque or sufficiently impervious to the passage of light, and with both transparent and opaque parts specially arranged as to position and configuration—is required in each of the said operations to be placed in the printing frame between the negative and the sensitised paper to be printed upon. The transparent portion or portions of the surfaces in each of the said mats or masks is made to coincide in shape or confirmation with the marginal line bounding the part of the negative required to be printed at one of the operations in the process of printing hereinbefore mentioned, and the opaque surface in each of these mats or masks blocks out or completely obstructs any transmission of light to those parts of the sensitised paper which may have been already printed in any previous operation or operations, or which during the pending operation are required to remain blank for a future stage or future stages in the process and with the appliances constituting this invention. These two or more operations in the said process being completed as herein indicated on one sheet of sensitised paper, the photograph containing the subjects so combined is toned and finished in the ordinary manner. The said mats or masks may be produced as follows: a drawing of the outline forming the margin or edge of the intended transparent portion or portions of a mat or mask is made upon any suitable material or medium to be used for lithographic, copper-plate, letter-press, or other suitable method of printing, and the surface surrounding the said outline and bounded off by it is so prepared or treated that the imprint or impression taken from it is blank or opaque, leaving blank a space or spaces of the figure or figures of the transparent portion or portions of the surface required in the mats or masks. The mats or masks may, therefore, be produced by printing upon any suitable material already transparent, or in which the blank portion or portions of its surface may be made transparent by varnishing after the opaque part or parts have been printed in like manner as before, and which the varnish being dry is then fit for use as shown herein.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—1. The process of producing photographic combination pictures upon the same sheet of sensitised paper by means of a series of photographic mats as herein described. 2. The mode of producing photographic mats by printing upon any suitable material, those parts of the said mats which are required to be opaque, the blank portions being either transparent before the said process of printing or subsequently rendered so by varnishing after the completion of the said process of printing as herein described.

PROCESS FOR PRODUCING FROM PHOTOGRAPHIC AND OTHER DESIGNS ENGRAVED PLATES OR ROLLERS FOR PRINTING.

No. 16,476. MARY WALKER and GEORGE EDWARD WALKER, Anchor Pottery, Longton, Stafford, and JEAN BAPTISTE GERMEUIL BONNAUD, Longton.—December 15, 1886.

IN our specifications, No. 13,609 of 1885 and 2770 of 1887, we described means of producing copies for lithography from photographic or other designs. Our present invention relates to a process whereby the operations described in these specifications are applied, along with further operations, to the production of engraved plates or rollers for printing. For this purpose the pellicule produced, as described in the specifications above referred to, consisting of a sheet of paper or a film of collodion, and having on it a layer consisting of a mixture of dextrine, starch, and kaolin, on which a tracing has been made with lithographic ink or crayons, is placed face downwards and pressed on the plate or on the surface of the roller that is to be engraved. The body of the pellicule or film is then removed, leaving the lithographic ink or colours of the drawing on the plate or roller. On this is electroplated a metal, which is less easily attacked by acid than the metal of the plate or roller itself. Thus, if the plate or roller be of zinc, copper is electroplated on it; if it be of copper, gold or platinum is electroplated on it. The metal thus deposited appears only on those parts of the surface which have none of the lithographic ink or colour. By applying a solvent, such as turpentine or benzine, the lithographic ink or colour is removed, and the whole surface is then treated with acid, whereby the parts which had been occupied by the lithographic matter are etched to any desired depth, the rest of the surface formed by the less corrosible metal remaining unaffected by the acid.

Having now particularly described and ascertained the nature of this invention, and in what manner the same is to be performed, we declare that what we claim is:—The herein-described process for producing engraved plates or rollers for printing, by transferring to the surface to be engraved the design lithographed on a film or pellicule, removing the body of the film or pellicule, leaving the ink or colour of the design, electroplating the surface, dissolving out the ink or colour of the design, and etching.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST Tuesday night, at a meeting of the above Society, held at 5A, Pall Mall East, London, Mr. James Glaisher, F.R.S., President, occupied the chair.

The following new members were elected:—Dr. E. W. Alabone, Messrs. W. M. Baylis, M. Boussod, J. J. Briginshaw, G. W. Catt, V. H. Chintanore, Lionel Clark, A. Deed, R. F. Dixon, W. R. Few, C. F. Fischer, M.D., W. W. S. Follett, G. E. S. Fryer, H. J. Gifford, A. J. L. Grimes, M. J. Harding, W. Hayes, B.A., Mrs. Brian Hodgson, Messrs. E. D. Lavender, E. J. Lezard, H. Little, Rear-Admiral Maitland, Messrs. Gustav Mullins, Paul Nadar, E. W. Parkes, W. Scorer, H. Senier, E. W. Shepherd, J. G. Sinclair, W. Tomlinson, J. Watson, J. B. B. Wellington, J. Whittaker, and The Hon. Lewis S. Wingfield.

Prize medals were then presented by the President to G. P. Carlland, *Elephants, &c.*; Henry Tolley, *Lonely Shore*; H. P. Robinson, *Carolling*; T. A. Green, *English Lakes*; H. Collis Pettit, *Lakeland*; J. F. Roberts, *Stage Scenes*; W. J. Byrne, *Direct Life-sized Heads*; Frederick Müller, *Enlargement*; Andrew Fringle, *Micro-organisms*; Boussod, Valadon, & Co., *Photogravure*; P. H. Emerson, *The Poacher*; Annan & Swan, *Dr. Bonar*; J. B. B. Wellington, *Studies*; P. H. Evans, *Photo-micrographs*; Frank M. Sutcliffe, *Studies Series*; W. H. Hyslop, *Yachting Studies*; Arundel & Marshall, *Plate Boxes*; Eastman Film Company, *Stripping Films*; and J. Gale, *Lantern Slides*.

Mr. ANDREW PRINGLE, in returning thanks for his medal, said that, although he had difficulty in being present that evening, he felt it to be a necessary duty. Some friends had been kind enough to express astonishment at the quick way in which he had surmounted the difficulties of photo-micrographic work, and he felt it to be his duty to explain that he had received help therein of the most valuable kind from a man who was well known, and who deserved to be better known—Dr. Maddox. Without his help he would have been unable to produce such good specimens. Dr. Maddox had taught him by letter, and had sent him objects to photograph.

Mr. W. H. WALKER, upon receiving the medal for the Eastman Film Company, said that he had had great trouble in producing stripping films in a commercial way. It was an afterthought that they were sent at all, as they were not originally intended for exhibition.

The CHAIRMAN, in some remarks about the more meritorious exhibits, spoke of the lenses by the Taylors, of Leicester, and said that young men should be encouraged to grind their own lenses. The English microscope had grown because of competition, the one maker improving upon the work of the other, until foreigners had been habitually beaten in some of the international competitions. He wished to see the same thing in photographic lenses, because it would mean progress.

Votes of thanks were then accorded to the Judges of Pictures, of Apparatus, and to the Hanging Committee, and also to the Assistant Secretary.

The PRESIDENT remarked that the Hanging Committee had not had their fair share of scolding this year. He had never known such a thing before. He then announced that the Exhibition would close on Monday, November 14. It had been affected this year by the meetings in Trafalgar-square, but had so far received 9600 visitors, and 2521. Last year 2714 had been received; still, before the present Exhibition closed, he hoped that it would exceed that of last year in spite of atrocious weather and of atrocious gatherings.

Mr. BUCHANAN WOLLASTON said that there was a desire to know whether the Mr. Parkes elected that evening was connected with the Cellerier Syndicate or not.

The PRESIDENT did not know.

Mr. W. S. BIRD responded that it was the same Mr. Parkes.

A MEMBER said it was a pity that this had not been known before the ballot box had gone round.

The proceedings then closed.

CAMERA CLUB.

On Thursday, November 3, an address, accompanied by a demonstration, on *Intensification of Gelatine Negatives with Mercury followed by Schlippe's Salt*, was given by Mr. W. E. Debenham. Mr. Francis Cobb occupied the chair.

The demonstration proved most interesting to those present, and several comparative experiments were shown by Mr. Debenham. The gradations of increased intensity obtainable by the method, and the easy means of reducing by hypo any excessive treatment of the plate with the iodide of mercury, were well illustrated. The only doubt which arose was as to whether the treatment left the film of the plate and the shadows of the negative stained. This appeared to be the case slightly in one case, though inappreciable in all others, the stain possibly arising from imperfect washing prior to intensification. The process has been already fully described in THE BRITISH JOURNAL OF PHOTOGRAPHY.

Some discussion and conversation ensued, Mr. LYONEL CLARK making interesting and useful comments upon the subject, and the members and

friends present then gave Mr. Debenham very hearty thanks for his practical illustration of so useful an intensification method.

Thursday, November 17, is a lantern evening, when slides will be shown at eight p.m. by Messrs. Newman (Swiss views), Fison (Norwegian views), C. B. Wright (Norwegian views), and Evans (Exeter Cathedral views), and by other gentlemen.

On November 24 the subject will be *Enlarging*, paper by Mr. P. P. Rodgers.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday, November 3, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. W. H. Prestwich presided.

Messrs. W. Wallis, P. Everett, and J. Joel were elected members of the Association.

The HON. SECRETARY announced that at frequent intervals papers on photographic subjects will be read, and that the following members have agreed to contribute memoirs:—Messrs. J. Traill Taylor, W. M. Ashman, Hume Nesbit, F. A. Bridge, E. Clifton, Norman Macbeth, W. H. Harrison, J. W. Wharton, W. Cobb, J. J. Briginshaw, David Louis, F.C.S., C. H. Trinks, and Andrew Pringle. The last Thursday in each month will be devoted to lantern subjects. The annual dinner will take place in January.

Mr. J. W. Wharton exhibited some photographic prints.

Mr. NORMAN MACBETH remarked that in one of them a column rose too near the centre of the plate; the print could be improved by cutting off a part of one of its sides so as to bring the column out of the centre.

Mr. L. MEDLAND said that one of the prints proved the value of a backing to the plate when taking interiors, for where the backing had not quite covered the plate the negative was less sharp.

Mr. J. TRAILL TAYLOR suggested that a large wedge-shaped white bank which projected in one of the pictures might be improved during the printing by deepening the shade at places upon the bank.

Mr. Higgins exhibited views of Lisbon and other places.

Mr. F. W. COX asked the best focus of lens to use for half-plate pictures.

Mr. MACBETH used an eight-and-a-quarter-inch rapid rectilinear, but would prefer one of longer focus; the one he employed would not do well for objects less than twenty yards off. The tendency of the times was to use lenses of too wide an angle.

The following question from the box was then read:—"Captain Abney, in his work, *Photography with Emulsions*, makes the following assertion respecting the use of iodide of silver:—"I am in a position to say that an emulsion of silver bromo-iodide can be made just as sensitive as the emulsion silver bromide as regards the ordinary so-called actinic rays, and can be prepared so as to be perfectly unacted upon by the orange or red rays, which is a step in the right direction, according to my way of thinking." Again, in the *Photographic News Almanac* for 1885, he writes as follows:—"Iodide in gelatine emulsions is the thing to give a negative all the qualities that are essential for it to be pronounced first-class." How can this be reconciled with the claims made on behalf of orthochromatic plates, which are supposed to render the yellow, orange, and red more correctly, and to subdue the violet and blue? Does the experience of members of this Society, so far as landscape work is concerned, agree with that of Captain Abney?"

Mr. W. COBB preferred some iodide in emulsions.

Mr. W. M. ASHMAN thought that the questioner was comparing two totally different things; it was possible to have a little iodide in orthochromatic plates, although several workers preferred plain bromide.

Mr. COBB added that Mr. B. J. Edwards had stated that a little iodide in orthochromatic plates did no harm, and Mr. Hyslop considered it to be an advantage. He (Mr. Cobb) preferred an iodide to an orthochromatic plate for landscapes.

Mr. A. COWAN imagined that the dates of the two quotations given from Captain Abney's writings might be very wide apart.

Mr. ASHMAN was using plates which probably contained an excessively large proportion of iodide of silver; their peculiarity was that they would give a good plucky negative when the daylight was nearly gone and men were beginning to light the street lamps; the plates would not work so well in a good light.

Mr. COX exhibited a platinotype print with clouds printed in from a second negative; the effect was good.

Mr. F. A. BRIDGE, to get rid of halation, used a piece of wetted black tissue laid upon the back of the plate; before development he simply peeled the tissue off and laid it aside.

Mr. W. H. HARRISON had once had a severe test object for halation, consisting of a wire rope stretched high in air across the River Reuss to aid in utilising the force of the stream to propel the ferry boat between the banks. The rope had a grey sky for the background except where some towers of the old city wall of Lucerne projected upwards; wherever the rope crossed these towers it looked twice as thick as where it had the sky for a background. But for this the negatives would have been considered to be totally free from halation. By means of glycerine he next put the backs of some plates into optical contact with pieces of black mackintosh, yet upon exposing such backed plates upon the same subject the defect was not removed or even ameliorated; why so he did not understand.

Mr. MEDLAND exhibited a lantern slide taken upon a Beech plate; by lapse of time the original grey image had changed to a warm colour.

Mr. TAYLOR once had a negative which changed so by time that observers were in doubt whether it represented *Conway Castle* or *Christ Blessing Little Children*.

Mr. HIGGINS backed plates with a mixture of glue, treacle, and lampblack.

Mr. TAYLOR called attention to alleged advantages of the metal plate boxes lined with paper for which the Photographic Society had just awarded a medal.

Mr. COBB thought that paper in contact with gelatine plates had a deleterious effect.

Mr. H. M. HASTINGS thought square-shaped grooving bad.

Mr. BRIDGE had had plenty of gelatine plates kept long in contact with paper without injury.

Mr. COX thought that when forcing became necessary in development marks of packing paper were more liable to show.

Some other members having spoken,

Mr. TAYLOR said that he gathered it to be the opinion of the meeting, 1. That the invention was not an improvement. 2. That it was not novel. 3. That it was a retrogression. He spoke of the legal responsibility of plate makers as to the quality of their plates, and called attention to a New York case in which with one developer all the films slipped off the plate, and with another developer they kept on and gave good pictures.

Mr. ASHMAN thought it impossible to render makers responsible; if one man complained of plates they could always bring experts forward to depose that other plates from the same batch were good.

Mr. COOKE knew a photographer who had received plates with all the films off the glasses.

Mr. COBB stated that it was in the experience of every plate maker that one photographer would get good negatives upon plates which gave bad ones in the hands of another photographer.

Mr. EDGAR CLIFTON did not see on what principle a jury could assess damages. One man might take bad plates to Richmond Hill and another man take them to South America, the latter incurring infinitely more loss than the former, indicating widely different penalties for the same offence.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE Committee of this Association met on the 3rd instant to consider the following case, which had been brought forward at the previous meeting and adjourned for inquiries:—

Early on Tuesday morning, October 18, the body of a man was found lying on the grass in Hyde Park; he was pronounced by Dr. Blackett to be dead. A letter was found upon him the contents of which were as follows:—"My dear Wife,—God the Almighty forgive me! Without work, diseased in mind and body, I am forced to give up my miserable life. He will protect my poor wife by good people's counsel and assistance. Farewell, dear Mary, till we meet again where there is no ill or sorrow.—M." The wife was communicated with, who stated deceased had been well-to-do, and earned much money years ago as a photographic artist, but of late years trade had been bad, and his circumstances became worse and worse.

This case was recommended by a donor under Rule 4, which gave them the privilege of recommending for the consideration of the Committee cases of non-members. The Secretary reported he had investigated the case, and found the widow perfectly destitute and without any friends to assist her. They had been married thirty years. For the last year they had existed in a condition bordering on starvation owing to the want of any regular employment.

The Committee, after careful consideration, granted the widow the sum of 5l.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

THE annual general meeting of this Society took place on Tuesday, November 1, at Myddelton Hall,—Mr. J. Traill Taylor, President, in the chair.

The HON. SECRETARY, Mr. H. M. Smith, read the annual report, as follows:—

In presenting their annual report your Council congratulate the members of the Society upon the success attending its proceedings since its reorganization at the commencement of the year, and upon the fact that the Society has gained for itself an established position among the Metropolitan societies.

The Society now numbers eighty-nine members, including eight honorary members, who, being members of the original North London Association, which ceased to exist in 1869, were recommended by your Council for election.

The meetings of the Society have been well attended, the average number present being thirty-six.

During the year lectures and demonstrations have been given upon the following subjects:—*Photographic Lenses*, by the President; *Cameras, Ancient and Modern*, by Mr. E. Clifton; *The A B C of Emulsion Making*, by Mr. A. Mackie; *Stripping Films*, by Mr. W. H. Walker; *Photography, Past and Present*, by Mr. E. Dunmore; *Systems of Numbering Photographic Slides and Plates*, by Mr. O. Smith; and *On the Preparation and Development of Collodio-Bromide Emulsion Plates*, by Mr. A. Mackie.

Well-attended outdoor meetings have been held every Saturday during the summer season, and on the various Bank Holidays. On some of these occasions opportunity has been taken to join with other societies, and this Society was well represented at the outdoor meeting of the Photographic Societies of London held at Watford on the Queen's Jubilee day.

In consequence of the appreciation of the lantern exhibitions held during the early months of the year, your Council have acquired a good optical lantern, which they trust will induce more members to devote attention to the production of lantern transparencies. Many of the difficulties incidental to the practice of this branch of the art have been removed by the introduction of suitable commercial plates and modifications in development; and the suitability and simplicity of the collodio-bromide emulsion process for this purpose have been amply demonstrated at the meetings of this Society. It is, therefore, hoped that during the coming season the lantern exhibitions will grow in extent and interest.

The question box has been in constant requisition, and many interesting and profitable discussions have resulted therefrom. Questions on almost every point in photography have been dealt with and much valuable information elicited. Young members are earnestly requested to avail themselves to the fullest extent of this method of seeking information, especially where the question may appear to them trivial, such questions sometimes leading to important results.

The Council have steadily borne in mind the avowed purpose of the Society, and have endeavored to place before the members as much information as possible in a readily comprehensible form, thus making the Society a thorough school of photography, where the veriest tyro may have his difficulties explained away and the most experienced veteran may find kindred spirits with whom to discuss the more abstruse points of our art-science.

It would be impossible in a record of our year's doings to omit some reference to the thoroughly amicable manner in which all have worked together for the general good, and it is hoped that this kindly feeling will always be a marked characteristic of our Society, while beyond their own walls the members have been cordially received by the older London societies.

Your Council desire to express their thanks to those members or visitors who have read papers or exhibited objects of interest at the meetings, and to particularly acknowledge the courtesy of the photographic press, which, by inserting reports of

the Society's meetings, has enabled the general public as well as absent members to keep touch with our proceedings.

The HON. SECRETARY then read the Auditors' Report, which showed a balance in hand of 8l. 3s. 8d.

On the motion of Mr. JOHN JACKSON, seconded by Mr. O. SMITH, the foregoing reports were then adopted.

Votes of thanks to the retiring officers and the Auditors were passed and suitably acknowledged.

The following officers were elected for the ensuing year:—*President*: J. Traill Taylor.—*Vice-Presidents*: A. Mackie and E. Clifton.—*Curator*: E. Traill Hiscock.—*Council*: F. W. Cox, W. Few, J. Humphries, J. Jackson, L. Medland, J. Nesbit, J. Oakley, and F. G. Reader.—*Hon. Secretary and Treasurer*: H. M. Smith.

On the motion of Mr. F. W. COX, seconded by Mr. J. HUMPHRIES, it was resolved to alter Rule 11 to enable nine members to call a special meeting of the Society instead of twelve, as previously.

On the motion of Mr. A. MACKIE, seconded by Mr. H. M. SMITH, it was decided to alter Rule 13, to prevent any member whose subscription was unpaid three months after application from voting upon any subject connected with the management of the Society.

The PRESIDENT announced that the next meeting of the Society would take place on November 15, when Mr. F. W. COX will deliver a lecture on *The Platinotype Process*. Visitors are invited.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

THE first ordinary meeting of the year was held in the Society's Rooms, Masonic Hall, on Tuesday, November 1,—Mr. T. S. Yeomans, Vice-President, occupied the chair. There was a very good attendance of members and friends.

After a prolonged discussion arising out of the minutes, the monthly competition, "Animal Life," postponed last month, was proceeded with, and the prize awarded to Mr. S. B. Lowe. For the picture for the month, subject, "Old Buildings within Ten Miles of Sheffield," the prize was awarded Mr. W. H. Bacon for his view of the ruins of Sheffield Manor.

WALLASEY PHOTOGRAPHIC ASSOCIATION.

THE first annual meeting of this Association was held on Wednesday, the 2nd instant, at the new address, 12, Bradford-terrace, Seacombe,—Mr. H. Wilkinson in the chair.

The CHAIRMAN, in a short address indicating the progress of the Association during the past year, felt that he could not do otherwise than congratulate the Committee upon the prosperity which the Association had enjoyed since its inauguration on October 15, 1886, and warmly thanked them for the ready manner in which they had assisted him on difficult occasions such as commonly beset the path of a young society; he also felt very confident that the past prosperity would not only continue but would be enhanced during the ensuing year. He was happy to say that the attendance of members at the meetings had been an extremely good one, and, speaking for himself, and he might almost say for them all, these meetings had left many pleasant reminiscences behind them, not to mention the numerous valuable hints which from time to time were mutually imparted; and in this connexion he could not refrain from mentioning that, although atmospheric conditions were not the most propitious at this time of the year for outdoor work, there remained plenty of scope for occupation in bromide-paper and lantern-slide development. In conclusion, he pointed to the satisfactory condition of the finances, as shown by the statement before them.

The HON. SECRETARY then stated that twenty meetings of the Association had been held, at first weekly, but subsequently monthly, at which latter interval it was decided the Association should continue to assemble. During the summer there had also been held eleven outdoor meetings, chiefly in the Wallasey district.

The HON. TREASURER then submitted his financial statement, which showed a balance in hand of 1l. 5s. 4½d., which he thought the meeting would agree with him in considering very satisfactory for a first year's working.

At this point the usual votes of thanks to retiring officers were made; but, before proceeding to the election of the officers for the ensuing session, Mr. FROST suggested that some memento of their first year should be obtained; and he suggested the insertion of the portraits of the members for the past year in a large mount, which should subsequently be framed. This motion found a supporter in Mr. E. MAYALL, and, after a short discussion, was carried unanimously.

The elections were then proceeded with, all the old officers being re-elected, and Mr. J. W. Gregg appointed Assistant Secretary, whilst, before the close of the meeting, it was decided to have a supper, at which the prizes should be distributed to the successful competitors in the recent competition, the result of which were as follows:—"Landscape," Mr. G. B. Frost; "Animal Study," Mr. T. Hill; "Marine View," Mr. G. B. Frost; "Portrait," Mr. E. S. Wilson; "Instantaneous," Mr. J. Walker; "Village Cottage," Mr. G. B. Frost. According to the rules of the competition no competitor can take more than one prize, and the prizes in the classes marked * go to Mr. Ashurst and Mr. Nicholson respectively.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, November 16, will be on *Rolling and Burnishing Photographs*.

The first meeting of the one hundred and thirty-fourth Session of the Society of Arts will be held on Wednesday, November 16, when the opening address will be delivered by Sir Douglas Galton, K.C.B., D.C.L., LL.D., F.R.S., Chairman of the Council.

THE LATE MR. FRED. SNARY.—We are sorry to learn of the demise of Mr. F. SNARY, the oldest photographer in Bristol. His death, which occurred on his fifty-eighth birthday, arose from an abscess in the foot, which eventually showed signs of mortification. An operation was performed, but it proved fruitless. By his genial temperament, happy disposition, and courteous manner, he won friends on all hands. He died on the 29th ultimo.

Correspondence.

Correspondents should never write on both sides of the paper.

NOVEMBER MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.—THE DELAY GRANTED FOR ADMISSION OF EXHIBITS TO THE FORTHCOMING WORLD'S SHOW OF 1889.—EXHIBITION OF BRUSSELS.—PINHOLE CAMERA AND PROOFS.—TWO PLATES GAVE DIFFERENT RESULTS UNDER THE SAME MANIPULATIONS.—M. PECTOR ON THE KEEPING QUALITIES OF GELATINO-BROMIDE OF SILVER PLATES.—THE PRESENT EXHIBITION IN PARIS.—A NEW AND CHEAP SET OF LENSES ("TROUSSE").—A NEW CAMERA.—ENAMELLED TRAYS.—A PORTABLE DEVELOPING TABLE.—LUNAR PHOTOGRAPH.—VIEWS OF THE EXPLOSION OF FIREWORKS, BY M. LE COMMANDANT MOESSARD.

The Photographic Society of France held their monthly meeting on Friday evening last, the 4th instant, M. Davanne in the chair.

A great deal of time was taken up in discussion on the Universal Exhibition of 1889. It appears that claims for space cannot be accepted after February 1, 1888, and that a longer delay must not be thought of. Notice to English photographers who desire to win fame at the forthcoming World's Show.

A great International Concours will take place at Brussels in 1888. The awards to be given amount to 500,000 francs; moreover, a great lottery, in which a million of francs will be spent in purchases from the products shown in the exhibition. The French photographers and amateurs will not think of doing anything in the way of exhibiting. At the present moment they are biding their time for the great Exhibition of 1889. At the present moment "l'Union Centrale des Arts Décoratifs" has a very pretty exhibition on in Paris, to which all photographers were invited; but the result is deplorable, and cannot be compared to the magnificent Photographic Exhibition at 5A, Pall Mall, London, which I had the extreme pleasure to inspect during my last visit to London.

M. le Dr. Martini de Turin sent some magnificent landscapes, which he had obtained by a pinhole camera. The focus was twelve centimetres, the exposure twenty seconds. These images were far superior to what I saw in London.

Mr. Sturme's publication, entitled *The Photographer's Indispensable Handbook*, was laid upon the table.

M. Vidal presented, in the name of a gentleman of Limoges, two clichés of the same objects, one being a good negative, the other being a positive. This gentleman says the plates were from the same batch, were exposed the same time, and developed in the same solution. One was a negative, the other turned out to be a positive. "Why is this?" he asks. A discussion took place, but to say the phenomenon was clearly explained would be going too far.

Professor Stebbing exhibited a metal dark slide, sent to him by Mr. W. Tylar, the inventor. The metal slide created great interest, and was generally approved of, excepting the weight.

M. A. Gorde exhibited a new "trousse" of lenses for landscapes, not unlike Darlot's *trousse*. It is composed of the body of the lens bearing a circular disc perforated with holes of different sizes, serving as diaphragms, and four *lentilles glaces* with focuses of 15, 25, 35, and 45 centimetres. The one of 15-centimetre focus will cover a half-plate 13 x 18, the 45 centimetres will cover 40 x 50. I forgot to put the question to M. Gorde as to whether or not other focuses might be obtained by combining such lenses. As an instance, screwing on the front focus 25, and on the back of the lens focus 15, which would give a focus of 10. This is found by adding the two focuses together, 15 and 25 make 40, divide by 4 leaves 10; near enough for all practical purposes. The 25 and 35 can be used together in the same manner, as well as 35 and 45, the last giving a focus of 20. It has been found necessary to put the higher number outside and the lower inside to get the best results, if M. Gorde's lens can be so worked. The *trousses* of other makers can be worked thus, and give a great power to a landscape photographer or amateur by allowing him to have what size image upon his plate he desires without changing his camera from the position he chose in the first instance. Thus, an amateur wishes to take a picture of a castle with ruins, &c. A river prevents him getting as near as he could wish. He has a half-plate camera, and a lens of 15-centimetre focus. On his looking upon his focussing glass, the image of the castle and its surroundings are too diminutive. He unscrews the No. 1 (15-centimetres) and screws on No. 4 (45 centimetres); he now finds that the whole image cannot be portrayed, the focus is too long; he then takes No. 3 (35 centimetres), and all is harmonious. The disadvantage of these lenses is, that in order to have sufficient sharpness a very small diaphragm must be used. M. Gorde told us the market price of his *trousse*, which is the cheapest I ever heard of (35 francs). He sent round a certain number of proofs, which were very good. Among them I remarked a view of the interior of the Exhibition now on in Paris—it was about 12 x 16 inches—a most remarkable view; the foreground, which could not have been more than six yards from the operator, was, as well as the rest of the picture, perfectly sharp and faithfully delineated.

M. Pector, speaking of the keeping properties of gelatino-bromide of silver plates, showed us a number of proofs which he had obtained from plates he purchased in 1885, which plates had been abandoned in his country-house all the winter to damp and cold; nevertheless, the results obtained were perfect.

M. Davanne read a long communication from Professor Aimé Girard, on the means he employed to obtain photo-microscopic images to be used as projections to illustrate his public lectures, and orders were given that it be published in the *Bulletin* of the Society.

M. Darlot, the well-known and highly esteemed optician, presented a new kind of camera for instantaneous work. The new features consisted of a very small camera on the top of the larger one, with a very small lens; the image from this lens is reflected upwards upon a small ground-glass, upon which the operator can follow all the changes of the moving object or objects he wishes to catch, and at the propitious moment let fly the instantaneous shutter. Naturally, all that was seen on the small ground-glass is reproduced in the large camera. The plates are all placed in a brass framework, and fit into a changing box having an exit and an entry. The exit is for plates to be exposed; the entry for the exposed plates to take their place behind the unexposed plates. This method allows the operator to take a great number of plates with him.

M. Maugin presented a number of enamelled trays, fitting one into the other. The remark was made that they were very good for laboratory purposes, but too heavy to carry about.

M. Fauvel presented a portable developing tray, which, when folded up is represented by Fig. 1, when opened by Fig. 2. It consists of a hollow

Fig. 1.

Fig. 2.

box, supported upon four legs of the same form as the ordinary camera stand. Inside the box is an oscillating frame, upon which is placed a transparent glass tray of the size of the negative to be developed. The frame with tray is kept in motion by means of a long bar of iron (A), to which is attached a heavy weight, and does the office of a pendulum. On the end near the operator is a mirror (B), which can be set to any angle. At the other end of the box is placed a lantern (C), having an angle cut off (D); on this is placed the red glass. The lantern can be raised or lowered at will. The operator is supposed to begin work: he lights his lantern, places his developing solution in the glass tray, and by means of the mirror reflects all the red rays emerging from the lantern through the bottom of the glass tray, and in consequence, when the operator plunges the plate into the developing solution, the formation of the photographic image can be seen and followed with the greatest ease. The pendulum is made to swing backwards and forwards so as to keep the developer in constant motion. It is to be noticed that the lantern in its actual position cannot throw direct rays upon the plate during development. If the operator desires to see the progress of the image by reflection, he has only to raise the lantern a few inches to obtain the desired result. The box not only holds the lantern and developing tray, but contains places for solutions, measures, &c. In fact, it is a compact and handy accessory to the dark room as well as to the amateur on a tour.

The Commandant Moessard gave us a long description of experiments he had followed up in photographing the moon as it passed through the heavens. He sets his camera at one of his windows, and as soon as the orb of night rises he uncaps the lens and allows the moon to print its portrait across the plate. Several were projected by means of the lantern; the different curves which the moon had followed in its different phases, together with the quantity of light emitted or eclipsed by passing clouds, &c. On some of the plates not only was the passage of the moon registered, but also the paths of the stars could be distinctly seen. The value of these experiments was criticised in an astronomical point of view. The same gentleman showed us a number of proofs which he had obtained of the fireworks at the *fête* of Versailles. Very interesting, but as the camera had been left open the sharpness of the picture naturally suffered. My opinion is that a better result would be obtained could four or five plates be exposed, one after the other, in order to trace the history of the explosions from the beginning to the end.

59, Rue des Batignolles, Paris.

PROF. F. STEBBING.

RESPONSIBILITY OF PLATE MAKERS.

To the Editors.

GENTLEMEN,—I have read with much interest the article under the above title in your issue of November 4, and, as I have some knowledge bearing upon the subject, venture to intrude upon your valuable space.

The conditions under which plate makers work in the United States are infinitely more difficult than those known in England; in summer the thermometer often indicates a temperature of 100° Fahr. in the shade for several consecutive days, which, with a naturally dry atmosphere reduces vast areas of the earth's surface and its vegetation to a condition in which the air becomes laden with solid matter, animal, vegetable, and mineral, which if not carefully filtered out before being passed over the undried plates causes no end of trouble. Frequently rapid changes in humidity takes place, sometimes an increase of moisture, without any sensible decrease of heat, and then the difficulties become almost unconquerable; vast quantities of ice or expensive refrigerating apparatus is required to cool the entire volume of air used, in many cases a reduction of fully 80° Fahr. being necessary. In my own factory I passed no less than three thousand cubic feet of air per minute through the drying rooms for fifteen consecutive hours daily, and careful examination of the plates with a half-inch microscopic objective proved that they were practically free from surface imperfections.

During the winter months the conditions are quite the reverse: long continued cold frees the atmosphere from a great portion of its moisture, which is precipitated in the form of snow, germs of all kinds likely to be deposited during drying on the damp gelatine film disappear in a great measure, and the problem of clean and perfect drying is reduced mainly to one condition, viz., a clean air current of uniform temperature controlled by automatic devices preventing any violent fluctuations, and the possibility of freezing the undried emulsion. My usual experience was to thoroughly dry 8 x 10 plates free from "dust" or drying marks in four hours.

I have not alluded to spontaneous changes of uncoated emulsions due to germs embedded in commercial gelatine; any intelligent plate maker must be aware to his cost of this possibility; if not, let him coat a plate with plain gelatine and subject it to continuous gentle heat and moisture, and examine the film with a good one-eighth microscopic objective and tell us what he sees.

My present object is to call attention to some other more apparent causes of trouble, and in passing I may cite the experience of the Eastman Company some years since as bearing upon the matter. We found that plates from certain emulsions were giving dissatisfaction to users in different parts of the world, and on examination of our own test plates from the same emulsions confirmed our fears that the plates lacked ordinary keeping qualities. We therefore issued a circular calling in any or all of these emulsions, wherever they might be, and paid out within sixty days no less than 2000l. This illustrates our idea of the responsibility of plate makers. We then obtained sample plates from all reputable makers in Europe and America, and first placed a portion of each in a damp but cool atmosphere, free from deleterious gases, for a period of about sixty days. The films at the time of testing were swollen almost to the proportions of a freshly coated but undried plate, but none showed any signs of fog or other deterioration. Second, slight heat after dampness rapidly injured the films. Third, other portions of perfect plates were placed in clean paper boxes and subjected to a gradually increasing dry heat. I regret that I am not able to give the exact results of each test with its accompanying temperature; suffice it to say, as many characteristics were displayed as there were plates, some being damaged at temperatures far below others, but all finally succumbing in hopeless fog.

Now, I do not communicate the above as evidence of any new characteristics of the materials used in plate making—on the contrary, I have no doubt that most of your readers are only too familiar with such facts; but if we assume that the plates leave the factory in a perfect condition we have only begun the investigation which should follow each and every complaint concerning them. I will not touch upon damage caused by wilful ignoring of manufacturers' instructions concerning development, &c.; that is too wide and fruitful a field for discussion, but certainly the manufacturer should be credited with a fair knowledge of the conditions under which his plates give the best results.

When the Eastman Company introduced their negative paper it was quite natural that extreme caution should be observed in guaranteeing its keeping qualities until experience accumulated, and they, therefore, very properly limited their responsibility to a period of six months, and imposed as a condition that a piece of the defective material, together with the emulsion number, should be forwarded to the Company by the claimant for compensation, which compensation was limited to an equal quantity of good material. The emulsion number was an important requirement, inasmuch as it enabled us to trace the cause of the trouble; but what is the practical outcome of all precautions taken by manufacturers of sensitive films? Let any one take a stroll about town and tell us what he sees in the windows; plates, bromide paper, films, &c.; some brands known to be of excessive sensitiveness, all exposed to the direct rays of the sun under glass. I have one exhibit fresh in mind as I saw it this morning in walking to my office, for there in a show case outside the shop window, and devoted exclusively to the display of plates and sensitive papers, I counted at least fifteen kinds of plates and papers,

some of which I thought looked very much like my own wares. Now, no plate maker should be held responsible for any damage to his goods when exposed in such a manner as above described, and I care not who the dealer is, he should be subject to just suspicion if he is not known to be a careful and intelligent man.—I am, yours, &c.,

WILLIAM H. WALKER.

13, Soho-square, London, W., November 8, 1887.

PHOTO-MICROGRAPHS AT PALL MALL.

To the Editors.

GENTLEMEN,—I have only just seen Mr. Pringle's letter, or I should have replied before, and that if only for one reason, to express my equal astonishment and pain that he should have supposed that I was in the least attempting to meanly depreciate his work.

But is not Mr. Pringle making haste to be offended? I cannot at all see that any expression in my letter can be justly styled as "venting spleen." My only desire was to place the superficial remarks certain papers had passed on my exhibits in juxtaposition with the favourable criticisms passed upon the same work by acknowledged experts, and to perhaps raise a smile at one paper's having passed two such contradictory estimates on the same work. As for "cracking up" myself, why, the very suggestion was such a shock to my modesty that I really believe—if I could only have seen it—my very soul blushed! I confess to having felt disappointed that the results of some years of hard work should be dismissed in influential papers with superficial and therefore damaging criticism. As regards what Mr. Pringle says about my "rare and beautiful objects," if he will turn to page 680 of your issue containing his letter, he will see a most opportune paragraph from "Free Lance" saying just what I did on this point, that this work is only worth doing in the case of the best possible objects; and further, that the best, or even good work, is hardly possible but to those having some training or experience in microscopy. I have been fortunate in acquiring and borrowing many objects really deserving the above title, and I was therefore justly gratified at hearing my efforts to adequately photograph them secure the genuine and critical praise they did from such experts as Dr. Dallinger, Mr. Frank Crisp, and others. "Free Lance" very evidently knows what he is writing about, and I was therefore glad to see from the last sentence of the paragraph already alluded to that he was not inclined to dismiss my exhibit as "commonplace," &c.

I knew Mr. Pringle would be vastly tickled at my suggestion *re* "exquisite decorative designs," but again he is in a hurry to extract the worst possible meaning. I avoided, as I do now, passing any criticism direct or indirect on his work in its scientific aspect, leaving that to abler hands; but feeling a measure of truth in the above idea, I could not resist giving a few lines to it, knowing that Mr. Pringle at least would see the humour and grotesquerie of it, but having no suspicion that he would only see a covert detraction in it. At any rate, I think your readers should be grateful to me for giving Mr. Pringle so congenial a text for such "exquisite feeling." I do not think I ever enjoyed an epistle of his more than this one; he has surely "out-Pringled Pringle!"

But seriously, with regard to my doubtless over-bold words *in re* bacteria, my lack of interest in them arises largely from the fact that my study of microscopy has been chiefly from a love of the beautiful and artistic; scientific research is not my forte. If bacteria, like diatoms, had "structure to pay for care in delineation" (I note that Mr. Pringle only quotes, and does not oppose this), I should no doubt have worked at them photographically. My chief aim in photo-micrography is to see how far it can compete with or replace drawing, so as to get more truth to natural effect. I therefore enjoy working at physiological sections, &c., more than at these structureless micro-organisms.

Audacious as I may be to venture a contrary opinion to such scientists as have been quoted, and unscientific as my objections may be, I still feel bound to confess that my lack of interest in bacteria deepens into horror when I review the mad fever of late months for inoculation against rabies—and even as a remedy for consumption!—and lest it should develop into compulsory inoculation against these or other diseases, as with that greatest of disgraceful tyrannies—compulsory vaccination. To my thinking this is nothing short of rank blasphemy against nature; her way is surely to let nothing into the blood but after the most stringent and delicate of testings and siftings. Inoculation and vaccination "trample upon her safeguards and wisdoms," and "mingle in a communism of blood the taints of the whole community every hereditary server opens up into every nursery." (I quote words and thoughts from Dr. Garth Wilkinson's wonderful books, *Human Science* and *Divine Revelation* and *The Greater Origins and Issues of Life and Death*). Bacteria are studied mainly, I suppose, in relation to disease, and, therefore, its cure or alleviation; but for this to be of any effectual value, bacteria should be causal of disease, and therefore found in the early stages thereof, whereas it is well known that it is only in the later stages that they are found. Does it not seem, therefore, a "plain fact that they are engendered in each case in the decay made by the disease?" (Dr. G. W.) How then does their study lead to new cures or remedies for diseases? If their study leads to *same* methods of cure, I devoutly wish it all progress, but if it breed only the insane methods of inoculation and vaccination, then to my humble thinking such study is fruitless for any physical or spiritual good.

I know that my holding such opinion at once disqualifies me for any argument on purely scientific grounds, but I do not regret this as I firmly believe that no real progress is possible to a de-spiritualised science.—
I am, yours, &c.,

FRED. H. EVANS.

158, Osbaldeston-road, Stamford Hill, November 4, 1887.

A MATTER OF HISTORY.

To the Editors.

GENTLEMEN,—In your issue of the 4th inst. I note these remarks by Mr. W. Jerome Harrison, at p. 698:—"Photography proper now rests, we may say, entirely upon the labours of three great Englishmen—Fox Talbot, calotype process, 1841; Scott Archer, collodion* process, 1851; Dr. R. L. Maddox, gelatino-bromide, 1871." But it appears to me that a most important link is missing, as nearly the whole system of photography to-day is based upon the use of the salts of silver in emulsion, instead of their creation by a double operation, involving a nitrate of silver bath, with all its uncertainties, as was the case with Scott Archer's collodion process, and I venture to believe that all conversant with the history of photography will admit this.

The first practical negative emulsion process was "collodio-bromide," the earliest stages of which were published in your JOURNAL in the autumn of 1864, and the editorial comment (happily the same worthy Editor is still to the front) on that occasion was, that it "solved a problem which had puzzled many and has been felt to be a desideratum." *Vide* BRITISH JOURNAL OF PHOTOGRAPHY, September 16, 1864, p. 359.

Gelatine is but another vehicle for the suspension of silver salts, but it has the decided advantages of increase in sensitiveness and absence of volatile solvents.

In the preface to the photographic section of the "Inventories" catalogue, Capt. W. de W. Abney, than whom none is better qualified to speak *ex cathedra* on matters photographic, wrote concerning the discovery of "collodio-bromide," describing it as that "*which was to revolutionise the production of negatives*," and that "*the possibility of doing away with the nitrate bath was a great matter in photography*."

The principle of emulsion photography was rendered practical in 1864, but we do not stand still in scientific research, and various modifications and improvements followed, culminating in 1871, seven years later, with Dr. Maddox's adoption of gelatine, which in its turn has evolved further progress, and now we "hark back" on old lines in the use of the roll-holder for the paper support of an emulsion film.

Emulsion carries with it certainty of result with ordinary care, but when the nitrate bath was the *main prop* on which we relied only those who worked then in our art-science can realise the difficulties which at times staggered the veterans of those days. I therefore claim a notice of collodio-bromide in all records of photographic progress, and have no doubt that Dr. Maddox will be as greatly surprised as myself at Mr. Jerome Harrison's omission of its introduction, marking as it did one of the epochs on which "photography proper now rests."

Another should be mentioned, viz., the albumen process pure and simple, which did good work in the decade prior to 1851, and to this day forms an excellent medium for transparent photographs.—I am, yours, &c.,
Redcross Chambers, Liverpool, November 5, 1887. B. J. SAXCE.

A CURIOUS PHENOMENON.

To the Editors.

GENTLEMEN,—A day or two since I had a curious experience, which if not entirely novel is sufficiently interesting, I think, to bear narration. Phosphorescent phenomena in connexion with gelatine emulsions and films have been previously noticed and recorded, but I do not recollect to have seen any account of any inquiry into the conditions that favour such phenomena.

I was developing a gelatino-bromide print, using the same paper, the same developing formula, and, in fact, proceeding in every respect as I have been in the habit of doing for many months past, when upon applying the usual clearing solution of dilute acetic acid, I fancied that a faint phosphorescent light came from the dish; but it was so feeble and transient, that I paid little attention to the matter at the moment. About an hour later a similar thing occurred, though some half-dozen prints had been developed in the meanwhile without any unusual appearance, but this time it was so unmistakable that I commenced to attempt a repetition. My experiments were, however, quite fruitless, and it was not until the following day in the ordinary course of development, I met with the same momentary flash of phosphorescent light, that I got a clue, if not to its cause, at any rate to one of the conditions that favour it.

I was printing from some very thin negatives with large masses of nearly transparent shadows, and in order to get contrast without spoiling the lights, I had to expose long to a feeble light and use a powerfully restrained developer. Under these circumstances I am able to reproduce the phenomena at will, but am wholly at a loss to explain the reason why they appear only after a long exposure.

The developer was the Eastman soda formula, and the clearing solution dilute acetic acid about one in sixty, applied immediately after develop-

* i.e. with a nitrate bath.—B. J. S.

ment and before washing. Perhaps some of your readers may have met with a similar experience, and may be able to throw further light on the cause. At any rate it may interest you to publish the facts.—I am, yours, &c.,
B. W.

ORTHOCHROMATIC PHOTOGRAPHY.

To the Editors.

GENTLEMEN,—On the occasion of Mr. Wellington reading his paper on *Orthochromatic Photography* at the Photographic Club, the question was raised during the discussion which followed, as to whether the use of orthochromatic plates was legitimate or not, the reason being, that in many cases the cracks in the original did not show in the copy; also, that the copy was much brighter than it should be, considering the state of the original. Consequently the impression was conveyed that the photograph, instead of being made from the original, was really taken from a freshly painted duplicate. Certainly this appeared to be the case with one or two examples shown at the meeting. The same kind of thing appears to me to exist also in the copies of the pictures in the National Gallery, published by Brann & Co., also in those in the present Photographic Exhibition. Must we not consider that these copies are all untruthful?—I am, yours, &c.,

ONE WHO WAS PRESENT AT THE MEETING.

THE MERCHANDISE MARKS ACT.

To the Editors.

GENTLEMEN,—I notice in your issue of to-day (November 4) a letter upon the above. I would like to ask a question or two that I think may be of interest and importance to your readers. The case is very simple. An amateur engaged in another calling, that being his legitimate means of income, takes a set of negatives of interesting subjects. He brings them to me, and liking them I purchase them of him at so much a-piece. In publishing copies from these negatives, as I did not produce them, am I compelled by the Act to affix his name as the artist to every copy, because under Clause 2 I cannot say "photographed and published by my firm," because that is false, and under Clause 3, second section, if I stamp them as other goods, I reasonably lead persons to believe that the goods are the merchandise or manufacture of my own firm, when they really are the manufacture and merchandise of another. Which, therefore, would you designate him, as he makes a profit by his work?

Lastly, if I employ a gentleman who poses as an amateur to make lantern slides for me for sale, and I pay him his charge for same, does this Merchandise Marks Act apply, and is he an amateur or a professional?—I am, yours, &c.,
HARDING WARNER.

The Hollies, Clyde Park, Clifton, Bristol, November 4, 1887.

To the Editors.

GENTLEMEN,—In my letter of the 1st instant, inserted in your last week's number, I gave a few extracts from the above Act, and alluded to its possible application to the photographic lens trade. I will now endeavour to show how, in my opinion, it does so apply.

It is pretty generally known that the *bona fide* makers of photographic lenses in this country are very limited in number, the following names probably including most, if not all—Grubb, Ross, Dallmeyer, Wray, Swift, Beek, Taylor, Burr—whereas the *sellers* of lenses with their own names attached may be reckoned by scores. Provided the lenses thus sold are manufactured abroad, and do not bear a mark indicative of their origin, it is an offence punishable under this Act, for a person in this country to attach his name or trade-mark or trade description, and sell or expose for sale, or use for the purposes of trade or manufacture, any lens so imported and marked; the penalties under this Act being perhaps rather severe. An offence as above renders the offender on *conviction on indictment* liable to imprisonment with or without hard labour for a term not exceeding two years, or to both imprisonment and fine; or on *summary conviction* to imprisonment, with or without hard labour, not exceeding four months, or to fine not exceeding 20*l.*, or on a second conviction to six months and 50*l.*

Even if a person innocently purchases a foreign manufactured lens with false trade-mark or trade description, and subsequently sells or offers for sale, or has in his possession for purposes of trade, any such lens, he renders himself liable to these penalties. For the future it will not only be *caveat emptor*, but rather "let the seller beware."
C. W.

November 8, 1887.

RED TAPE.

To the Editors.

GENTLEMEN,—A short time since I entered a well-known photographic shop and asked for six ounces of carbonate of soda, which were weighed out and handed to me, when the following conversation took place:—

Buyer.—"How much?"

Seller.—"A shilling."

B.—"That seems very dear; how much is it by the pound?"

S.—"Eighteenpence a pound; twopence an ounce."

B.—“Can't you sell less than a pound at the rate of eighteenpence a pound?”

S.—“Yes, you can have half a pound for ninepence.”

B.—“So you charge a shilling for six ounces, while you give eight ounces for ninepence; doesn't that seem very absurd?”

S.—“Can't help it, that's our rule.”

B.—“Now look here—I don't want eight ounces, I want six—I'll give you ninepence for the six.”

S.—“No, can't take it; can't break our rule.”

B.—“Well, if you give me two ounces more that will make half a pound, and you can charge me ninepence.”

S.—“Yes, we can do that.”

B.—“All right, give me two ounces more.”

Which was done; the extra two ounces were weighed out and put up in a separate parcel, and I paid ninepence for the eight ounces. As has been remarked before, “Comment is needless.”—I am, yours, &c.,

A.M.

Exchange Column.

*. No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as “anything useful” will therefore understand the reason of their non-appearance.

I will exchange enlarging apparatus for first-class studio furniture.—Address, W. DAKIN, 1, High-street, Sheffield.

Will exchange whole-plate view lens for magic lantern suitable for enlarging.—Address, J. LILLIE, Forster, N.B.

Wanted, whole-plate tourist's camera; will give in exchange photographic books.—Write for particulars to EDWARD J. HUGHES, Graigue, Co. Kilkenny.

Wanted, tourist's 10×8 set in exchange for 12×10 folding camera (little used) and Ross' whole-plate portrait lens.—Address, ASU, 4, Hampton-street, Walworth-road, S.E.

Will exchange a carte lens by Cox, or a cabinet lens by Voigtlander, for a pair of twin stereoscopic lenses. Difference adjusted.—Address, CHARLES WHITING, 370, Usbridge-road, London, W.

Exchange, a fifty-four-inch Coventry Special bicycle, balls throughout, and all latest improvements, for a 9×7 or 10×8 long-extending camera and symmetrical lens.—Address, J. ATKINSON, Photographer, Worthington.

Wanted, pair of stereoscopic two-and-a-half or three-inch Dallmeyer's portable rectilinear lenses; give in exchange other lenses, quarter-plate camera, &c.—Address, 17, Grosvenor-square, As-t-on-on-Mersey.

Will exchange an Ottewill's changing box for eighteen plates, 8×6, dark slide, and all complete, good condition, for tripod, sliding legs, or metal dark slides (Taylor's whole-plate preferred).—Address, A. E. BANNISTER, 31, Clifford-street, Southampton.

Rifle, revolver, trout rod, complete, box of Newman's dry colours, silver lever (English), Leicoult half-plate portrait lens, and large medical coil, in exchange for modern studio camera, whole-plate field camera and rapid rectilinear lens, backgrounds, and rapid shutter.—Address, R. H. THOMAS, The Rhine Studio, Youghal.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessary for publication. Communications may, when thought desirable, appear under a NOM DE PLUME as hitherto, or, by preference, under three letters of the alphabet. Such signatures as “Constant Reader,” “Subscriber,” &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

A. HAMILTON (Bristol).—Thanks.

G. F.—Imperfect fixation is the cause of the marking.

ELIMINATOR (Northampton).—The address is, Scovill Company, 423, Broome-street, New York.

J. HETHERINGTON.—Having the negative no other apparatus is required beyond that described.

CRYSTAL.—Consult our advertising columns. Every manufacturing optician supplies lenses wholesale.

W. ELSDON.—The intensifier with cyanide of silver given on page 241 of the ALMANAC, 1883, is practically the same. It will answer the same purpose.

J. W. MARKS (Bowes Park).—You will find an article on the subject on page 456 of our volume for 1882. The Platinotype Company will supply you with the article.

C. MORLAND.—For the early history of photography consult Hunt's *Manual of Photography*. For your question as to the history of the gelatino-bromide process, see our ALMANAC for 1880.

J. R.—The fault is not with the paper, or with the toning bath; it is simply imperfect fixation. Either the bath is too weak, the time of immersion too short, or the prints are allowed to stick together while in the solution.

R. G. C.—Undoubtedly you can get the effect desired by employing the proper combination of lenses, but we cannot give you information as to anyone who will carry it into execution. You will have to conduct the experiments for yourself.

PERPLEXED SUBSCRIBER (Monkwearmouth).—You will not get good portraits in your studio as it is; they will always be hard and flat. The best plan will be to block out the light at B entirely, and put the background there. Then stop up two-thirds of A at the B end, and put in glass up to the end of C or a little further, stopping out all the light from the side window facing A. The light C might also be enlarged somewhat, say twelve inches each end.

STANLEY ROBERTS.—The best plan of getting a “practical knowledge of lighting” is to take some lessons from a practical photographer who is well versed in the subject. Write the title on the negative with a sable pencil charged with black varnish. It will then print white in the print.

A. G. FIELD.—1. There is no such work published. Many articles on the subject have appeared in our back volumes, also in the ALMANACS.—2. Seavey's backgrounds may be obtained through any of the large dealers. Try Mr. Atkinson, of Liverpool, or Messrs. Marion & Co., Soho-square.

R. J. HOLCROW.—Any person possessed of a passion for printing on wood, fulfilling the conditions required by you, would not care to part with the information under a very heavy amount. We have heard of very large sums having been paid for tuition in this branch, but the method taught did not come up to your estimate of what is necessary.

X. Y. Z. asks: “Would the addition of soda carbonate to the fixing bath answer as well as liquid ammonia? My printer is not very strong, and finds ammonia fumes very trying, so should be very glad to discard its use if not detrimental to the pictures.”—Carbonate of soda will render the solution alkaline as well as ammonia, and, for all practical purposes, it will answer.

A. B. M.—1. No.—2. Strength, four ounces to the pint of water. The time will depend upon the make of plate. Leave them in the bath until they are clean, and for some little time after.—3. The same strength will do for prints. Let them be immersed with constant movement for fifteen minutes.—4. Until the whole of the hyposulphite of soda is illuminated.—5. The ultimate ruin of the negative.

A. F. M.—The sketch shows the studio to be a very good one. Fit curtains at the sides, so that they can be moved laterally; and blinds at the top working up and down. Place the sitter at the south end, and the camera at the other. The sitter can then be illuminated either by the east or west light as the time of day may determine. With this arrangement of blinds no papering up of the glass will be required.

R. WEST writes: “Will you kindly state how silver prints are burnished? I have Burton and Hepworth's Handbooks, but neither of them give the method of procedure. I had some fairly good pictures but have spoilt some of them in trying to burnish them.”—In the first place, lubricate the prints by rubbing over the surface with a piece of soft flannel moistened with a solution of one grain of Castile soap in one ounce of methylated alcohol. Then heat the bar of the burnisher as hot as the hand can well bear it or a little hotter, and pass the prints two or three times through the machine, sufficient pressure being arranged to produce the desired gloss.

F. A. C. writes: “1. You advocate washing prints with a squeegee; will you kindly tell me the method and how long it takes, and whether it is really better than the prolonged ordinary washing?—2. Can you tell me where I would be likely to get *papier-maché* in stout sheets? I want it to build a camera with, and it strikes me it would be capital stuff—light, stiff, and not likely to warp in India, but I have found a difficulty in getting any.”—In reply: 1. An article on the subject of washing large pictures in which the squeegee is utilised will be found in the number for January 7. The plan there advocated involves more labour than simply soaking the prints in water, but it is more efficacious.—2. We expect the flat sheets of *papier-maché* will have to be made to your order. Any manufacturer will, we surmise, make them for you.

*. With this number we give an engraving of Mr. H. P. Robinson's medal picture, *Carolling*.

On our editorial table, and soon to be transferred to the wall of the *sanctum*, is a large and fine photograph, said to be a good likeness, of the President of the North London Photographic Society, printed in platinotype by Mr. James Martin, of New Southgate, from a negative taken by Mr. John Stuart, of Glasgow. It is mounted on an Indian tint and makes a nice and effective picture.

MR. W. S. BIRD, the Honorary Treasurer of the Photographic Society of Great Britain, being about to sail for Australia for the benefit of his health, was entertained at dinner in the Holborn Restaurant on Saturday evening last by about thirty of the leading Metropolitan members of that Society, Mr. James Glaisher, F.R.S., President, occupying the chair. A pleasant evening was spent, and many wishes expressed for the speedy restoration of the health of the departing guest, whose absence from this country will probably extend to eight or nine months.

PRESENTATION.—At the Smoking Concert of the Camera Club on Monday evening last, occasion was taken to recognise the invaluable services rendered to the Club by Mr. G. Davison, the Honorary Secretary. In name of a large body of the members Mr. F. Machell Smith, who presided, after recounting what Mr. Davison had done to further their interests, presented that gentleman with an ornate gilt clock and a purse of sixty guineas. Mr. Davison made suitable reply. What with the “feast of reason, the flow of soul,” and the fragrant clouds from the *Nicotiana Tobacum*, a pleasant evening was spent.

THE JENKINGS'S FUND.—Dr. Muldoon (Greenbank, Park-road, Portsmouth, Southampton) desires to acknowledge the following sums:—Frederick York, Esq., 3*l.*; A Friend, 1*l.*; W. M. A., 2*s.* 6*d.*

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1437. VOL. XXXIV.—NOVEMBER 18, 1887.

PHOSPHORESCENCE IN THE DARK ROOM.

A LETTER in our correspondence column of last week once more calls attention to a matter that has cropped up on more than one previous occasion, namely, the manifestation of phosphorescent phenomena in connexion with photographic operations. But as our correspondent suggests, no systematic attempt has hitherto been made to investigate or explain such occurrences. It will be remembered that Mr. W. K. Burton, a year or two ago, directed attention to similar phenomena produced in stirring an emulsion, and more recently the production of phosphorescent light under conditions practically identical with those now recorded were reported in the journals.

A tendency has been shown to discredit these alleged manifestations as mere illusions, at least on the part of some experimentalists who have failed in their attempts to reproduce them; but we are in a position to say that the statements are fully justified, and to show how the results may be produced with as much certainty as the development of a photographic image. As to any explanation of the causes, we can say but little beyond that they are purely chemical, and in no sense photographic, inasmuch as they can be produced in the dark room without the assistance of light or the interference of any photographic film or other material sensitive to light in the ordinary sense.

Only a fortnight ago we published a letter from Mr. F. E. Ives, of Philadelphia, combating the conclusions arrived at by Mr. D. Winstanley with regard to the possibility of photographic action being set up in the dark upon photographically sensitive films by the invisible phosphorescence of otherwise inert substances. But the question we have to discuss is one altogether different, and relates merely to visible phosphorescence produced without any but chemical action. Phosphorescence produced by exposure to light is a phenomenon well known in connexion with certain substances, notably phosphorus, from which the term is derived, and many of the sulphides, the most familiar to the photographer being the sulphide of calcium which forms the basis of Warnerke's "luminous tablet" and Balmain's paint. It is not, however, so generally known that nearly all substances in nature possess the property to a certain extent, though it is so feeble and lasts so brief a period as to be invisible under ordinary conditions. Becquerel, however, has shown such to be the case, and he devised an instrument by means of which the phosphorescent properties on exposure to light of hitherto unsuspected substances was demonstrated.

Other substances, again, exhibit phosphorescent properties when submitted to friction or percussion. Loaf sugar, for

instance, if bruised, or pounded, or rubbed in the dark, displays this characteristic, and a very beautiful effect is shown by shaking a bottle containing dry crystals of uranium nitrate under similar conditions. These manifestations, however, may be classed rather as electrical than chemical, while the phenomenon mentioned in our correspondence column would seem to be purely chemical, if indeed a fine line can be drawn between electrical and chemical reactions.

In our correspondent's case an exposure has been made to light, and from his letter he evidently, and perhaps naturally, attributes the subsequent phosphorescent appearance to that action, as it was only after a long exposure that the transient flash of light occurred. But we shall show that the exposure to light is unnecessary, and that the chemical conditions of development alone produced the manifestations when they did occur.

Our first experiments were made in this direction some months ago under somewhat similar conditions to those detailed by "B. W.," but we have, since reading his letter, repeated and extended them. It was in connexion with paper negatives, we may remark, that we first noticed the phosphorescent appearances, and this has been the case with several observers, more than one of whom for that reason have attributed it to some peculiar property of the paper support. This, again, we shall show to be quite erroneous, as the phosphorescence is as readily produced with glass negatives as with paper, and as readily without either. The only reason why paper negatives and positives enjoy almost the monopoly of this property is because it is only with paper films that the clearing solution is applied *before washing away the developer*. We are extremely sorry to demolish any carefully elaborated theories on the subject of the phosphorescence of white paper, but there lies the sole explanation.

It is, in fact, the mixture of the *acid* clearing solution with the developer that excites a momentary phosphorescence lasting sometimes perhaps a second or more, and, under favourable circumstances, so vivid as to resemble a moderately excited tablet of Balmain's paint. As we have said, the glass or paper negative has no part whatever in the performance, all that is necessary being a developing dish and developing and clearing solutions.

And now a word as to the active agent in this matter. We have to deal with pyrogallol, in combination with which we always employ sulphite of soda, alkali, bromide of potassium, or other alkaline bromide, and a free acid. Pyro alone, when mixed with the acid, has given us no sign of the occurrence, while pyro and alkali, or pyro and bromide alone, are almost equally free from any susceptibility. But when the three

are present simultaneously, the manifestations commence, and it is interesting to note that the degree of phosphorescence appears to depend entirely upon the proportion of bromide present. Thus, though the other two ingredients of the developer are absolutely necessary to the production of any sign of luminosity, variations in their strength produce little or no apparent effect on the result; whereas, in proportion as the quantity of soluble bromide is increased, so the luminosity acquires greater strength.

The effect varies with the character of the clearing solution used, or, more accurately speaking, with the acid; an organic acid, so far as our experience goes, being indispensable. Nitric, hydrochloric, and sulphuric acids have given negative results under all conditions, while acetic, citric, oxalic, and tartaric all produce phosphorescence, the first named most vividly.

The experiment is easily performed. In one developing glass mix solutions of pyro and of alkali in the proportions usual in development. We are not aware that the nature of the alkali matters. We have obtained the result with both soda and ammonia, though the former is what we have usually employed from convenience. In another glass mix a solution of acetic acid, say, one drachm of the glacial acid in six or eight ounces of water. Now pour the alkaline pyro, or developing solution, into a clean dish, and after allowing it to flood the bottom and sides, return it to its glass, and pour into the dish the dilute acid. Most probably not the faintest sign of any luminosity will be visible, though we have on occasions fancied we could detect a faint glimmer, but have never been able to distinctly affirm such to be the case in the absence of bromide.

Now rinse out the dish, and having added to the developing solution a drop or two of sixty-grain bromide solution, repeat the operation of flooding the dish, and again return the developer to its glass. Upon now pouring the acid solution into the dish, a distinct phosphorescence, varying with the quantity of bromide used, will present itself. If the quantity of bromide is but small, there will be a momentary and faint flash, chiefly visible on the corners and along the angles of the dish, while, as the strength of the bromide is increased, it gradually spreads over the whole surface, and acquires greater brilliancy, until, with a large proportion of bromide, the contents of the dish assume for a second or more a most beautiful appearance of liquid fire. The same quantities of solution may be used over and over again, and if the quantity of bromide be gradually increased, the corresponding growth in brilliancy can be noted. When the solutions are mixed, a bright flash of light occurs, and then all further action is destroyed.

Now, to vary the experiment, and show how a photographic film *may* take part in the reaction, though only chemically, we will proceed, with pyro and carbonate of soda alone, to develop a positive, and afterwards treat it with the same acid solution. We will purposely select a negative to print from which possesses but little heavy shadow and no violent contrasts, and let the exposure be so timed that the development is not forced. In fact we will endeavour to produce a soft picture devoid of heavy deposits in any portion. Upon development being completed, pour the solution into a glass, and keep for further use, and without washing treat the print with the clearing solution. The chances are that no result will accrue, or, if there should be any luminosity, it will be so faint as to have escaped notice entirely, unless carefully watched for. But now proceed to develop a second picture with the same quantity of solution, and a third, and it will be found that

each successive one exhibits a stronger phosphorescence than its predecessor upon applying the clearing solution.

The explanation of this is extremely simple. The first time the solution was used it contained no soluble bromide to commence with, and the quantity acquired from the reduced bromide of silver in the film was, under the circumstances, comparatively small, hence the negative result. But on each successive development the quantity of bromine liberated and retained in solution is increased, and consequently the conditions improved for the production of luminosity. This, again, explains why our correspondent only occasionally meets with the experience. We imagine that, as a rule, he employs simply the solutions of pyro and sulphite and of carbonate of soda which comprise the formula he mentions. Under such circumstances he is practically carrying out our experiment above; but, under the exceptional conditions he quotes, not only does he resort to bromide as a restrainer, but he also liberates a large proportion of bromine from the films themselves, and thus brings about the very requirements of the case.

Whatever may be the chemical explanation of this phenomenon, it is clear from what we have said that it is entirely distinct from any photographic action, and is equally free from any influence of light or of silver salts. Our own view is that the phenomenon is entirely due to the action of the acid upon a compound of pyro and bromine, which are known to enter into combinations which exhibit peculiar properties of fluorescence. However that may be, we regret, as we have said, to have to destroy the picturesque theories that might have been woven round the subject. But there is no surmounting hard facts, and all that can be said as to the connexion of photographic action with the phosphorescent manifestation is that *it does not interfere with it*.

A PHASE OF ORTHOCHROMATIC PHOTOGRAPHY.

IN a letter which appeared in our last issue an important point, in one sense, is touched upon in connexion with orthochromatic photography. It appears that in the discussion following on the reading of Mr. J. B. B. Wellington's paper on this subject at the Photographic Club, the question was raised as to whether photography when employed orthochromatically does truthfully render an oil painting—say, the work of one of the old masters which has suffered somewhat at the hand of time.

We know quite well that when an old oil painting, in which the colours themselves and the varnish have become dingy, yellow, and cracked, is copied in the ordinary way by photography, the result, as a rule, is far from satisfactory. The colours, as seen by the eye, particularly if the yellows and blues predominate, are very incorrectly rendered, and the fissures in the varnish and pigment are very strongly pronounced, however skilfully the lighting of the original may be accomplished and the other portion of the work executed. We have ample evidence, on the other hand, in the examples which have from time to time been shown where orthochromatic plates and the coloured screen have been used, that with the same picture under similar conditions of lighting, not only are the colours of the painting more discriminatively rendered but that the defects due to age—the crack, for example, and the yellowing of the vehicle and varnish—are far less prominently reproduced. In a word, orthochromatic photography seems to have the happy property of ignoring, to a great extent, the worst features in an old painting which has suffered by time, while

ordinary photography appears to exaggerate them in a marked degree. Which is correct?

There is no question that if cracks exist in the original they should show in the copy, that is if mechanical accuracy be the main point in view; and unless they do, as has been pointed out, it is quite possible that the idea may arise in some minds that the copy was not made from the original painting but from a modern replica. At one time many persons imagined that the excellence of the work issued by certain Continental houses was due either to the negatives being taken from copies of the paintings, or that they were most elaborately retouched. Sufficient, however, has been demonstrated during the past year or two to prove that it need not have been due to either if orthochromatic photography were employed.

If it be necessary, in order to convey a correct idea of the original, that the fissures in all their details should be shown, and all the defects arising from age reproduced, then orthochromatic photography would certainly seem to be out of place, simply because it ameliorates them to a great extent. But is it essential to do this? Is it far more desirable to render the painting in the photograph as nearly as possible as it was when it left the artist's easel? Discoloured varnish and cracked pigment add nothing to the beauty of a painting or to its value, except, perhaps, in the neighbourhood of Wardour-street. This being the case, why should they be reproduced in a photographic copy when it can be avoided? It is partly through these defects being so much subdued in the recent productions of Messrs. Braun & Co. from our own and the Continental galleries, that the reputation of this firm as copyists of works of art has been so much enhanced. Few, we imagine, will be inclined to question the fidelity of their reproductions of the pictures in the National Gallery, simply because of the unpleasant rugosities seen in previous copies being so much subdued.

Suppose an engraver were commissioned to engrave a plate from the work of one of the old masters which had suffered from age, would he reproduce the cracks and convey in his work the idea that the brilliancy of the colours had to a great extent been subdued by the discolouration of the varnish. Certainly not; nor would the fidelity of his work be questioned on that account. If this be so, why should the efficiency of orthochromatic photography be called in question, particularly as it does not entirely ignore the ravages of time, which an engraver would do, but only somewhat subduces them?

The object of the engraver when he reproduces an old master is not to represent it in its cracked and faded condition, but as nearly as possible as it was when it left the artist's hands. This being the case, why should not the object of photography orthochromatic or otherwise, be in all respects similar?

CHRISTMAS cards formed the subject of two lawsuits in the High Court of Justice last week. In both it was on the question of copy right. In the first case, one firm of publishers sued another firm for infringement of copyright, praying for an injunction restraining further publication, damages, penalties, &c. The pictures in question were illustrations in children's books, and the alleged infringements were reproductions of these, issued as Christmas and New Year's cards. The defence to the action was, that the copies were purchased from a firm carrying on business in Germany, and that the defendants were not aware that the pictures were an infringement of any copyright. In the end the jury awarded the plaintiffs three hundred pounds as damages, and for this amount the judge gave judgment, and also ordered all the piracies to be destroyed.

He, however, stayed judgment on payment of four hundred pounds into Court within a week.

In the second case an important point in connexion with photographic copyright was in question. A motion was made in the Chancery Division by the plaintiff to restrain the defendants, Messrs. Tuck & Sons, from reproducing and selling copies of a photograph which he had registered. It appears that some two years back the plaintiff's two children were photographed by an operator in the employ of Mr. Goodman, of Margate. From the report of the case it appears that *cartes* were taken in the first instance, and, subsequently, six cabinets at a reduced price on consideration of an extra one being taken for the photographer's own purpose. Mr. Tuck purchased from Mr. Goodman a copy of the cabinet picture, and proceeded to make copies, which are now being sold as Christmas and New Year's cards. On this coming to the knowledge of the plaintiff he proceeded to make the picture copyright, and, ultimately, a writ was issued. The defence raised was that the plaintiff had not complied with the Act; and, further, that there was a contract by which the negative, in consideration of the reduced price at which the picture was taken, became the property of Mr. Goodman, who, therefore, had the right to sell it to Mr. Tuck. In the end the judge ruled that the plaintiff had not complied with the provisions of the Registration Act; adding, that according to the authority laid down in the case of *Nottage v. Jackson* the copyright in the negative was the property of the artist who arranged the instrument and posed the objects to be photographed, unless a special agreement was made to the contrary. He refused the injunction asked for.

From the above decision it is apparent that the sitter has no copyright in his own portrait, as it belongs to the one who arranges the camera and poses him. Now, in some first-class establishments the proprietor makes it a rule to pose the sitter and arrange the lighting himself, while an assistant focuses and exposes the plate, and, subsequently, develops and finishes it. In such a case as this in whom is the copyright in the picture vested? Evidently it is not in the sitter. Can it be in the one who poses and lights him? Or is it the property of the assistant who focuses the image, exposes, and afterwards develops the plate? It is the latter who actually makes the negative. There is no denying that the copyright question, as regards photography, is indeed a vexed one, and the sooner the present law is amended, or a new one passed, the more satisfactory it will be for all concerned.

A FEW weeks back we alluded to the fact that *carte* and cabinet portraits of actors and actresses, printed on opal glass by the carbon process, were now being sold at the same price as those on paper. Now, the question naturally arises in many minds, What will the purchasers do with them? Paper pictures are, of course, put into albums, but glass ones cannot be. Will they be put into miniature frames and hung upon the walls? or on fancy stands and stood about on whatnots and the like? If so, a collection of portraits of celebrities on glass, such as some persons possess on paper, will soon become little less than a nuisance in the house, particularly to the housemaid who has to keep them clean. If these pictures become popular some convenient means will have to be devised for their preservation.

WHAT has just been said with reference to glass portraits applies to other small pictures on opal. During the past few years there has been a rage, and it appears to be increasing, for pictures on opal as Christmas and New Year's "cards." Usually these are sent out fixed on a small stand, or in a neat frame. But clearly there is a limit to the disposal of them even in this form. In some families Christmas cards are received through the post by the dozen, and most people like to keep them as a memento. If they are on paper they can be placed in albums, and mounted in scrap-books, or put into fancy trays or baskets, hence a large collection may be kept in a compact form. But if the "cards" are on glass what can be done with them? They cannot be mounted in albums. On the little stands they will accumulate dust and, by continual wiping, will

quickly become dirty and spoilt. If they are placed in trays it is manifest they will soon get scratched by contact with one another—or broken. If they are framed what can be done with them if the number be large? If opal glass is to take the place of paper for portraits of celebrities, and for complimentary cards, the fortunate recipients may find an accumulation of them something like a “white elephant,” unless some means are devised for keeping the collection as compact as in the case of cards. Here is a hint to manufacturers.

ECHOES FROM THE SOCIETIES.

PROFESSOR STEBBING'S experience of photographic dark rooms must have been singularly unfortunate, if I may judge from his remarks on the subject during a discussion at the London and Provincial Photographic Association. Markings are caused upon collodion emulsion plates, he says, when coating in a damp room, “from the rapid evaporation of the ether and alcohol, and the condensation on the film of the damp atmosphere.” Certainly, if Professor Stebbing's laboratory is adjacent to the back kitchen when the family washing is being done I could quite understand such a result, but otherwise not. The rapid evaporation of the ether and alcohol requires a dry and warm, not a moist, atmosphere. The Professor's explanation of a not-unknown fault seems to me an erroneous one. Given an emulsion made with weak solvents, or overcharged with water on sensitising, the result mentioned by him is just what would ensue—the ether and alcohol evaporate, leaving the less volatile water mixed with a portion of alcohol, in the form of dew on the surface of the film. It would, indeed, have to be a moisture-laden atmosphere that would deposit its water so rapidly and copiously upon a plate, even when we take into consideration the lowering of the temperature of the latter from evaporation.

Mr. Adcock is an enthusiast in art photography, and has done much good work in the department he has made his own; but I scarcely think he will obtain a large following of amateurs who will be willing to give up “rustic scene-hunting” for the “beauties and opportunities” of the London streets. “Slumming” promised to become a popular pastime a short time ago, but it soon died out; there was more realism than beauty to be met with, and the aristocratic mind and eye were not educated to separate the artistic from the merely repulsive. Besides, the pursuit was surrounded and accompanied by troubles and inconveniences that the fashionable mind turned against. It was all very well talking on the subject in the drawing-room, but when it came to real “slumming” it was *rather* different. So it is all very well talking and writing about street photography, but when it comes to the actual “unlimbering” in a crowded thoroughfare the amusement at once assumes a different complexion. The “chaff” alluded to by Mr. Sage in the Camera Club discussion is one of the least of troubles—in fact some individuals are blest with such thick skins as to be perfectly impervious to it. I confess I am not, and under no circumstances that I am acquainted with does chaff appear so pungent, and telling, and soul-annihilating, as when you *know* you are causing an obstruction with your camera.

I remember on one occasion I formed the perspiring centre of a not inconsiderable crowd, having foolishly, as I then felt, taken a fancy to photograph one of the old and fast-disappearing landmarks of London. I had managed to get on fairly well by keeping my temper and pretending I really enjoyed the fun, and I was biding my time till the crowd should get tired and clear off. Futile hope! I had stood a vast amount of mild chaff, and replied to the best of my power in a friendly way, but I was quite taken off my guard, and in fact “knocked into a heap,” by a confidential question, scarcely asked in a whisper, just behind me—“Jim, ain't that the bloke as ‘sneaked’ th' other cove's picture-box at Hampstead that Sunday? I believe it is.” I don't know whether it was the unmistakable earnestness of the tone—whether real or assumed—or the suggested “dirtiness” of the trick in robbing a “pal” of his means of livelihood, but I winced and did not reply. After the lapse of a few seconds the same voice in a louder tone and with evident satisfaction, continued: “I know'd it was! See him colouring? The bloke heard me!” Then I turned round and I am afraid used bad language, and it was all up with my photographing. I had eventually to beat a most ignominious

retreat, attended by a crowd and followed for some distance by a policeman, who was evidently uncertain in his mind whether he ought not to arrest me as a suspicious character. That was my last attempt at street photography, and, as I feel at present, will continue so.

But returning to Mr. Adcock's address. I think he underrates the difficulties, as well as overestimates the artistic value, of the subjects to be derived from the streets. How often is it as we pass along that we meet with a composition that is really suitable for a camera reproduction? I am not speaking of large masses or crowds, or even of extensive groupings—these are never either “artistic” nor capable of perfect rendering—but of simple figures, or combinations, or incidents, such as the painter selects for his subjects. I venture to say that in a day's journeying Mr. Adcock will not find one of which he could honestly say, “That will do.”

I quite agree with Mr. Adcock that vulgarity and repulsiveness are not necessary adjuncts to pictures of low life; quite the contrary, for some of the most pathetic and truly refined ideas have been clothed in the homeliest garb. But where the photographer labours at a disadvantage is in depriving the subject, if not exactly of its vulgarity, at least of its repulsiveness or “commonplaceness.” Say what we will of the beauty, the artistic and the dramatic effects to be found in humble life, idealise such subjects as we will, it would be folly to attempt to clothe the fact that to the camera they are inexpressibly ugly, and too frequently, also, vulgar. Examine all the best photographs of the class, and I think it will be found that wherever the subjects are *bond fide* “low-life” characters, they fail to make pictures, though as photographs they may be perfect. I am speaking, mind, of the class of work Mr. Adcock refers to, namely, quick shots in the streets or alleys of our large towns, and where the subjects are equally unpolished in mind and physique. Of course, when an educated and refined model is chosen, and “levelled down” to the low-life standard and made to masquerade in a false character, we gain the beauty and finish that can be imparted to a “paste” imitation, but the real-gem truth is absent.

Take the class of subjects for which such painters as Luke Fildes are known. In almost every instance the sentiment of the picture turns upon the expression, it may be of the whole face or of a single feature, or it may be the gesture or pressure of a hand. Not only that, the natural “vulgarity” or repulsiveness must be smoothed away in order to leave as much beauty as can be got into the picture without destroying its truth. The mere posing of a few figures with a “property” or two thrown in will not answer, the figures must belong to the picture and seem as if they knew they did. How can the photographer attain this without educating his model? And if he succeeds in doing that the model becomes something he or she was not before.

Look at a picture I have in my mind's eye as I write—*A Sermon in Charity* I think it is called. A child, a dog, and a doorstep are all it consists of, yet it speaks as no photograph of the sort ever spoke, simply because the artist is supreme. The expressions of both child and dog are perfectly natural because they are what we can *imagine* as natural. But how could the photographer call them up for the occasion? I fancy if he tried to do a *Sermon in Charity* on the same lines in some of the slums of Seven Dials or Clare Market, his little girl would be enjoying a game of hopscotch along with her bread and butter, while the dog, if he were not “chevying” some cat not belonging to his street, would most probably be lying asleep, either of which occupations his experience would tell him were less disappointing than begging for bits of bread the local children were too hungry themselves to spare. The artist's conception is none the less natural on account of its improbability, but while it is possible to him it is beyond the power of the photographer. MONITOR.

IODINE AND SODIUM HYPOSULPHITE.

SOME little time back a question was asked with regard to the efficacy of iodine as an eliminator of hypo from prints, and as none of the members present had apparently any experience with, or knowledge of, the combination, a few lines on the subject may be useful, as warning photographers of the worse than broken reed they trust to in using iodine for the purpose.

The method as I take it from the report, consists simply in soaking the prints in a dilute solution of iodine, which at once turns them deep blue from formation of iodide of starch, and afterwards washing in water until the colour is discharged, when the hypo also is presumed to be removed. The appearance of the prints so treated cannot, I should think, be very encouraging, which is perhaps the reason why the "process" remains unknown, although it was published and passed without comment in a contemporary some few years back.

Our old friend hypo has acquired such a bad name that it is not surprising there should be a demand for "eliminators," many of which have been put forward, but I hold that, even granting the desirability of using such substitutes for fair washing, the first condition should be that the substance chosen, be it what it may, converts the hypo into something innocuous, or, at least, less injurious than itself. Of the more usually employed eliminators, alum has been proved to be dangerous on account of the decomposition products it leaves behind it, while the hypochlorites and hydroxyl, though less dangerous in that respect, possess other disadvantages which necessitate their use with the greatest caution.

Iodine, however, appears to be more objectionable in every way than any of the substances named. In the first place, its discolouring action upon the sizing material of the paper is scarcely a recommendation in its favour, except in so far as it compels the most careful operator to give a certain amount of washing in order to restore the print to a presentable appearance. But, however carefully this washing may be performed, it is scarcely possible to conceive that the whites of the picture are not to some extent degraded. Add to this that the iodine has a direct and powerful action upon the silver forming the image and we have another reason for looking upon it with suspicion. Even granting then that the hypo has been perfectly removed by washing, and that the iodine is only used as a final safeguard, it presents features which render its use inadvisable, to say the least.

But if we turn to its chemical reactions with hypo, its employment as an eliminator or destroyer of that salt is to be viewed with still greater suspicion. Destroyer, here, is scarcely the correct term, for though the hypo no longer exists as such, it becomes converted into a substance which is hypo *plus* sulphur and a compound of perhaps as unstable a character as itself. The new compound is tetrathionate of sodium, a combination of sodium with one of a series of acids more highly sulphuretted than thiosulphuric, and commonly known as the polythionic acids. The relation of these compounds to hypsulphurous or thiosulphuric acid is shown in the following list of the sodium salts and their comparative chemical constitution:—

Thiosulphate of sodium (hypo)	$\text{Na}_2 \text{S}_2 \text{O}_3$
Dithionate of sodium (hyposulphate).....	$\text{Na}_2 \text{S}_2 \text{O}_4$
Trithionate of sodium	$\text{Na}_2 \text{S}_3 \text{O}_6$
Tetrathionate of sodium	$\text{Na}_2 \text{S}_4 \text{O}_6$
Pentathionate of sodium	$\text{Na}_2 \text{S}_5 \text{O}_6$

Comparing it with hypo, the tetrathionate (which is also called bisulphuretted hypsulphate of sodium) will be seen to possess two atoms more sulphur and three of oxygen. Its method of formation is by the action of iodine upon the thiosulphate, or precisely the action of iodine when used as an eliminator, the reaction being as follows:—

Or two equivalents each of hypo and iodine result in the formation of two equivalents of iodide of sodium and one of the tetrathionate. Tetrathionic acid itself can be prepared by acting upon the lead or barium salt with sulphuric acid, taking care not to use an excess. It forms a colourless liquid, free from smell, and in the dilute state is tolerably stable; but the concentrated acid is decomposed by heat into sulphuric and sulphurous acids, sulphur being separated. Strong acids decompose it at a gentle heat, and even in dilute solution sulphur or sulphuretted hydrogen being formed in each case. It is also easily decomposed into trithionic acid and sulphur under certain circumstances, the latter acid being even less stable.

From this it will be seen that tetrathionic acid and its salts belong to a curious class, so delicately constituted that very little suffices to bring about decomposition; and possessing as they do so large a

proportion of sulphur, it is scarcely surprising that that should be almost invariably one of the products.

Dithionate of silver has been examined, and is found to enter into combination with the dithionates of the alkali metals forming double salts, in the same manner as hypo; and these salts are similar in their characteristics to the double thiosulphates. No doubt analogous double salts of the higher acids of the series exist, and we can scarcely expect that they will differ very materially from any of the rest of their family. Therefore I am constrained to think that the conversion of hypo into tetrathionate is not a gain to photography.

Indeed, if we examine the reactions of the tetrathionates with the salts of other metals, and study them in relation to photographic operations, we shall find we are no whit better off in dealing with tetrathionate of soda than with hypo, if, indeed, we are not worse. With silver nitrate they form a yellow precipitate, which rapidly changes to black, in the same manner as silver thiosulphate. With salts of mercury a yellow precipitate is first formed, which blackens in some cases spontaneously, in all with heat. The precipitate formed by bichloride of mercury has been found to be composed of a mixture of calomel, sulphide of mercury, and free sulphur. By the addition of ammonia to the solution of tetrathionate some of these reactions are arrested, and no precipitate is formed.

Thus we see that for practical photographic purposes the tetrathionate behaves precisely in the same manner as hypo, and that, therefore, a print or film which has been treated with iodine to eliminate the hypo is in just as bad a state and as unprepared for further treatment, or to resist atmospheric and other influences, as before the application of the eliminator.

It is really surprising how such a substance as iodine, with its well-known reaction with hypo and its products, could ever have been seriously put forward as an eliminator. If it has been used for the purpose, and not found wanting, it can only be because the previous washing has been sufficiently well performed to leave no hypo, or practically none, to be eliminated. But even then there remains the nuisance of the discolouration, as well as the possible reducing action upon the silver image. Indeed, if I mistake not, a dilute solution of iodine has been recommended—by Mr. William England, I think—for the express purpose of reducing over printed proofs. The necessity for hypo elimination and the reduction of the print do not invariably go hand in hand.

The members of the North London Photographic Society, to whom the question I have referred to was addressed, if they be at all in the habit of using eliminators, may, therefore, remain easy in their minds, and not let the doubt as to whether iodine may not be an improvement put them out of the way in the least—*cau de Javelle* will not yet be displaced.

C. BECKETT LLOYD.

A CONVENTION IN MANCHESTER.

SIGNS are not wanting to prove that the cold reservedness of the typical photographer of the near past, more especially of the provinces, is rapidly giving place to a process of substitution. The existence of the numerous local societies, the operations of the National Photographic Convention, and the many smaller gatherings of the brotherhood, in which the social element is an integral part, indicate most unmistakably that greater harmony and better feeling exist at the present time than formerly obtained.

For the second time since its formation, I had the pleasure of attending a meeting of the Manchester and Hull Photographic Convention, which met in the great centre of cottonopolis on last Friday week. This is a somewhat unique body in its way, having at present no fixed code of rules to squabble over, no sharply defined programme to adhere to, and no utopian scheme under its consideration whereby it hopes ultimately to upset the balance of power in the main body. Now, to the strict adherent to orthodoxy, this might possibly appear a very erratic development, but we are becoming so accustomed nowadays to abrupt departures from ruts almost hallowed by antiquity, that we cease to wonder at any new movement taking root and flourishing, however inconsistent it may appear when gauged by old-fashioned standards and ideas.

Among other gentlemen who attended this convention and took an active part in its proceedings may be mentioned the following:—Mr. G. Caldwell, Nottingham; Mr. J. Hibbit, Sheffield; Mr. T.

Illingworth, Halifax; Mr. A. Seaman, Chesterfield; Mr. Sale, Leeds; Mr. Wellsted, Hull; Mr. G. V. Yates, Sheffield.

Meeting in Manchester about midday it was but natural we should pay a visit to its great attraction—the Jubilee Exhibition, whither we were conducted by Mr. Sadler, one of the partners of the enterprising firm of Leather, Sadler, & Holmes. The photographic section occupied a large share of attention, being, perhaps, one of the most interesting collections of photographs ever brought together under one roof. Our next visit was to the warehouse of the firm just referred to. Now, it is one thing to speak glibly of warehouses as we are frequently accustomed to do, but it is quite another to stand and gaze on those colossal piles common to Manchester bearing that designation which call up our feelings of astonishment, and even national pride, at the commercial greatness of that world-renowned city.

We were very courteously received by Mr. Holmes, who conducted us over the establishment—a large building of four storeys, every floor of which has been consecrated as a receptacle for the varied requirements of the photographic art. The principal object of interest, however, was a new camera stand, invented and patented by Lafayette, of Dublin, from whom they have purchased all rights belonging thereto, and are about to introduce it to the profession. An invitation to visit a new studio, just erected by Mr. E. Ireland, a well-known photographer in Manchester, was accepted and highly appreciated. Strangely in contrast with those elaborate complications and scientific adjustments in which some delight in, is the simplicity and effectiveness of this studio. One huge skylight in the centre of the roof of a large room is all that need be said to convey an accurate description of it, and yet without the aid of blinds or screens of any kind the most effective and varied forms of lighting can be easily secured without the heat and glare which so often militate against the comfort and convenience of the sitters in our ordinary *ateliers*.

Now, whatever may be the failings and shortcomings of the component parts of this little convention, they are not so erratic as to ignore the fact that the best medium to get at an Englishman's heart is a feast, and I, too, would be one of the last to argue against that theory; what, therefore, could be more natural than an adjournment to Lloyd's Hotel, Chorlton, near Manchester, where, being presided over by Mr. Sadler, the vice-chair being occupied by Mr. W. Barry, of Hull, we all sat down to a capital dinner, which time-honoured and revered institution, believe me, was done ample justice to, and

Whilst brilliant the sallies of Lancashire wit,
Which were flavoured with Yorkshire sance without grit,
Repartee and tit-bits, too numerous to mention,
Were freely dispensed at this little Convention.

Dinner being over, amongst other subjects which came under discussion was the influence of amateur work on professional photography, which was handled by several of the gentlemen present in right good style. Mr. Barry, of Hull, in a neat little speech, expressed a decided opinion that it was a question of the "survival of the fittest," and if the professional photographers were so apathetic as to allow themselves to be surpassed in the quality of the work produced, they must bow to the inevitable. Mr. G. Cooper, formerly of Hull, having fully endorsed these views, recommended professional photographers to look to their laurels and not allow the wind to be taken out of their sails by the superior work of amateurs. Then followed Mr. J. Crosby, of Rotherham, bristling with eloquence, who expatiated at considerable length upon the gravity of the situation, referring almost pathetically to the reprehensible practice of some amateurs, who, to the great detriment of the profession, habitually sold copies of their productions at little more than cost price for the purpose of covering their own expenses. On Mr. Crosby resuming his seat, a gentleman humorously reminded him that there was nothing like music to soothe his savage breast. The suggestion, amidst loud laughter, was immediately acted upon, and music and song became the order of the evening, in which the Chairman, Messrs. Cooper, Ireland, Crosby, and others took part, until the small hours of the morning were encroached upon, when it was deemed expedient to allow the curtain of forgetfulness to surround the past, and, after wishing each other bright visions of the future in realms of dreamland, we somewhat reluctantly retired. C.

PHOTO-MICROGRAPHY ON THE CONTINENT.

In the *Annales de l'Institut Pasteur* for the month of May, is an excellent article by Dr. E. Roux, sub-director in Pasteur's laboratory, and one of his assistants for carrying on the preventive inoculations in the noble effort, if not curing the malady entirely, at least of lessening the mortality from rabies or hydrophobia.

As the article contains some valuable remarks and is illustrated by several photographic prints, ranging from the magnification by the common or ordinary camera lens through the figures of 250, 350, 850, and 900 diameters of the objects, portraying the aspects of bacteria under these amplifications, as the work may not be of easy access to some of your readers, a short review of the paper may be acceptable to them through your valuable pages.

Dr. Roux's contribution is of some length, but here only some of the more interesting points will be stated, as likely to prove of most interest by presenting some novel arrangements in this fascinating branch. It will possibly be remembered by some that Dr. Roux exhibited at M. Pasteur's table in the "Healtheries" some beautiful very small negatives with enlargements from them, and which struck the writer as possessing very much merit, though Dr. Roux, at the present time, is rather in favour of direct magnifications if the enlargements are to exceed 250 diameters. From some work by my friend Mr. Pringle, and which lately gained an award, as also from some of my own small negatives, though these were larger than the small ones exhibited by Dr. Roux, I hardly am ready to agree with this point, yet I freely confess much must depend on the beauty of the original small negatives *per se*, and the microscopic preparations from which they were made. This question may be left *sub judice*. The camera was made according to instructions by MM. Verick et Stiassnie, but Dr. Roux does not consider this form as indispensable, though favourable for high-class work. The microscope is by Verick, his model No. 4, as supplied for histology and bacteriology. Two figures are given, one with the microscope arranged for the production of the negatives, the other as where the object is under microscopical examination. An intermediate piece with sundry motions and removable at will forms the union between the body tube of the microscope and the bellows of the camera, the entire length being 1 m. 80, the bellows having an extension of 1 m. 15, and supported to prevent bellying by a kind of lazy tongs arrangement. Sundry diaphragms are placed in the intermediate piece, and near the sensitised plate, for limiting the circle of light. The intermediate piece is furnished with an additional microscope, provided at the upper part with an eye-piece with crossed wires, and at the lower part with a removable rectangular prism for the purpose of examining and centering the same by the crossed wires on the centre of the screen. The body of this second microscope is capable of being withdrawn, so that when unnecessary it is racked up, as when taking the negative. The microscope with its stand it made to rotate on a pin, so as to conveniently snit for examination of objects in the ordinary way, using the mirror and a small lamp. When the intermediate piece and the microscope are detached, the camera proper can be employed as an ordinary camera. There are arrangements for the coarse and fine adjustments. The slide carrying the sensitised plate is extended in such a way that one end, furnished with a plate of grey or polished glass, becomes the examining screen, while the other end, which is the slide proper, contains the sensitised plate and shutters. The under surface of both plates being exactly in one plane they can be substituted without loss of time or risk of displacing to the focus.

The illumination adopted seems to have very many advantages, and consists of a lantern with a vertical jet (Brins's system) for the oxygen-hydrogen method. The jet consists of two concentric tubes capped and furnished with apertures, the inner one having a central hole to retain the radiant in position. The outer tube is for the passage of the oxygen, the inner for the hydrogen, these two gases striking the radiant vertically from beneath. Instead of using Brins's plan with alumina for the radiant supported on a fine platinum wire, which is held in the central hole of the jet, Dr. Roux makes the little pencils and balls from magnesia.

The method of making them is very simple. Ordinary magnesia in fine powder is mixed in a mortar with water into a stiff paste; this is pushed into a glass tube corked at one end and of somewhat larger bore than is needed for the pencils. When compressed sufficiently, the cork is removed and the mass is forced out and cut off in determinate lengths, a short bit of platinum wire being fixed in the centre of each at one end. If required, these pencils are sub-divided into smaller masses, which are rolled in the fingers into small balls, and then the platinum inserted. These are then subjected to the heat of a stove at the temperature of boiling water for three or four hours. They are now very brittle, and are further dried (*singly*) by being set in the central hole of the jet tube, the hydrogen being gradually turned on so as from a small flame to an increased one; then, after a certain time, the oxygen and hydrogen are allowed to play on them until perfectly dried, when they have acquired a very hard condition and become unalterable in the air—one of these little pencils, three to four millimetres in diameter, lasting for fifty hours continuous work. The lantern is small, portable, and of peculiar construction, with

vertical and horizontal movements for centering, and is made by the noted firm of Dubosq. It is supported on a step from the end of the baseboard with additional legs, but little heat is given off; the light is intensely and highly photogenic and concentrated in surface, and has its own system of lenses and mirror for the production of convergent or divergent illumination. The lantern can be pushed nearer or withdrawn from the microscope, yet remaining central. Coloured glasses or solutions or greyed glass are used to modify the light according to the staining of the preparation. To meet more particularly the various tints given by the aniline dyes, Dr. Roux uses only the "isochromatic plates" of Attout Tailfer, with the addition of a yellow glass screen, which with the above light lengthens the time from one minute to six minutes exposure, according to the preparation and the power or construction of the objective. Dr. Roux praises very highly the "isochromatic plates." The objectives are by Verick et Stiassnie, of Siebert, of Hartnack, and of Zeiss, and are well spoken of; the $\frac{1}{2}$ homogeneous immersion of Verick, or Siebert, or Zeiss, being used for the magnifications from 800 to 1000 diameters; the $\frac{1}{3}$ of Zeiss and the $\frac{1}{4}$ of Hartnack for greater magnification, as 1360 diameters. The eye-piece is generally dispensed with. The apochromatic objectives and their projection eye-pieces, as constructed by Zeiss, are most highly approved of as possessing excellent qualities for photo-micrography.

For photographing unstained objects, as bacteria, a magnification not exceeding 500 diameters is recommended, and the illumination to be made by the use of a paraffin lamp. The plates with yeast globules and anthrax, bacillus anthracis *in situ*, which are really excellent, were taken by Verick's No. 8 at 350 diameters, the mirror being used and the microscope placed vertically. Dr. Roux does not mention using the paraffin light without the mirror, as in the crucial test method, and with the aid of the bull's-eye, but most likely this forms part of his practice, as he is a most accomplished microscopist.

The plates are reproduced by the methods known as phototypic, photoglyphic, and heliogravure, Placet's plan, which is, in fact, a galvanoplastic process on copper, light being the direct agent for the reproduction, the artist's hand being unneeded. There is this difficulty, as pointed out in the article, of making the plates in a large page of equal tint or density. Dr. Roux uses the ferrous oxalate developer, with small quantity of the iron solution and some bromide, intensification, when necessary, being made by the use of bichloride of mercury and ammonia. There are numerous precautionary statements and points insisted on, as the camera base resting on caoutchouc to prevent vibration, the method of supporting the intermediate piece and excluding the light at the points of junction, and sundry other details. The arrangement differs from that in general use in this country. The first camera with the additional microscope was suggested by Dr. Miquel and exhibited at his table at the "Healtheries" as made for him by Nèchet, along with many most ingenious devices for registering the diurnal variation in the numbers of the bacteria in the air, and the monthly variation—a subject replete with the greatest interest and of moment to all in a hygienic point of view. There is a plan now proposed by M. Raftio, U.S., for utilising two microscopes, one removable the other stationary.

This review has extended beyond the proposed limit, but as the season has now set in for winter employments with the camera and microscope, it is to be hoped it may not be considered as of undue encroachment on the valuable pages of the JOURNAL.

R. L. MADDOX, M.D.

PHOTOGRAPHY IN NATURAL COLOURS.

THE PROBLEM NOT YET SOLVED.

THE following, written by G. G. Rockwood, appears in the *New York Tribune* :—

"It has been announced of late that persons in London had discovered the art of reproducing and retaining by photography the colours of nature. Surely nothing in an artistic way could have been more interesting or valuable. Important as was the invention of the Daguerreotype and the subsequent development of the art-science photography, there has always been a desire to see the exquisite tints which we see in nature, and have in miniature upon the ground-glass of the camera, reproduced in some tangible and permanent form. Niepce de St. Victor and other French scientists have obtained upon the Daguerreotype plate some of the colours of foliage, a red-brick house, &c., but the range of colour was limited and the pictures could only be seen in a feeble, non-actinic light—soon fading from view. This was accomplished some twenty years ago, since which time no material advance has been made in this direction. So far as the art of photography as now practised is concerned, I have no expectation that the development of colour will be attained direct from nature.

"Light, as is well known, has three distinct qualities—illumination, heat, and actinism. The latter is the chemical ray, and is that which affects the sensitive plate. A beautiful though somewhat intangible theory obtains that inasmuch as it is this actinic or chemical quality in light which imparts all colour to nature, and without which all vegetation bleaches and becomes white and dies, so we have a right to hope that it will also so affect the photographic plate as to give us the beautiful tints of the rainbow! But, unfortunately, colour has value to the photographic plate only as it reflects the rays of light. Some colours, red, yellow, dark green, black (if it is a colour), reflect so feebly the chemical properties of the light as to fail to decompose or reduce the film on the sensitive plate. Photography is based upon the principle that certain salts of silver are decomposed by the action of light. Just in proportion as the film receives the light reflected from the object, so is the deposit of silver compound upon the plate. Simply putting it, a white collar perfectly reflects the light; the black coat reflects but little, and hence a slight action to the plate and a thin deposit. Blue, violet, and their combinations with white, strongly reflect the actinic ray; red, yellow, and their modifications do so but feebly. So, colour has but little effect on the present basis of photography in the way of repeating itself. In view of the wonderful things that have been given to the world in the line of invention during the last half century, I would be a rash man to say that the reproduction of colours is impossible. I think, however, that when it comes to us, it will be through the discovery of some entirely new basis or principle in photography—some colour-sensitive compound entirely away from the present fundamental basis, the salts of silver.

"Now, concerning the alleged discovery by an eminent photographer in London: I was prompt to visit him upon my arrival in London the past summer, and was, I confess, surprised at the results exhibited as the outcome of 'twelve years of study, experiment, and chemical research.' The awful nomenclature adopted by the artist both in his verbal and written comments would impress one with the belief that something novel, to say the least, would be forthcoming. Introducing myself as connected with the *Art Amateur*, and giving no intimation of my occupation as a photographer, I was led into the dimly lighted apartments where the pictures were to be seen. Here were a few indifferent hand-coloured photographs, such as are done (the colouring) for 25 to 50 cents in most establishments. After colouring they had evidently been as we term it, 'glacéd' or given a fine finish by being laid down upon glass with hot gelatine, and then when cold stripped off; the precise thing which the fraternity in America discarded a long time ago, owing to the instability of the aniline colours, or, as this inventor designates them, 'the hydrocarbons.' Noticing duplicate pictures of the same subject, I innocently remarked that 'it must be arduous to a subject to be obliged to sit for each picture as one must do, I suppose, to get the natural colours.' Here followed a cyclone of big words—a few of which my early experience as a reporter and his circulars enabled me to secure. Placing his hand impressively upon me he said: 'The colour rays affect the negative plate in a latent manner, so that they may be made manifest afterward, when a proper medium for their appearance, either selective or otherwise is provided. . . . Therefore the positive plate (which is paper!) being prepared, these vibrations of colour, stopped off and stored up in the negative film, are allowed to become active on the positive film when the exposure again to light (under the negative) takes place! . . . At this point the positive, in conformity to the general idea running through the whole process like a beautiful thread of exactitude, takes up the rates of vibration and the qualities of the vibrations of the negative in a complementary manner, and gives to the positive plate all the characteristics of molecular condition (including latent colour vibrations) that it would have had without the intervention of a negative. It is the true idea of the conservation of energy; it causes the already vibrating molecules to take up and swing in some complicated manner with those particularly absorbed rays!' and so on to the verge of lunacy.

"If we could reduce the above to simple text, our friend claims that he stores up colour vibrations as one would electricity, and the negative thus loaded fires off colour when used to print from. The sitter I took to him had a rich complexion and was dressed in crimson velvet waist and suitable accompanying colours. Whether the negative forgot to do its work or the colour had leaked out I do not know, but the 'proof' was precisely what I would expect from the subject if photographed in the ordinary manner, although assured that 'the greatest opportunity had been given for the various interactions, actinic, photochromatic, and selective, to offset themselves according to the original vibrations (colour and otherwise), to which the beautiful sitter was subjected during the sitting!' I retired to think it over.

"I fear that 'photography in natural colours' is not yet at our command—from this source."

REGISTERING DISSOLVING VIEWS.

ALL lantern exhibitors find the perfect registration of views and effects the "hardest nut to crack," and many systems of carriers, frames, and registration stops, have been arranged to secure coincidence of two views or photographs when projected on the screen. One of the best for showing by means of dissolving view lanterns all

commercial photographs, irrespective of make, is Beard's automatic self-centering carriers. It is only when it is necessary to show views that shall apparently change from one season to another, or from day to night, *without* movement of the objects included in the picture, that the operation is difficult. I shall endeavour to show how this can be performed with absolute certainty. In the first place, the lanterns, two or three, as the case may be, whether side by side or one above the other, must be so constructed that their optical systems are absolutely alike, and capable of projecting the same size discs on the screen; then they must have adjustments to their stages or bodies, so that the angle of inclination can be such as to make the discs superimpose so there is no overlapping.

After lighting up and getting the discs to agree when the lenses are in focus for the particular distance from the screen, the next thing is, get the picture in the optical axis. Now, how is this to be done? If the lanterns were required to be exhibited at one distance only the difficulty would not be great, but as a hinge or hinges, or movement in the vertical or horizontal planes, have to be provided in order to get superposition at different distances, a slight variation is made in the direction of the rays, because no ordinary hinge or movement can be made sufficiently true to always preserve the same line at all portions of its motion, and this variation is magnified by reason of the distance travelled in reaching the screen. It has been usual in first-class apparatus constructed to within recently, to make the stages as true as possible, and then for the operator to register his slides at the distance he generally uses the lanterns at; and even then, if the slide or effect was registered to one stage, it could not be guaranteed that it would register equally well if put into another stage of the lanterns. Mr. J. H. Steward, the optician, has just taken out a patent for a perfect registering stage for lanterns that will achieve exact coincidence of discs and superimpose similar views at any distance from the screen in any of the stages.

It consists of a rising platform or slide runner to the stage that can be elevated by a screw at either end, and when perfectly horizontal that particular position of the front clamped rigidly. Then, as regards the adjustment for securing the stopping, an extra stout and strong pivoted metal finger or stop is provided at the reverse side of the stage to that from which the slides are inserted, and this moves to and from the optical axis of the lantern front, and can be rigidly clamped in that position. By this means, if slides are employed that form a standard, or that have been once registered to the lantern, all dissolving pictures can be made to register to them, and when once registered will always be absolutely true and exactly coincide on the screen.

For existing lantern these registering adjustments are fitted to a metal back plate that slides into the ordinary stage and can be rigidly fixed in position by clamps. It also holds the metal masks for cutting down pictures to a definite size. So that without sending the apparatus to the optician the owner can fit the patent improvements himself; and if he marks the sliding tubes so that they can always be placed back in the original position if moved, he can preserve the same relative optical angles. For it is found that a partial rotation of the draw tube disarranges the centering.

In order to secure the preliminary adjustment of the lanterns prior to an exhibition, or before registering new lantern slides, special slides are employed. They can be of various designs, but for convenience those employed with the apparatus described are plane cross lines and letters in the open spaces. These are photographed by contact so as to be absolutely alike, and are then (by carefully calipering) fixed with putty into a frame very accurately made to a given size, say, $7 \times 4\frac{1}{2}$ (or if the smaller frames are preferred, 7×4). With these frames each absolutely alike in the lantern stages, the clamps (milled head) are released and the adjusting screws raised or lowered, or moved backwards and forwards, until all the crosses and circles agree. The clamps are then screwed home, and the registration is perfectly fixed. For perfect dissolving of views and effects it is a *sine qua non* that all slides must be framed. A simple method of getting photographs and pictures central in their frames is to have the grooves made full large, so that if the glass is not very exactly cut true, or the mat is not exactly central, the glass can be raised, or lowered, or moved right and left, and the difference between it and the wood filled up with cardboard. If the view and the effect be held up to the light a very close approximation to superposition can be obtained, and then, when the slide is put in the lantern (previously adjusted as explained), the frame can be planed off or added to until the view and the effect or the two similar views exactly agree. For this purpose a shooting board and plane are required, as well as narrow strips of mahogany and glue. From experience it has been found best for new, unframed views and effects to use mahogany frames having about one-sixteenth more wood one edge than the other; this, then,

in nearly every case, prevents any addition being necessary, and the process of planing off this superfluous wood is simple until just the amount is left. Pieces can be added to the end of slides that are short, and those that are long can have the part cut away just where the registering stop comes, or with panoramic movements a brass or wooden stop can be securely screwed to the bottom of the frame to stop dead against the commencement of runner. The end adjusting screws turn down to allow of long slides passing through the stage. Mr. Steward supplies these special brass stops and screws, as well as the thin strips of wood, and if there is any difficulty in getting a local carpenter to supply a shooting board, he can also furnish that. With these materials, the only thing necessary to achieve the *beau ideal* of the lantern operator—viz., perfect registration—is a fair stock of care and patience.

G. R. BAKER.

HARVARD OBSERVATORY AND THE HENRY DRAPER MEMORIAL.

IN 1872, Professor Henry Draper first succeeded in photographing the lines of the stellar spectrum. Having secured this triumph for America, he pursued his researches in the same direction until his death in 1882. His skill and ingenuity were alike remarkable. He was not one of those observers who, leaving details to others, try merely to do the final operations. He possessed the quality of thoroughness, and personally attended even to the mechanical details of his investigations. He ground his own specula. It is not too much to say that the work done by him derives a character of value and reliability from the attention to detail that only such an investigator could give it. His powers of handiwork, combined with his scientific standing, make him a model for astronomers. Had dry-plate photography been at his service, his work would have taken a far wider range. But using wet plates that can only bear comparatively short exposures, he was at an immense disadvantage. One interesting feature of his labours was the scientific fellowship of his wife. It is said that he rarely went to his observatory without her. Hence it was with peculiar grace that Mrs. Draper became the founder of the Henry Draper Memorial. From funds of her providing the expense of continuing Dr. Draper's sadly interrupted labours is sustained. No more fitting and useful memorial of the great scientist than this can be thought of. Besides this, Mrs. Draper continues to take a personal interest in the work as done. Apparatus formerly belonging to and constructed by Dr. Draper is soon to be added to the working appliances of the observatory by her liberality. Photographs of the spectra are sent her, and she maintains a vivid interest, because an intelligent one, in the results.

The different buildings containing the instruments and laboratories of the Harvard College Observatory are situated in Cambridge, at quite a distance from the college whose name they bear. They are scattered over the crown of a grassy hill. On entering the grounds the first building seen is the residence of the director, Professor Edward C. Pickering. Directly in the rear of this is the old Harvard College Observatory, with its equatorial and its fifteen-inch telescope, a German instrument, in its day one of the great telescopes of the country, now relegated to the background by the triumphs of Alvan Clark and his sons. Back and to the side of these are what now constitute the principal working portion of the observatory. The most important work done is of the photographic class, and it is this division that we particularly describe. Professor Pickering, however, is also engaged on another investigation, which we can only allude to—the photometry of stars. This is executed by himself personally, with an assistant. A polarisation photometer is employed. The results are of much practical value for use in connexion with astronomical work, and when completed are destined to form a most important standard of reference.

In a recent article on the Alvan Clark establishment, where the great telescopic objectives of the world have been ground, reference was made to photographic objectives. The photographic objectives used by the Harvard Observatory owe their excellence to the Clarks. Such glasses have to be ground with a special view to focussing the actinic rays. A perfect photographic lens would be quite useless for visual work. In testing them, therefore, recourse is had to photography. Photographs are taken of a star, generally Polaris or the pole star, on both sides of the chemical focus. If the lens is such as to bring all the actinic rays to a focus, the effect of photographing the star as described will be to produce a series of images, varying from a disc to a mere point, and then increasing in size again to a disc. The discs will be given by photographs out of focus, the point representing the focussed view. If the lens is perfectly ground, these discs will appear all as evenly illuminated images upon development of the plate. If the lens is out of adjustment, one portion of the disc will develop darker than the rest. One of the discs on the side showed a

Medal.

THE THISTLE.

[W. H. HYSLOP.

spot in the centre, indicating a faulty shape, which had to be remedied by the manual skill of the Clark Brothers. A spectrum of a bright spot is photographed. Such portion of the rays as are brought to a focus will produce a spectrum of even width. If the more actinic portion acts thus, the lens is proved correct. The interpretation of these results demands the highest order of skill in the maker of the lens, and it is not too much to say that the high quality of the Harvard Observatory work could only be obtained through, and is due to, the unrivalled talent of the makers of the objectives.

The telescope is erected on a very solid foundation, one which had been used in observing the transit of Mercury in 1878. Attached to its base is a circular level of exceedingly great delicacy, by which it can when necessary be adjusted. The building in which it stands is rather peculiar. The gable roof is in two sections, being divided across its centre, and is mounted on wheels running on tracks parallel to the ridge. When the instrument is in use, these two segments are pulled apart, to the entire length if desired, of the building, the rails in prolongation of the plate beams being carried outside on each end of the house a distance equal to one-half its length. The mounting of the telescope is also peculiar. A steel tube is carried by trunnions in the end of a large fork. Into this tube the brass tube containing the lenses is screwed. The polar axis is in prolongation of this fork. Hence, if the glass is directed to a given star, and rotated on the axis with sidereal time, the star will occupy the same position in the field of view.

As a simplification of the usual methods of mounting, the plan is of interest. The telescope is carried symmetrically, so that no counter-weights are needed. This saves weight. With it any star can be followed uninterruptedly from rising to setting. Polar stars are as easily kept in the field as any others. It does not seem well adapted for visual work, as the fork mounting would interfere with the observer in the case of polar stars.

The lens is a Voigtlander photographic objective of eight inches aperture, and about forty-five inches focus (exactly 114.6 centimetres). To adapt it for stellar work, two of the faces had to be reground. This brought it into perfect condition. With it much work was done in stellar photography under an appropriation from the Bache fund of the National Academy of Sciences, awarded in 1885. It is now devoted to photography of spectra. In front of the objective a battery of two prisms is carried. At the other end of the tube a sensitive plate occupies the position of the focus. By this extremely simple method, first suggested by Fraunhofer, the spectra of numerous stars are obtained upon a single plate.

For driving it the Huyghenian motion is used. The peculiarity of this system is that it can be rewound without affecting the running of the apparatus. The wheel furnished with a ratchet wheel and pawl is the winding axle. When this is turned, the large driving weight is raised and the small weight descends. But during the winding the driving wheel, the one to the extreme right, is continually urged to rotate just as when the winding ceases. The driving weight never ceases to exert its pull upon this wheel, which represents the drum of the ordinary gravity train.

The original work done by this telescope was purely photographic. Under the Bache appropriation the investigation took the direction of stellar photography. Under the Draper Memorial fund the work of stellar spectroscopy was taken up. The work is now carried on in the following manner.

The prisms are set with their edges horizontal, so that the spectra are vertical. By five or six trials the adjustment for focus is secured, and this lasts for an indefinite period. If now a photographic dry plate is exposed, while the instrument rotates by sidereal time, the spectra of all the stars in the field will fall upon the sensitive plate. However long exposed the plate was, assuming all to be in accurate adjustment, the spectra will appear as very fine lines. Their width in general terms is equal to the diameter of the images that would be photographed were the prisms removed and the telescope directed upon them. The largest of the stars would give only a thread-like line to represent its spectrum. The width of this has to be increased for the spectrum to be visible. While this might be done by magnifying the image, a very ingenious application of the principle of "trailing" is used to partially effect the desired result. If the telescope were kept immovable, the stars by the rotation of the earth would sweep across the field of the instrument. This motion with the prisms in place would affect the spectra in the same way. They would be widened into bands. Except in the case of stars near the poles, the motion of the stars across the field would be far too rapid to sufficiently affect the sensitive film, were the telescope kept motionless. Hence in practice it is rotated, but at a rate slightly less than the angular motion of the earth. This slowly widens the spectra, but allows them to act for a long enough time upon the plates to pro-

duce a good actinic effect. The exposures under present practice are in the neighbourhood of one hour's duration. In this way, instead of narrow, line-like spectra, bands a sixteenth of an inch wide or more are produced. In a subsequent issue we will show how these spectra thus produced appear.

The relative action of the different parts of the apparatus is now clear. The light from the stars strikes the faces of the prisms, and passes through them. The pencil of light from each star is thus refracted, and produces a spectrum with vertical axis and horizontal lines. This falls upon the photographic objective, and is brought thereby to a focus at the lower end of the tube. There it is received upon the sensitive plate, while the telescope by its motion, slightly slower than that of the earth, draws the image out so as to increase its horizontal dimensions and amplify the breadth of the spectrum.

After a sufficient exposure, the plate is taken from the telescope to the dark room and is developed. From the negative thus produced a greatly enlarged positive is produced by the use of the apparatus. The negative is set on edge in a box with ground-glass, and by two brass strips and dark paper it is completely covered, except the narrow area containing the spectrum. Next to this a concave, cylindrical lens is placed. Owing, it may be, to irregularities in the motion of the telescope or to changes in the transparency of the air, the spectra always contain a number of longitudinal streaks. The cylindrical lens, by its dispersive effect, destroys this imperfection. A photographic lens receives the light transmitted through the negative and cylindrical lens, and brings the image to a focus where the image falls upon a sensitive plate. The horizontal streaking is not the only defect of the original spectra. Owing, probably, to variations in the refractive power of the atmosphere, the lines or bars are not perpendicular to the axis of the spectrum. The cylindrical lens is mounted so as to be susceptible of rotation. It is for each spectrum so turned that its axis shall be perpendicular to the inclination of the bars.

The general process is the familiar one of photographic enlargement. Its most characteristic feature is the use of the cylindrical lens and of the metal strips and screen. Great care has to be exercised in this part of the operation to keep the edges of the metal strips clean. Little particles of dust might otherwise appear on the magnified image as spectral lines.

The plate, after due exposure, which is executed by daylight, is developed, and gives a spectrum that may be several inches wide and proportionately long. The bars still appear as crossing it at an angle. To produce a straight spectrum, a portion is marked out, giving the lines at right angles to the axis. Thus the faint light of the stars is re-enforced by the daylight, which produces the enlargement, and which acts like a telegraphic relay.

Such is a brief summary of the methods as now used. The work is still in development. A great many of the spectra are photographed with a large glass and with prisms of higher dispersive power. Neither can the full scope be understood or the progress of the last few years be grasped without an inspection of the different final photographs and of the successive stages in their production.

—*Scientific American.*

PRINTING AND ENLARGING ON BROMIDE PAPER.

[A Communication to the Derby Photographic Society.]

THE subject of 'bromide enlarging' and contact printing is, no doubt, familiar to many present this evening. My reason for bringing the subject forward and demonstrating before you to-night is, as questions are frequently being asked on this subject, I thought by explaining my method of enlarging, and also by developing a few prints, it might prove beneficial to some of you, and be a practical answer to many queries.

The prints I purpose developing before you to-night have been enlarged by daylight. I usually get a four-legged table and place it near a window having a north-east aspect, and upon it place my camera, with the ground-glass next the window, then darken the room by blocking out the light from all the windows, except the one next to which I am about to work; upon this latter window I put a piece of canary medium, and hang loosely over this a sheet of brown paper. This being done, I fix a mirror outside the window at which I have placed the camera at such an angle that the rays of light from the sky are reflected through the negative about to be enlarged. The negative is then placed in the dark slide of the camera and put in its position, both shutters are drawn, and care must be taken that no light comes into the room except that which comes through the lens. If an enlargement is to be made from a whole-plate negative, or a larger size, the focussing screen can be removed and the negative

put in its stead. An easel with a drawing board attached is then placed at such a distance from the camera according to the size of the enlargement required. A piece of white paper or card is then fixed on the drawing board and the image sharply focussed thereon. When sufficient sharpness has been obtained, the paper or card on the easel is marked with pencil as a guide where to fix the bromide paper which is to receive the enlargement. The lens is then capped, and the piece of brown paper which is hanging loosely over the canary medium on the window is slightly raised to give sufficient light, thereby enabling the operator to fix the bromide paper in its proper position ready for the exposure to be made. Nothing but experience can determine the exposure, but such experience can be gained by one or two trials made on scraps of bromide paper. I may say, however, the greater the enlargement the longer the exposure required. The picture I am now about to develop has been enlarged from a whole-plate negative in the manner already described. The exposure it had was nine minutes. It may seem rather a long time to give, but being one of the dullest months in the year (November) I find it none too much, as you will see.

Now, the next picture, although enlarged to the same size as the last, was from a negative 10×8 . The light being much brighter at the time, the exposure was one and a half minutes, but, of course, much depends upon the negative. I need not mention to you the proportions of the developer, as full directions and proper formulæ are sent out with each packet of paper. With reference to contact printing, I need say but little. Very thin negatives are best printed by a weak, yellow light, like that obtained from a paraffin lamp; this will ensure a vigorous print from a negative that would otherwise be too thin and flat. If daylight is used, one second will be found sufficient in diffused light, or even too much: I should, therefore, recommend artificial light in preference. Again, as regards the exposure, much depends upon the density of the negative. The negatives I shall now print from will require about twelve seconds exposure one foot away from an ordinary gas burner. The development, as you will perceive, is exactly the same as for enlargements. I may add, the paper used to-night is Eastman's A and C.

In conclusion, I must thank you for the kind attention you have paid, and hope that the remarks and demonstrations made to-night may be the means of producing beneficial and practical results.

THOMAS SCOTTON.

HYDROKINONE DEVELOPER.

HAVING since writing, for experiment, doubled the amount of chloride of potash in my formula, and putting up, also as an experiment, one of the highly coloured prints from Routledge's *New Tale of a Tub*, I was surprised to find that the plate came out on development with a yellow tinge over it, as if it had been taken on yellow glass. I tried and tried again, by daylight for the negative and by night (exposing to a duplex burner lamp) for the lantern slide, and the result was that an *unexposed* plate came out yellow all over, and the yellowness disappeared in proportion to the length of the exposure in both cases. The original motive for adding this salt to the developer was that on experiment I found it aided—what shall I call it? how express it?—the dilution of the developer, *i.e.*, a strong solution of the developer would develop up to a dozen plates, but a twelfth (without the chloride) would not develop. I fancy also that it helps to produce a more vigorous negative or lantern slide (positive), but after this (to-day, Saturday) I made up the developer without the chloride, also varying the sulphite by reducing the amount to three-quarters of an ounce, and making up the difference by a quarter of an ounce of meta-bisulphite of potash, and the result is *no* yellowness under any length of exposure, as great, if not greater, density than before, due, I think from old past experiment, to the tartrate, but—well, if not my fancy—a loss of vigour; but, anyhow, if these experiments are of interest, perhaps some explanation, which I am unable to give, of the yellow colour may be afforded by you. It is evidently due to the chloride and length of exposure. If ample exposure is given there is no yellow colour, and the last place it disappears from is the part of the plate resting on the flange of the carrier. In my last I might have added, develop down until the image appears on the reverse of the plate. This developer never stains or “blackens” a plate.

W. T. F. M. INGALL.

THE REGENERATION OF SULPHITE-PRESERVED PYRO SOLUTIONS.

It often happens that, through long keeping or exposure to the air, pyro solutions preserved with sodium sulphite become discoloured, and the sulphite oxidised into sulphate, forms an agent which exerts

powerful retarding action on the developer. This has always been considered one of the main disadvantages consequent on the employment of sodium sulphite as a pyro preservative, and the removal of this objection should, in a great measure, tend to increase the popularity of this method of keeping stock solutions of pyrogallol. It is usual to employ an acid to neutralise the alkaline tendencies of the sulphite, but except in the “Beach” formula, where the acid used (sulphurous) is itself unstable, and liable to be converted, by oxidation, into a sulphate, the small quantity present will exert little or no influence, and may be disregarded in the following method of procedure.

The chemical equation representing the oxidation of the usual sulphite preservative is:—

Or when sulphurous acid has been added:—

It is well known that soluble salts of barium undergo double decomposition with soluble sulphates, throwing them down as a finely divided sulphate of barium, insoluble in water and in all acids. It is this property that I have made use of in the regeneration of sulphite-preserved pyro solutions. When barium oxide is added to water it unites with it, forming barium hydrate, which, when added to the oxidised sulphite and sulphurous acid solution as above until precipitation ceases, undergoes double decomposition with them according to the equation:—

If we now add sufficient sulphurous acid to cause the solution to smell strongly of burning sulphur, we shall obtain the following reaction:—

Which is precisely similar to the one originally prepared for the preservation of the pyro; and thus the oxidised solution will have been regenerated and granted a new lease of its life of usefulness.

As in the above operations the pyrogallol (pyrogallous acid) in the solution remains unchanged, I have omitted it in order to simplify the calculations. The copious white precipitate of barium sulphate formed on the addition of the barium hydrate to the oxidised sulphite-pyro solution may be disregarded, or if objected to should be allowed to subside and the clear supernatant liquid removed by decantation, filtration not being in this case available, as the precipitate is so finely divided as to pass through the pores of the filter-paper with the liquid from which it is desired to separate it.

Briefly, the whole operation is as follows:—To the oxidised sulphite-pyro solution add barium-hydrate solution; until precipitation ceases. Then add sulphurous acid until, after well shaking, the liquid continues to smell strongly of burning sulphur.

The barium hydrate should be kept in a closely corked or stoppered bottle, as the carbonic acid present in the air precipitates it in the form of an insoluble carbonate. Should there be any difficulty in obtaining barium oxide (baryta, BaO) it can be easily prepared by heating barium nitrate to redness in a crucible.

Whether this process will prove to be of any practical value I cannot say, but some pyro-sulphite solution, prepared in the early part of 1884, which I recently treated as above described, developed some plates in a very satisfactory manner.

A. P. HIGGINS.

A CONVENIENT WASHING TANK FOR PLATES.

WHILE in Scotland last summer with my detective camera, I bought a few things needed in developing my plates from a dealer in Edinburgh. I enclose you (*Anthony's Photographic Bulletin*) a sketch of a washing tank I obtained from him, that has proved so very useful that I think an account may be of interest to your readers. The device consists of a well-painted tin box, nine and a half inches long, six inches wide, and eight and a half inches deep. In this is a frame stand of painted wire, with loops of wire at each end to be used as lifting handles in taking it out of the tank. To this wire frame is attached a horizontal strip of tin having grooves to catch the bottom of the plates. A vertical strip of the same character, also provided with grooves, is placed near the top of the frame, but below water level. At one end of this tank is a siphon pipe, but of this more anon.

I had for my dark room a very small china closet in the cottage where we had our lodging. I bought two metal pails, one for clear water, the other for slops. Convenient to my right hand I placed the tank I have described filled with water, but not up to the height to

start the siphon. As soon as I had developed a plate and cleaned it, I gave it a washing, say, of one dipper of water from the clear water bucket, then at once placed it in the tank, and so on until I was tired, or had my plates all finished. Then I carried the tank down to the back of the cottage, and when the "burn" was running clear I lifted the frame with its load of plates out of the tank and stood it in the rapid running water of the stream. When this little stream was swollen with rain I filled and emptied the tank, using water from a tap in the yard until I deemed that I had given them changes enough. When going from one place to another I found this tin box took up little room in my trunk, for in it I always packed my glass bottles or graduated measures. Since my return home I have used it in preference to any other form of washing tank, but I have discarded the siphon pipe. That is, I have bored a hole into its high leg, putting it out of use as a siphon, and inserted a run off above its top. I allow a constant stream of water to pass from a tap into this tank, and the outflow is from the siphon and from the opening I provided above it.

The great convenience of this box consists in its loose frame. The plates when lifted from the box can be set on the tank to drain, as I have shown in one of the sketches I send you. The whole thing is inexpensive, but I have not been able to find one like it in America.

—*Anthony's Bulletin.*

COLEMAN SELLERS.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Association on the 6th ult., the President, Mr. G. D. Macdougald, gave an address from which we extract as follows:—

The two great lines along which photography is advancing are—first, as a means of furthering the acquisition of scientific fact; secondly, as a means of producing works of art. And he would, indeed, be rash who would indicate which side or facet of this interesting art-science has the greatest claim to attention.

The art photographer looks upon all technicalities of the art as secondary matters. Experience gained during his ordinary work forces him to recognise the subtle properties which belong to each lens in what he terms his battery, and the wonderful nature of the transformations which occur during the chemical processes, but these things are interesting only as means to an end. So long as these lenses and processes give pictorial results which may appeal through the eye to the heart or mind, he troubles himself little about what appears to him as the terribly dry-as-dust outs and ins of the scientific photographer. The other section of workers are those who look to the scientific possibilities connected with the art. They are photographers because this drawing by the action of light on chemical substances provides them with a weapon of original research, and a powerful instrument for adding to human knowledge. The dynamic or chemical changes which are induced by light are appreciated, in themselves, as a kind of side-door through which may be seen just a little of the manner of the building of the great mystery which we call the universe. The art enables them to write down things that come and go too fast, or which through other causes may not be capable of recognition. An ungenerous artist photographer might be apt to laugh at a scientist's pictures, and to wonder, with some show of reason, why a tiny dot, or a thin line, or a tongue or flame-like mark appearing on a plate, should give exuberant joy. But such things, insignificant in themselves, may have made clear what was before scarcely visible, and have made "the crooked straight, and the rough places plain;" altogether giving ground for as genuine pleasure and satisfaction as the production of a perfect work on canvas or paper.

The picture maker or photographic artist has a rich field in which to exercise his talent—a field, moreover, which in the nature of things must always appeal to a very large, if not the largest, class of persons. It does not require much thinking to become convinced that the power for good or evil of pictures is very great. Pictures speak in a universal tongue. Young and old, rich and poor, lettered and unlettered, may look and understand. The meanest may take away something which may enrich, and make nothing the poorer. It has always appeared to me that in picture exhibitions and galleries we have as powerful a means as is easily within reach of doing good—making gentle the manners and giving tone to a community. Scenes from life, the fruits of the imagination, and nature herself, are reflected in pictures, and it follows that pictures must prove in the highest degree attractive so long as nature and life are interesting.

There has been considerable discussion among photographers on the one hand, and other picture producers on the other, as to whether photography has a right to be considered a fine art, and I would be the last to drag into review what has appeared to me on more than one occasion to be very unprofitable discussion. Whether photography be reckoned a fine art or not, it must be borne in mind that if it has advantages over the brush, in one or two particulars it is balanced by weak points, and very weak ones too.

The absence of colour would not be so much felt if the art was com-

petent to reproduce the photometric values of various colours. But in this the ordinary processes of photography fail very conspicuously. Coloured objects not only cannot be photographed in colour, but the shades which represent these colours in the photograph have not the proportionate luminosity that the colours present to the eye. This is a very serious defect, and renders photography unable to reproduce certain effects. The ordinary photograph is a picture which may be compared, as regards light and shade, to what may be seen while looking through coloured spectacles. The difficulty of overcoming this defect is increased by the fact that the various sensitive substances used by the photographer have each their own way of interpreting colour. Iodide of silver gives one tone value, bromide of silver another, and chloride of silver a third, so that any attempt to isochromatise, if it be successful, will prove of value only when used with one or other of the sensitive substances.

Efforts have been made to overcome this shortcoming. These are based on filtering through coloured media the light which is to operate on the sensitive material, the colours being adapted to the particular sensitive material, so as to increase their value in proportion to the want of sensitiveness for those colours on the part of the plate. I have likened an ordinary photograph, as regards shade value, to what one may see through a pair of coloured spectacles. Now, if when looking, say, at a landscape, through a pair of coloured spectacles, we take another pair of a colour complementary to the first pair, and look through both pairs simultaneously, we will see the landscape reduced in intensity, but, as regards shade value, as if we had no spectacles on at all. An exactly similar process is adopted in recent photographic methods. The sensitive substance on the plate is acted upon by light which has passed through a coloured medium, either present as a stain on the plate itself, or as a piece of coloured glass at the back or in front of the lens. But, after all, such devices, although they effect an undoubted improvement, do not altogether overcome the difficulty.

Photographing in colour is yet a thing of the future. It is known that chloride of silver, under certain conditions, exhibits the various colours under which it may have been exposed to light. But the effect is fugitive. The molecular grouping, or vibratory condition which gives rise to the colour, is at once destroyed on the application of the chemical substances necessary for fixing. During the present year the newspapers announced that some fortunate individual had succeeded in photographing in colour (an announcement which, by the way, has been made at intervals during the last twenty years), but so far as I know, specimens of the new process have not yet reached the album of this Association, and we may fairly assume, although the album is filling very slowly, that specimens, when they do arrive, will not find room in its pages. And were this photographing in colour an accomplished fact, I question if it would take the high place some people are prepared to give it. The most perfect colouring, together with perfect outline and detail, will not make up for the difference that exists between a photograph and a painting. The photograph will always bear an impress as of machine make. We may imagine the photograph of the future already in existence, and assume the presence of colour produced by a photographic process—it will then bear as perfect a resemblance to nature as is possible, and yet, in my view, the direct painting will certainly hold its own in point of human interest. And why? Because the painting is an interpretation of things, wrought out from first to last through the living agency of a human being. The photograph, although controlled by mind, and evidently bearing the impress of thought, is the result of the operation of a machine. The producing force in the one case is mind, which carefully and laboriously, and by prolonged effort, aided only by a bundle of hairs, or a palette knife, converts a few pigments into a picture. In the other case, although the guiding force necessarily is mind, the actual producing force may be summed up in the touching of a spring, and in the operation of lenses and chemical processes. There is no laborious striving and constant effort of the mind during production.

It appears to me that this looking at things through the mind and eyes of another human being, which in fine constitutes the difference between pure photography and painting, is the point round which centres the peculiar interest of direct art, and that which to the end of time will place painting outwith the reach of an art which calls in the aid of machinery. Pictures and poetry are two things which are not improved by machinery.

Painting will always be as interesting to the art public as novels are to the reading public. In both we see in as perfect a way as possible the impressions that life and nature make on our fellow beings. To certain minds it may appear that painting is a laborious and highly unscientific method of making a picture as compared with photography, which is so instantaneous, and so much in keeping with the times, but an impartial judge must admit that the breath of life which is in the best works of painted art is not to be found to the same extent in photography. As well look for the peculiar poetical force of the opera in a drama.

In one department of photography literal representation by the camera has become unfashionable. Portraits are not now given to the public which are altogether the work of the camera. The friction which existed between the professional portrait photographer and his clients has resulted in the discovery that pure photography will not do, and we have now in modern portraits, almost without exception, a combination of camera and pencil. Now, how has this come about? It used to be quite a popular fancy, and it is so still to a great extent, that the camera alone will give a faithful and true facial representation. A more or less dissatisfied sitter was reminded by the photographer that the camera

could not lie; the carefully cherished and apparently axiomatic doctrine which asserted that any representation was neither worse nor better looking than the sitter at the moment was brought into requisition. But all this kind of thing proved of little use against public opinion; "against a sea of trouble" the pencil had to be taken in hand.

Now, speaking mildly, the tendency of the camera alone is to produce a portrait which does not flatter; and speaking with scientific accuracy, the unaided camera does not give a true and faithful representation of the human face. The human face is a more or less red-coloured object, and any line, or depression, or mark, or the most mildly coloured freckle, is magnified in intensity out of all proportion to the intensity as seen by the eye. The light emanating from lines, hollows, or other inequalities is altered through reflection and absorption, and of course does not possess a photographic effect on the plate equal to the luminosity appreciated by the eye. The photographer, through pressure of unsatisfied clients, and a wish to do his best at any hazard, has found a remedy, as I have already indicated, in the pencil; and in using his remedy we cannot very much object if he errs a little towards idealisation, and the production of portraits which do occasionally pleasantly astonish those who have a mild opinion of their own good looks, but which in the majority of cases, after all, come but barely up to expectation and self-appreciation. The pencil, then, has already taken its place permanently as an implement in the photographic artists' tool-box, and no instrument has a better right to be there for the correction of defective tones or shades.

Whether it is legitimate to materially alter *form* as well as *shade* I do not dare to express more than a very humble opinion. I observed not very long ago a photograph of Mrs. Langtry, in which, with the aid of the pencil, some inches—I was about to say three or four, but I hesitate to say so much—were neatly cut off her waist, and an inch and a half—I am perfectly certain about that figure—was sliced off what had been in the original photograph her shoulders. Is this legitimate? Well, I am inclined to think, yes, so long as it is done so well as to baffle detection. I do not, in this instance, mean to affirm that the camera lied as to Mrs. Langtry's actual form or contour, which apparently, in the view of the artist, required some slight modification. On the contrary, I believe what was tried to be hidden was very nearly, if not quite the truth, and what was wanted to be shown was very decidedly not the truth, and yet with this plainly before me I confess I was quite pleased that the artist had done something to assist nature. I am personally quite willing to look at a carved figure—something moulded into bewitching proportions—if it be well and cleverly done, and, above all, beautiful. In the pencil the portrait photographer possesses an instrument of Mephistophelian power. The old are made young, and the plump are sliced down. Things, by the force of circumstances, are no longer kept as they are. Complete power is given to make them, from the artistic point of view, as they ought to be. And it cannot be gainsaid that things should be made, even in a forcible manner, as they ought to be.

In pure landscape work, is the use of the pencil legitimate? In "doctoring" a negative are we stooping to something which we ought to keep secret and be ashamed of? So long as the object in taking a picture is pictorial effect and not that a Procurator-Fiscal or Coroner may use it in their professional capacity, then every available aid is perfectly legitimate, and instead of being ashamed to admit that a negative has been "doctored," pride should be taken in the amount of judgment and skill displayed towards enhancing effect. Doctoring and masking for cloud effect is now, by general consent, allowed, but anything further on a landscape is as yet looked on, by some at least, as outside what should be allowed, say, to compete in a photographic exhibition. If I may be permitted to express my opinion, I think that the use of the pencil or brush to modify negatives ought to be encouraged amongst the members of such societies as this, for in and by it we have a means of raising the art of picture production to a high level, and combining the undoubted advantages of photography with the supreme advantages of direct art.

It may be advanced by those opposed to this view, that were it carried into effect, the sharp line which separates photographic from direct artwork would disappear, and in many cases it would be difficult to say of particular pictures how much was photograph and how much was not. On the other hand, it will be admitted that the most elaborate retouching of a negative will never take from it the characteristics of a photo-picture, and allowing this were not the case, it is a question whether the sharp line which separates the arts should not be suppressed as much as possible. Is it of importance that we should discover how much is due to the operation of one tool and how much to another? While looking at some masterful painting, do we ask how many models have been before the artist during its production? In other words, how much is copy and how much is imagination? As a rule, we are content with the result of copy and imagination in any proportion, if there be produced a thing of sufficient interest or beauty to give pleasure. I think we may look forward to great development in the application of direct art to photography, with a corresponding increase in interest and artistic excellence.

THE headquarters of the Carliff Society narrowly escaped serious damage in the early morn of the 13th instant. The telephone rooms on the same floor suffered severely, and the adjacent lecture theatre, together with four shops, were completely gutted.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
November 21 ..	Notts	Institute, 9, Shakespearo-street.
" 22 ..	Great Britain (Technical)	5A, Pall Mall East.
" 22 ..	Bolton Club	The Studio, Chancery-lane, Bolton.
" 23 ..	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
" 24 ..	Burton-on-Trent	
" 24 ..	Liverpool Amateur	Royal Institution, Colquitt-street.
" 24 ..	Oldham	The Lyceum, Oldham.
" 24 ..	London and Provincial	Mason's Hall, Basinghall-street.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.
On Thursday night, November 10, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. J. Traill Taylor presided.

The Chairman exhibited a pneumatic shutter invented by Mr. Perken, jun., which gave either instantaneous or time exposures of any duration at will. It had an aluminium flap which was actuated by a circular plate in such a manner as to avoid all vibration or jar from the up and down motions. Although operated by a pneumatic ball and tube, this was not a necessity in its construction, as there was also a small trigger by which the exposure could be made. He (the Chairman) considered it one of the best shutters he had seen, and, in reply to a question, said it was manufactured by Perken, Son, & Rayment.

The shutter was passed around and examined with much attention, and elicited expressions of approval.

Mr. COOKE exhibited a negative covered with objectionable stains which he thought might have been caused by the possible use of an unclean dish which had contained perchloride of iron.

Mr. A. COWAN thought from the colour that it was an iron deposit.

Mr. W. M. ASHMAN said that in such case it was best to soak the plate for some time in water, and then treat it with cyanide of potassium; any faint blue colour afterwards left would not be likely to interfere with printing.

Mr. W. BEDFORD remarked that the stains upon the plate were in tears, so seemed to have been formed in the process of drying.

Mr. BUCHANAN WOLLASTON said that the plate appeared to have been splashed with some solution.

Mr. C. HEINRICH TRINKS thought that removing the iron stain with cyanide of potassium would be likely to reduce the negative a little.

Mr. H. M. SMITH had that day spoilt some negatives by dropping pyrogallol solution over them; it had acted upon the plates for an hour before he became aware of the accident.

Mr. HIGGINS suggested that citric acid and alum might remove the pyrogallol spots.

Mr. EVERETT thought that makers should put more emulsion upon their plates; he had been working upon an interior which gave a good picture upon a properly coated plate and a bad one upon all thinly coated plates.

The CHAIRMAN said that anything dark in optical contact with the back of the plate would stop halation.

Mr. W. COBB remarked that as halation existed in nature he did not see why it should not be reproduced in photographs; he had seen beautiful pictorial effects produced by so-called halation.

Mr. COOKE said that the eye did not see halation as produced in photographs.

Mr. COWAN had taken a photograph by daylight of a dead body with four lighted candles near it; the wet process was used, and he went to lunch during the exposure. When the plate was developed an oval was above the top of each candle, produced by the lowering of the flame as the candle burnt down.

Mr. F. W. COX had taken notes in a public exhibition of certain paintings in which the artists had purposely introduced what photographers call halation, notably in one instance in which the edges of trees were softened, the background being the light of the setting sun.

The CHAIRMAN said that a member desired to call attention to a statement in an American journal about a negative which included an alleged rainbow, which negative had been exhibited before a London society some time ago by Mr. Plumer, who had received it from a friend.

Mr. COOKE remarked that it was no rainbow, but a rope or something of that kind out of focus.

Mr. TRINKS had recently, at Molde, in Norway, seen a rainbow with four others beneath it—five rainbows in all. He regretted that he had no camera with him at the time.

Mr. J. JACKSON exhibited the lantern slides accidentally coloured by a gold deposit, as described at a previous meeting.

Mr. COOKE remarked that the colours had accidentally distributed themselves upon the plates in such a manner as to represent fine sunsets.

Mr. L. MEDLAND exhibited a lantern slide in which a warm brown image had been obtained by hydrokinone development. He also exhibited another plate on which dark spots had flashed out in the first moments of development.

Mr. ASHMAN said that the spots were due to an imperfectly cleaned glass plate. When a plate is cleaned with whiting the latter may lodge in any minute holes in the plate and afterwards cause spots, especially in the wet process.

Mr. TRINKS had been experimenting with Professor Abbe's new microscopic eye-piece for projections; it gave an exceedingly flat field and equal illumination. The eye-piece was a valuable new auxiliary in photo-micrographic work.

The CHAIRMAN asked whether it could not be made of larger size for larger objects, such as lantern slides, so as to project more perfectly defined images upon the screen.

Mr. TRINKS saw no reason why that could not be done. The new eye-piece permitted the use of diaphragms and the distance between the lenses could be varied.

The CHAIRMAN said that the tiny locket lenses now on sale at a cheap rate would project large objects, such as flies, admirably with a good light.

Mr. TRINKS added that Abbe's eye-piece had several reflecting surfaces, nevertheless, the available light was utilised to more advantage by its aid. Long exposures did not matter for most photo-micrographic work if the spring of the fine adjustment screw were removed to prevent change of focus by change of temperature.

Mr. J. J. BRIGINSHAW stated that another remedy was to let the instrument get thoroughly and equally warm before commencing operations. The best English microscopes had not the spring spoken of by Mr. Trinks, but an exceedingly fine screw in place thereof.

The CHAIRMAN asked Mr. Jackson whether he knew how M. Nadar obtained almost chocolate tones in his bromide enlargements.

Mr. JACKSON did not know. Could the Chairman tell him?

The CHAIRMAN thought that instead of throwing away the old ferrous oxalate developer it was kept and used again and again; the longer it was kept in use the better tones did it give. A good way to keep the ferrous oxalate developer in solution was to have a little spout at the bottom of the bottle, to which spout an india-rubber tube was attached; after drawing off what was wanted the mouth of the tube was passed through the neck of the bottle, so that it remained below the level of the surface of the iron solution. That surface was covered with paraffin oil to protect it from the action of the atmosphere.

Messrs. Herbert Fry, Norman Macbeth and D. W. Allen, were elected members of the Association.

CAMERA CLUB.

ON Thursday, November 10, Mr. W. H. HYSLOP read a paper entitled *Marine Photography*. Mr. Lyonel Clark occupied the chair. The screens and walls of the room were adorned with pictures all bearing on the subject of the evening, a course which will be adopted in future, as, for instance, on the 24th, when *Enlarging* comes on for discussion. In the course of his paper Mr. Hyslop gave a general description of his apparatus and of his method of working his large camera at sea, and expressed an opinion that a certain amount of seamanship was requisite in photographing moving vessels from a vessel itself in motion.

Mr. A. HAMILTON CLARK followed with particulars of his experiences, and the discussion was carried on by Messrs. G. Davison, C. Burton Barber, E. R. Shipton, Moens, A. Deed, J. F. Roberts, and Plomer.

The CHAIRMAN, in conclusion, gave an address upon the same subject, and explained a table he had prepared from a well-known formula for finding the distance (lens and plate being given) at which an object of a certain size would about fill the plate.

The subject for Thursday, November 24, is *Enlarging*, when Mr. D. P. Rodgers will read a paper, and Messrs. Anstin, Lyonel Clark, Bolden, and others, will arrange to follow and show examples. Meeting at eight p.m.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE Exhibition of the Photographic Society of Great Britain was open on the 11th instant for the benefit of the Benevolent Association, and was exceedingly well attended.

Mr. T. SEBASTIAN DAVIS, addressing the assembly, said on behalf of the Committee of the Photographers' Benevolent Association he desired to express gratification that such a large number of ladies and gentlemen were present that evening, thereby showing a widespread sympathy with the movement. He then briefly alluded to the objects of the Society, and especially its important function of, as far as possible, procuring employment for members, the best means of preventing them falling into a needy condition. The Society, he said, founded in 1873, had of late made rapid strides. Since they met in the Exhibition Gallery last year all present would be interested to learn that no less than one hundred and forty new members had been elected. He was glad the Photographic Society of Great Britain fully recognised the claims of the Benevolent Association and gave the Committee a helping hand. He considered it a duty of every photographic society in the country to help forward the aims of the Photographers' Benevolent Association by strengthening the hands of the Committee.

Slides lent by the following gentlemen were then shown on the screen:—Messrs. Wilson, Short, Davison, Samuels, Briginshaw, Klosz, H. M. Smith, G. Smith, England, Freshwater, Pilkington, and Hastings; Messrs. Briginshaw, Clifton, and Mackie acting as Lantern Committee.

At the conclusion of the lantern display, Professor W. F. DONKIN projected an image of the electric arc used in the lantern on the screen, and gave a lucid explanation of what takes place at the carbon poles in the production of an intense electric light.

Mr. DAVIS, in terminating the proceedings, thanked the visitors for their presence, and hoped they had enjoyed the display of so many excellent transparencies. He desired to tender the thanks of the meeting to those gentlemen who had kindly lent slides, and to the Council of the Photographic Society for the use of their Exhibition.

These remarks were received with much applause; so also was the announcement that three hundred and seventy persons had passed the turnstile that evening, meaning a considerable addition to the funds.

BOLTON PHOTOGRAPHIC SOCIETY.

THE annual meeting of the above Society was held at the Baths, Bridgman-street, on Thursday, November 3.

The Hon. Treasurer, Mr. C. K. Dalton, produced his accounts for audit, which were pronounced correct, and a decent balance to carry forward.

The ballot papers were then counted and the following gentlemen declared elected to the Council:—*President*: Mr. J. R. Bridson.—*Vice-Presidents*:

Messrs. R. Harwood, T. Parkinson, E. N. Ashworth, J. W. Cundey, W. Knowles, and J. W. Hawksworth.—*Council*: Messrs. J. Boothroyd, J. Leash, R. Mercer, J. Lomax, Thomas Davis, and William Laithwaite.—*Hon. Treasurer*: Mr. C. K. Dalton.—*Hon. Secretary*: Mr. B. H. Abbott.

Messrs. J. H. Cowan, Walter Staton, W. F. Bowen, and A. Harper were elected members.

The SECRETARY then read the annual report, which was approved.

Mr. W. Laithwaite exhibited one of Newman's patent diaphragmatic time shutters, which was much admired.

The Secretary exhibited one of R. Thomas's (of Leicester) Simplex changing box and dark slide combined.

There was a lantern exhibition by Mr. W. Boothroyd, and Mr. J. Boothroyd showed some ninety slides he had made, many of which were highly commended.

The meeting dispersed shortly after ten o'clock.

DERBY PHOTOGRAPHIC SOCIETY.

THE second indoor meeting of the winter session of this Society was held in their Rooms, 33, Victoria-street, on Tuesday, November 8, when upwards of fifty members were present to witness a demonstration on *Printing and Enlarging on Bromide Paper*, by Mr. Thomas Scotton [see page 729]. The process, as deftly manipulated by Mr. Scotton, was much admired, both in the development of the enlargements and in the printing of pictures from small negatives by the aid of an ordinary gas flame.

Discussion upon various questions ensued, and votes of thanks were passed to Mr. Scotton for his excellent paper and demonstration, and to Mr. R. Keene for presiding.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

THE usual fortnightly meeting of the above Society was held at the Technical Schools, Bridge-street, Birmingham, on November 10,—Mr. A. Pumphrey in the chair.

Mr. John Graham Keys was elected a member.

The HON. SECRETARY (Mr. J. H. Pickard) read a letter from Mr. W. J. Harrison, proposing a new rule, that three Vice-Presidents should be elected for the ensuing year, and offering to resign the office of Vice-President. Also letters from Mr. R. Godfrey, offering a paper, subject, *Don't*; and from Mr. E. H. Jaques, subject, *The Land of the Midnight Sun*; from Mr. W. Tylar, paper on *Double Contact Printing as applied to Lantern Slides*; and prizes were offered by Messrs. A. Constantine, F. Hoskins, E. H. Jaques, and W. Tylar, the first-named mentioning as competition for his prize "Stereoscopic work," saying he thought this class of work had been sadly neglected of late years. He also read the list of twenty-one names nominated for election at the annual meeting on the 24th instant, from which the officers and Council for the ensuing year will have to be selected; also the attendance list of Council for the past year; and gave notice of proposed new rules and alterations.

A number of frames filled with very fine photo-micrographs on Eastman bromide paper were shown by Mr. J. F. Hall Edwards, which were much admired, and the thanks of the meeting were given to the exhibitor for the loan of the same.

Mr. E. C. MIDDLETON then gave his paper on *Collotype and Photo-lithography*. He exhibited a fine collection of collotype prints, and explained the process of their production from the taking of the negative to the finished prints. He then went more fully into the process of photo-lithography, and successfully inked up several transfers from line subjects. Afterwards he entered with great minuteness into the carbon process, and gave a very practical demonstration, from the sensitising of the tissue to the finished print, including development on both opal and paper. In the course of his remarks he mentioned the ease with which these can now be done from the Eastman Company's stripping films, through being able to print from either side of the film negative. Single transfer only is needed, thus obviating the extra trouble and time taken up by double transfer.

The lecturer was listened to with great attention and received much applause.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

THE annual meeting of the above was held in the Free Public Library on Thursday evening, the 10th instant,—The President (Mr. J. A. Forrest) in the chair.

The minutes of the previous meeting having been read and passed, the election of officers for 1888 was proceeded with, when the following gentlemen were unanimously elected, viz.:—*President*: John H. Day.—*Vice-President*: Paul Lange.—*Treasurer*: Edward Whalley.—*Auditors*: F. Evans and A. W. Cornish.—*Council*: A. W. Beer, B. J. Sayce, G. A. Kenyon, M.D., J. A. Forrest, H. H. Williams, W. P. Riley, R. W. Hill, H. Lupton, P. H. Phillips, and T. C. James.—*Secretary*: George A. Carruthers, Woodley, Rock Ferry.

A hearty vote of thanks, proposed by Mr. A. W. BEER, and seconded by Mr. B. J. SAYCE, was tendered Mr. Forrest for his indefatigable exertions on behalf of the Association, in which both gentlemen spoke of his unvarying courtesy and *savoir-faire* during the three years he had occupied the chair.

In replying, Mr. FORREST, among other matters, alluded to the fact that he was then celebrating his jubilee of photography, and handed round photographs of several pioneers of the art, *collaborateurs* with himself when he first commenced its practice.

The annual report and Treasurer's accounts were read and passed, the latter showing a balance in hand to the credit of the Association of 11l. 2s. 10d.

The resignation of the Vice-President, Mr. H. N. Atkins, through failing health, was received with regret, his labours on behalf of the Association being highly appreciated.

The annual competition prints were handed in during the evening, the new

medals of the Association offered as prizes having apparently a favourable influence on their number and quality as compared with previous years. The Judges, Messrs. G. E. Thompson, R. Hartley, and H. J. Whiteside, unanimously awarded the prizes as follows:—Silver medals: "Best picture," John H. Day; "Best set of pictures," H. Lupton. Bronze medals: "A pretty face," George A. Carruthers; "Village street view," A. W. Beer; "Flower study," James A. Forrest; "Instantaneous," H. Lupton; "Animal study," George A. Carruthers; "Winter scene," Paul Lange.

The number of competitors in comparison with the strength of the Association not being as large as they should be, it was felt that the present mode of awarding the prizes, viz., for previously selected subjects, was capable of improvement. Mr. J. H. DAY, therefore, to test the feeling of the members on the subject, brought forward the following recommendation:—"That the system which has hitherto prevailed of selecting special subjects for annual competition be abolished, and that in place thereof a silver and bronze medal be awarded for the two best sets of six pictures respectively, irrespective of subject or size, which may be sent in upon a date selected by the Council, of which due notice be given upon the circular."

An animated discussion *pro* and *con* then took place, but, on being put to the vote, the proposal in its original form was passed by a large majority.

In reference to the above plan of giving medals for the best pictures of six specially selected studies, Mr. SAYCE said he had always considered such a practice was no test of skill on the part of the prize winners, but that success in such competitions was principally attributable to opportunities of securing such subjects under the most favourable circumstances; and those who had most time and funds at their disposal had a much better chance of carrying off the medals than others who, perhaps more skilful, did not possess the advantage of liberty to roam in search of models. In athletic competitions, for example, all candidates for the prize must be present when the moment for trial arrives; prizes for a race are not awarded to those who run the same distance in different localities, but all must assemble at the same spot and do their best, under fixed conditions, to secure the coveted prize. He considered that the only fair way of awarding a prize for best work of a society was to have a day and *rendezvous* appointed when all desirous of ascertaining their relative position as photographers should assemble, and, no matter what might be the state of the weather—line, windy, wet, or foggy—each should do his utmost to arrive at the best photographic and artistic reproduction of the neighbourhood selected; all conditions being thus equal the award to skill would be more truly granted.

After considerable discussion as to conditions, in which Mr. BEER suggested that the number of exposures should be limited to six, Mr. SAYCE proposed the following resolution, which was seconded by Mr. P. LANGE:—"That, on a given day, and at a given *rendezvous*, members of the Birkenhead Photographic Association shall meet for the purpose of testing their skill in photography and artistic treatment of subject, and that on such occasion only six exposures shall be made by each competitor, and a resulting print from the untouched negative of every exposure shall be handed in by the competitor at the second ordinary meeting after such outdoor meeting, and that the Judges shall award a silver medal for the best and a bronze medal for the second best set of six exposures."

The idea met with the approval of the members, and the resolution, on a show of hands being called for, was carried.

Mr. H. WILKINSON remarked that he hailed the innovation with much pleasure, for, only having had some three days' holiday, all of which with one exception were wet, he had been entirely debarred from entering this year's competition.

This being all the business there was to transact, the meeting broke up.

LEICESTER AND LEICESTERSHIRE PHOTOGRAPHIC SOCIETY.

A regular meeting of the above Society was held in the Mayor's parlour, Old Town Hall, on November 9.—Mr. George Bankart, President, in the chair.

The minutes of the last meeting were read and confirmed.

Two members were proposed and two members balloted for and unanimously elected.

The PRESIDENT then called on Mr. Wilkinson to give his promised demonstration on *Bronide Printing and Development*, more particularly with reference to double printing from cloud negatives.

In his opening remarks, Mr. WILKINSON premised that he was unable to understand why amateurs so persistently stuck to silver printing when the beautiful results which the bromide papers gave could be obtained with ease and success. Carbon and platinum printing, both giving results excellent in their way, could only be practised by daylight, while the Eastman bromide paper, with little attention, would give results equalling either. In proof of which assertion, he proceeded to demonstrate by printing by gaslight from a somewhat dense negative of Tintern Abbey, and by an arrangement of masks roughly cut out of paper and registered in two frames; he inserted in the print a double print from a separate cloud negative, the result showing an admirably exposed print with the clouds faithfully rendered.

After explaining *in cetero* the detail of the process, and replying to several questions asked by members, a vote of thanks, proposed by Mr. TUCKER and seconded by Mr. HEELEY, was unanimously accorded to Mr. Wilkinson for his useful and instructive address.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE opening meeting of the Session was held on Thursday, November 3, in the Philosophical Society's Rooms, 207, Bath-street.—Mr. William Lang, jun., F.C.S., presiding.

Minutes of last meeting were read and confirmed.

Mr. Andrew Bryce, Engineer, 13, Abercromby-street, was unanimously admitted a member.

The President now vacated the chair for the purpose of delivering his opening address, and the Vice-President (Mr. A. Robertson) occupied the chair during the rest of the meeting.

The subject of Mr. Lang's address was *Photography on the Continent*, and, being illustrated by some splendid examples of lithdruck, phototype, and photogravure prints, proved exceedingly interesting.

Mr. LANG, as convener of the Photographic Section of the Glasgow International Exhibition, 1888, was delegated to proceed to the principal cities on the Continent for the purpose of procuring exhibits. He, therefore, gave a graphic account of his travels; the various towns he had visited; the men well known in photography, such as Vidal, Stebbing, Liesegang, Obernetter, Otto, &c., he had come in contact with; the studios and photo-engraving works he had been kindly permitted to see through; and many little things which occurred *en route*; the whole proving very interesting and racy, and was thoroughly enjoyed by all present.

PRESIDENT'S ADDRESS.

GENTLEMEN,—Since our last meeting a good deal has happened that is not without interest to a Photographic Association such as ours. The Photographic Convention of the United Kingdom held its second meeting in our own town early in July, and that it was a success I think no one will be prepared to dispute. We were favoured, on the whole, with charming weather for the excursions, and the photographic material in the shape of papers brought forward night after night during the week the Convention lasted was a sufficient evidence that photography is by no means to be considered dormant, that whether we regard it as an art or as a science, it possesses a vitality that is all its own. I need not enlarge further on this matter, but simply express the hope that when the next meeting comes to be held in Birmingham, as many of our members who can possibly spare the time will wend their way southwards next summer to Birmingham, to testify by their presence their interest in the annual gathering of the photographers of the United Kingdom.

Gentlemen, time rolls on and each succeeding year brings with it its invariably series of changes. Since last we met two honoured names have passed away—Tunny, of Edinburgh, and Robert Hunt, F.R.S., of London. With the former many of our members had a personal acquaintance, while the fame of the latter was not confined to our own shores. What man interested in photography is there who has not heard of Hunt's *Researches on Light*? Nor is his *Manual of Photography* to be reckoned as worthy of less notice than the *Researches*. True, it has been superseded by other treatises and other manuals, but this has been due to the progressive nature of our art. This manual went through many editions, and it is interesting to note that the publishers were a Glasgow firm, Richard Griffin & Co., and formed a volume of the *Encyclopædia Metropolitana*. A copy of the two works in question lies on the table, as also two others from Hunt's pen, *Panthea*, the *Spirit of Nature*, and *The Poetry of Science*. The later editions of Ure's *Dictionary of Arts, Manufactures, and Mines* were edited with Hunt's name attached. Hunt for many years has not identified himself with matters photographic. That the work he has done still bears good fruit, I may perhaps be permitted to state the fact that while at Vienna Dr. Eder mentioned to me that although he had access to Hunt's *Researches on Light* in one of the public libraries in Vienna, he had not so far secured a copy for himself. I told him that on my return to Glasgow I would be able to put this right, and accordingly, having picked up a copy at a second-hand bookshop, I posted it to him without delay. One word more regarding the *Researches* and I am done, and it is this, that there is no work in our own or any other language that is so full of suggestive material for the photographic experimentalist, and that, although it is now thirty-three years since the first edition was published, much of the original matter therein brought forward by the author has never further been added to. It may not be without interest to state that at the first meeting of the first Photographic Society in Glasgow, with the late Sheriff Bell in the chair, Hunt was present. The date of this meeting was March 8, 1854, on which occasion the late Jabez Hughes read a paper on *The Prospects and Progress of Photography*. All the information I have on the subject regarding Hunt's part in the proceedings of that evening's programme is that he addressed the meeting. Are there any members present who can further enlighten us?

Before passing on to the more immediate subject matter of my communication this evening, perhaps I may be allowed to refer for a moment or two to those classical researches of Carey Lea's which have been published during the term of our recess; nor do I purpose taking up your time by going into the production of the coloured compounds to which Lea has given the name of photo-chloride, photo-iodide, and photo-bromide of silver (it will be within your recollection I discoursed on these in my paper at the Convention), but simply to refer to a later communication in which Carey Lea described what he called "image transference." This consisted in taking paper covered with a salt of silver, other than a haloid salt, say a tartrate, and exposing to light, and afterwards in the dark room applying a solution of hydrochloric or hydrobromic acid, then a solution of dilute nitric acid, to be followed by washing. On applying the developer the effect produced by light in the first instance was made manifest. I have always been expecting to see some English experimentalist going into these matters, and giving us some further insight into these unlooked for phenomena. Another most interesting experiment brought forward by Carey Lea for the first time is that of the application of a solution of sodium, hypophosphite which works the same change upon a silver haloid, giving a developable image exactly as if the salt had been exposed to the impact of light. It has been ascertained that this salt in question acts in no way as a developer, and the outcome of the whole of Lea's work may be briefly set down as an attempt (and I think a successful one) to establish the identity of what is known as the latent image with the coloured photographic compounds, produced in quantity by the various methods detailed in the original memoir. These researches have opened up a fresh field for those interested in the photo-chemistry of our art, and whether practical applications may or may not follow in their wake, the American investigator is entitled to receive from the hands of an Association such as ours a full recognition of the good work done.

At the close of the address he handed round a detective camera of foreign make for going inside the vest, the lens protruding through a buttonhole, and being provided with a shutter for snap shots.

The CHAIRMAN, in proposing a vote of thanks to Mr. Lang, said they were greatly indebted to him for the very vivid description which he had given them of his tour and the many fine specimens of photo-mechanical work he had brought back with him and which had been placed before the meeting.

Through the kindness of Mrs. Baden-Pritchard, the first picture procured by the action of light by Niepce was handed round. This picture, done in 1827, had been brought by Niepce to this country to illustrate his paper read before the Royal Society, and had been presented by him to the Secretary of

the Royal Society, and after a time had fallen to the late Mr. Baden-Pritchard at an auction sale.

The original memoir of Niepee that had been read at the same time when the picture was exhibited was also handed round, and, after the members had examined both, a hearty vote of thanks was accorded Mrs. Baden-Pritchard for her kindness in allowing this interesting relic to be exhibited.

There being no other business, the Chairman intimated that a popular meeting would be held on the 10th instant, when Mr. Armstrong would lecture; and, after a vote of thanks to the Chairman, the meeting separated.

CARDIFF AMATEUR PHOTOGRAPHIC SOCIETY.

THE November meeting of the above Society was held on Friday, the 11th instant, at headquarters.—The President, Mr. S. W. Allen, in the chair.

The following gentlemen were elected ordinary members:—Messrs. Horton, Travers, F. Thomas, and W. H. Thomas.

A communication was read from the Town Clerk re National Institute for Wales, and Messrs. Allen and Kellar were deputed to watch the interests of the Society.

The second annual meeting was afterwards held and largely attended.

The report as presented was taken as read, received and adopted.

The officers for the ensuing year were elected as follows:—*President*: Mr. Alexander Kellar.—*Vice-Presidents*: Messrs. H. Dyer and S. W. Allen.—*Hon. Treasurer*: Mr. G. H. Wills, jun.—*Hon. Secretary*: Mr. G. H. Bedford.

A private exhibition was also held, and although short notice had been given, a most interesting collection was brought together, embracing all the different processes. A chief feature was the enlargements shown, many of these being extremely well executed.

Although not definitely decided upon, we understand either a public exhibition or *conversazione* will shortly be held.

A vote of thanks to the Chairman and past officers terminated an agreeable evening.

Correspondence.

✉ Correspondents should never write on both sides of the paper.

PHOTO-MICROGRAPHS AT PALL MALL.

To the Editors.

GENTLEMEN,—There is hardly a line in Mr. Evans's letter to you dated Nov. 4, to which I might not, if so inclined, take exception, not personally but from a scientific point of view. But your space and my time are too limited to justify me in following Mr. Evans specifically into his extraordinary explanations and statements.

Even his first letter in no way offended me personally—if Mr. Evans was not hurt by it certainly I was not; in proof of which I sought and obtained a personal interview with Mr. Evans, not with intent to assault or batter, but to talk matters over in a quiet way. At that interview I told Mr. Evans, as quietly as might be, my opinion of his work, so that I need not say anything about it here.

At this interview I learned that Mr. Evans had not read any of the accepted classics of bacteriology—in other words, that he knows nothing whatever about it. He appears to have read some wonderful book by a Dr. Garth Wilkinson, truly wonderful if it says that inoculation and vaccination “trample upon Nature's safeguards and wisdoms.” But as Mr. Evans confesses himself an unfit receptacle for argument I need not pursue this subject. But I must say some of Mr. Evans's assertions (as that bacteria “are only found in the later stages of disease”) are fairly dogmatic for one who confesses to know nothing of such matters, as he does in his letter by implication and did to me directly.

There was no covert detraction in Mr. Evans's statement that my prints would make fine “decorative designs.” It was good plain English.

If there is one thing to be avoided above all others in photo-micrography it is the attempt to make “pretty pictures”—“a love of the beautiful and artistic,” as Mr. Evans puts it. The beautiful and artistic in this sense may be found elsewhere, and may be as easily rendered by ordinary photography as by micro-photography, with much less risk of doing harm by misrepresentation. One of the first lessons the photo-micrographer has to learn is to dismiss all thoughts of pictorial effect.

Of course, if Mr. Evans's only object in writing his first letter was not to make invidious comparisons between his work and mine, but only to draw me out in a jocular letter, then I am pleased to note that in his flattering opinion he succeeded. As he can blush to his very soul no doubt he can also laugh in his very *tendo Achillis*.

I do not propose to continue this discussion. Mr. Evans got his medal, and I hope he will do it again. I got mine, and I hope that my work may be greatly improved before next Pall Mall Show.—I am, yours, &c.,

ANDREW PRINGLE.

Beale's Heath, November 12, 1887.

BACTERIOLOGY.

To the Editors.

GENTLEMEN,—As the subject of bacteriology has been introduced into your columns, you will, perhaps, allow me to add a word or two which

shall be strictly matter of fact, and shall not deal with disputed matters, though it can hardly be said to have any direct bearing on photography. Mr. Evans appears to me to abandon an entrenchment which is well capable of scientific defence, and the question which he opens can only be permanently decided on the grounds of scientific fact, and by the assistance of that bacteriology which he contemns. It is now undisputed that the protection against smallpox given by vaccination is much less absolute than was supposed by Dr. Jenner, while careful analysis of statistics has shown that some of those which appeared strongest in its favour were really influenced by other causes. It is equally undisputed that vaccine inoculation may be the means of communicating more serious diseases; and even calf-lymph is in this respect not above suspicion. The ready communication of tubercular disease by accidental inoculation (see Klein, *Micro-organisms and Disease*, third edition, p. 218), is also matter for serious consideration. The point, then, for discussion is whether the degree of protection obtained is worth the risk incurred, and especially whether the balance in its favour is so clear as to justify the interference with personal liberty involved in compulsory vaccination.

With regard to Pasteur, all who have studied his work in other directions than that of rabies, while they must recognise his splendid genius and brilliant experimenting, are bound to regret a certain precipitancy in accepting conclusions which renders him an unsafe guide to follow without mature reflection. His so-called “vaccination” for anthrax has been shown by eminent English bacteriologists to entail greater risks than advantages, and it is gravely suspected by many that the same is true of his latest discovery.—I am, yours, &c.,

Tynemouth, November 13, 1887.

HENRY R. PROCTER.

SULPHUR AND GELATINO-BROMIDE PRINTS.

To the Editors.

GENTLEMEN,—On page 692 of your present volume you insist on the absolute necessity of elimination of acid before fixing gelatino-bromide prints to prevent sulphuration. Without questioning the expediency of this on general principles, it seems evident from recent experiments that these prints are very differently affected by sulphur to those on albumenised paper. I may also draw your attention to the opinion on sulphur-toning of these prints (*Instruction in Photography*, fifth edition, p. 191), expressed by Captain Abney, who says, “It is the organic compound of silver which gives rise to fading, and not the sulphuration of the metallic silver. Sulphide of silver is about as permanent a silver compound as can exist, and there can be no danger of its fading.” Where such eminent “doctors” differ there is clearly some room for inquiry; and from a practical point of view the question is worth settling, as Eastman paper can be toned with sulphide of ammonium to a colour not unlike albumenised paper.—I am, yours, &c.,

HENRY R. PROCTER.

AMATEUR PHOTOGRAPHIC EXHIBITION.

To the Editors.

GENTLEMEN,—In connexion with our Third Annual Photographic Exhibition it will doubtless interest both your professional and amateur readers to learn that this Company has just paid the sum of 32l. 5s. to Mr. Harland, the Secretary, in aid of the Photographers' Benevolent Association. This consists of the amount received for entrance fees, which were fixed at 2s. 6d.; but as we have sent out some thousands of circulars to amateurs setting forth the aim of the Association, we believe that we have benefited the Society to a far greater extent than the sum actually sent as above.

The exhibition will be open to the public, on presentation of visiting card, on and after December 7, when, although no actual charge will be made for admission, visitors will be invited to place a small contribution in a box that will be provided for the purpose by the Association, and we trust we may thus be able to collect a further goodly sum from amateurs and others.—I am, yours, &c.,

S. M. CLARK, Secretary.

London Stereoscopic and Photographic Company, Limited,

110 and 108, Regent-street, W., and 54, Cheapside, E.C., Nov. 14.

Exchange Column.

* * No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as “anything useful” will therefore understand the reason of their non-appearance.

Wanted, books and periodicals on photography in exchange for other books, apparatus, &c. All letters answered.—Address, HARRISON, Science Laboratory, Icknield-street, Birmingham.

Exchange quarter-plate camera, view lens, double slide, and tripod, complete, for enlarging lantern or burnisher.—Address, E. C., 6, Fore-street, Salcombe, South Devon.

Wanted, stereoscope by Smith & Beck, Dallmeyer, or other good maker, in exchange for photographic apparatus.—Address, W. I. CHADWICK, Brooklands, Manchester.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *NOM DE PLUME* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

PHOTOGRAPH REGISTERED:—

T. Ball, Kidderminster.—*Photograph of Kidderminster Jubilee Committee.*

J. JONES.—No.

T. C.—The rapid.

J. A. FORREST.—Thanks for enclosure.

HIGH PEAK.—Your letter has been sent to the gentleman named.

SCOTUS.—Yes. Magnesium will answer. Conical form not necessary.

WAX PAPER.—We shall be glad to see you when you are in this quarter.

V. C. YEALTT.—The sulphate of baryta is intended to remain insoluble.

C. E. PEACOCK.—We do not undertake the testing of lenses professionally.

ADOLPHUS.—The spots appear to us to be caused by some defect in the paper.

J. W. COFFEY.—Both your questions will be found fully answered in the forthcoming ALMANAC.

A. G.—The "battery" has been received. Trials will be made and the result published in due time.

HENRY E. DAVIS.—We imagine the gentleman who wrote under that *nom de plume* has left this country.

WM. BISHOP.—We rather think that the Brius's Oxygen Company do not wish to court publicity as regards photographers.

J. D. HUMPHREY.—The roundness of field is not unreasonable. It could be flattened by the separation of the lenses, but we question its advisability.

QUANDARY.—Try the effect of slightly increasing the strength of the fixing bath, although we think the prints ought to be sufficiently fixed by your treatment.

BICHROMATE.—The white spots are caused by not placing the carbon tissue in perfect contact with the paper on which it has been squeezed. Procure the new manual issued recently by the Autotype Company.

A. M. L.—1. Get a larger camera.—2. See an article by Mr. J. Hubert in our issue for February 25 of the present year.—3. We have not had an opportunity of becoming acquainted with the Iris diaphragm of the maker indicated.—4. Two ounces.

W. JONES.—Having decided upon the nature of the lighting as regards its primary and secondary directions, screen out all that militates against this. You will arrive at a solution of the question much better by making a few trials than by all the written or printed instructions in the world.

W. T. Z.—Let the walls of the studio be seven feet high and the slope of the roof an angle sufficient to allow melted snow and rain to run off easily. Commence the glazing three feet from the end. It is better to have too much than too little glass, as the proper amount of light can be easily regulated by blinds or screens.

AJAX.—To remove the old silver from the black cloth trousers is easy enough. Apply first a strong solution of cyanide of potassium followed by a strong solution of iodine in cyanide. But concerning the probable discharging of the dye and the restoration of the spots to their primitive blackness, we are a little uncertain what to advise. The services of a dyer will probably be required.

E. H. EARL inquires: "1. Will you tell me if I can get as good a light for the limelight supposing I fill one bag with coal gas from the gas main instead of pure hydrogen?—2. If not so good, would it be any better than using the oxyacalcium or blow-through jet?"—In reply: 1. Opinions vary. See articles that have appeared on this subject in our columns during the past two years.—2. Very much better.

A. B. C. writes: "I am about to build a studio; would you kindly give me the best size—I can have fourteen feet in width and without limit as to length—giving the size of side and top lights; also where I could procure the blue wings now so much in use for top lights?"—A convenient length for a studio for general work is about thirty feet. Four feet six or five feet at the background end of the roof and side should be opaque; then about twelve feet of glass top and sides will be sufficient; all the rest may be opaque. Any blind-maker will construct the blue wings to your order.

JUSTINIAN.—We do not imagine for a moment that any slur was intended by the writer of the article to be cast upon professional photographers.

W. A. Z. (Amsterdam).—1. By "back focus" is meant the distance between the ground-glass and the surface of the lens next to the ground-glass screen.—2. The lens inquired about will probably be similar to that which you now possess, neither better nor worse.—3. We are not acquainted with either of the shutters named. Both the Grinston shutter and one just brought out by Perken, Son, & Rayment, will fulfil the conditions required.—4. Avoid actinometers when exposing in the field.—5. We do not know what will keep cockroaches away from the leather bellows of a camera when on shipboard.—6. The thicker the plate the more widely spread will halation be. But why not adopt means to prevent halation altogether?—7. Not having tried the Bernaest plates we do not know their rapidity.

* * WITH this number we give an engraving of Mr. W. H. Hyslop's medal picture, *The Thistle*.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—Thursday, November 24, will be a lantern evening. Visitors are invited.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, November 23, 1887, will be on *Development*. Mr. B. J. Edwards will demonstrate the working of a new process of development.

THE JENNINGS'S FUND.—The following additional sums have been received:—P. D. R., 10s.; Frederick York, 3l.; A Friend, 1l.; Editors, *W. M. A.*, 2s. 6d.; W. Bedford, 10s. 6d.; K. A. B., 5s.; E. Gail, 10s.; A Friend, 2s. 6d.; John E. Fawcett, 5s.

THE PHOTOGRAPHIC EXHIBITION.—In addition to the exhibits of apparatus already noticed the following were also shown:—A developing portmanteau, G. Houghton & Son; Two cameras and roller slide, S. D. McKellen; Patent roller slide, Morgan & Kidd; The Secret Camera, J. Robinson & Sons; Improved camera, Sands & Hunter; Roller slide and camera, J. E. Thornton; Camera with winding focussing screen, T. Samuels; Portable camera, detective camera, adjustable bamboo and other stands, C. G. Collins; Double band shutters, W. Tylar; New shutter, detective camera, negative book, and camera case, J. F. Shew & Co.; Plate boxes, Arundel & Marshall; Stereoscopic shutter, Reynolds & Branson; Detective camera, J. B. Thistleton; and two of Eastman's new model roll holders, Eastman Dry Plate and Film Company.

A NEW ANTISEPTIC AGENT.—At the last meeting of the Manchester Section of the Society of Chemical Industry Mr. Watson Smith gave some particulars concerning a new antiseptic agent called alpha-oxynaphthoic acid. It was, he said, a body strictly analogous to salicylic acid—in fact, it might be termed the salicylic acid of the naphthalene series. Dr. Von Heyden, of Dresden, had kindly sent him a specimen of the new antiseptic. It consisted of a crystalline powder, free from odour, becoming electrical on friction, and melting with decomposition at 186° C. It had a pungent taste, was sparingly soluble in water. Boiling water only dissolved three-quarters of a gramme per litre. The alkaline and earthy salts were all soluble in water. Experiments had shown that, as regards the effect of solutions, tried side by side with those of salicylic acid of the same strength on solutions of sugar and yeast, the influence of alpha-oxynaphthoic acid as regarded antiseptic power was more than five times stronger than that of salicylic acid. It had, moreover, been found that the new antiseptic was especially powerful in killing certain bacteria and some low forms of animal parasite.—*Brewers' Guardian*.

THE annual dinner of the North London Photographic Society was held on Monday evening in Beal & Co.'s Restaurant, Holloway-road, and was very numerously attended. Mr. J. Traill Taylor, President, occupied the chair. After the toast of the evening, "The North London Society," responded to by Mr. Hedley Smith, Hon. Secretary, the various other societies there represented were duly toasted. These were, the Photographic Society of Great Britain (acknowledged by Mr. W. Bedford), the Photographic Club (Mr. E. Clifton), the London and Provincial Photographic Association (Mr. L. Medland), the Photographers' Benevolent Association (Mr. John Jackson), and the Photographic Convention of the United Kingdom (by Mr. Mackie). The Photographic Press was responded to by the Chairman; and various informal toasts were proposed by Messrs. Humphries, J. Nesbit, and others. The proceedings were enlivened with music and recitations, lasting up to a late hour. A novel feature was introduced, viz., that of making an impromptu collection in aid of the funds of the Photographers' Benevolent Association, and a goodly sum was collected.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1438. VOL. XXXIV.—NOVEMBER 25, 1887.

WINTER NEGATIVES.

We recently dealt with the subject of veiled shadows, a topic which would naturally be embraced by the title of our present article, which has, however, many other aspects. We see a great amount of trouble experienced, and are witness to the production of large numbers of prints of most indifferent character, all of which might be modified, in the direction both of prevention and cure, by a well-thought-out system having regard to the exigencies of the season. The season of frost will soon be upon us, when those beautiful effects of frosted bough and spangled hedgerow form such entrancing subjects for the camera; but in the main winter negatives are devoted to portraiture.

The subject that lies heaviest on the photographer's mind just now is the length of time it takes to execute a commission, and this, coupled with the liability to the production of negatives of indifferent calibre so common to winter photography, is well worthy of consideration so as to arrive at the best way to meet the evil. It is an excellent method of working to endeavour to produce a negative all the year round of as uniform a type as possible; but whereas, in summer, a little extra density does not mean any additional trouble, the slightest increase in light-resisting power in the winter months is fraught with the possibilities of the dragging on of printing operations to an inordinate length of time to obtain a single print. A negative may be put out on a Monday and, in some weather, almost be insufficiently printed on a Saturday. It is then obvious that every step taken to prevent the production of over intensity will be of advantage in winter weather. One little observed, but exceedingly fertile cause of undue strength, lies in ignoring the fact that when a developed negative is judged to have arrived at the correct density, the mere operation of giving it a rinse under the tap and placing it to soak in water is by no means sufficient to keep the intensity at the stage it had arrived at when taken out of the developer. When a large number of negatives are being developed at once with the idea of fixing all in one operation afterwards, it is quite possible to find that, though the utmost care be taken, the last negatives developed are always the weakest, the fact being that though first rinsed and then put to soak in clean water the developing or intensification will continue to progress—at a slow rate, after a time, it is true—almost the whole time the plate is in the washing water. It is therefore obvious that uniformity of results, and the absence of too great an amount of density, may be facilitated by always keeping in view this tendency. As to preventing its action, if the plate be fixed after a slight washing only it is obvious that the evil would be prevented; but many operators object to this plan on account of the rapid darkening of the hypo brought about.

The plan that commends itself to us is one we have before mentioned as being employed by a well-known professional, namely, to place each negative into an acidified alum bath as soon as taken out of the developer and rinsed. The acid neutralises the alkali of the developer, and at once destroys the power of any pyro left in the film to continue in action; added to this is the advantage of having films perfectly colourless and unobstructive of light, so far as the film alone is concerned; so that we are surprised that we do not hear more frequently of the adoption of such a simple arrangement, whose usefulness is by no means restricted to the winter months alone. We are, however, aware that the question of colour is a disputed point.

Then, again, it is quite permissible to make negatives giving excellent prints in winter, but which shall be considered too thin in summer; for the dull light of the present time is just the condition calculated to give good prints from thin negatives, and, after all, it must, we should think, be the case that not more than, perhaps, one out of a dozen winter-taken negatives are wanted for summer printing afterwards; so that it is not objectionable in policy to take them with characteristics best adapted for the time of year they are produced at. As to the physical peculiarities connected with the season, absence of frilling tendencies is a great boon when some brands of plates are employed, though the evil is greatly reduced in frequency and extent nowadays; but this gain is almost counterbalanced by the difficulty experienced in drying the finished negative without the use of methylated spirit, which is both expensive and troublesome. A drying box, such as has been described by many writers in these pages at one time or another, is almost a necessity where time is any object.

We have had brought before us an extremely singular defect brought about solely by the use of spirit in this connexion. A negative was required for instant use, and was put through the usual process; when drying before the fire to expel the last trace of water left from the spirit a peculiar opalescent appearance was left—in certain portions only—in the film, and it materially interfered with the printing. We surmised that the spirit employed must have been used for dissolving the varnish from some negative and the fact have been forgotten. But, upon trying the experiment ourselves with another negative, and with spirit of undoubted purity, the same effect was seen; any doubt as to the shellac idea was set at rest by the fact that the opalescence disappeared if the negative was placed in water. It presented the appearance of some substratum insoluble in spirit but soluble in water having been employed. Be the explanation what it may, the phenomenon was remarkable enough, and the plates could not be used in the circumstance.

Many photographers print from their negatives without first varnishing them; but at this time of the year it is a most dangerous practice, for there is now always more difficulty in getting the daily sensitised paper sufficiently dry, even in fairly well-heated rooms. Add to this the danger of there being condensed atmospheric moisture on the film, or of the hygrometric condition liable to be induced by breathing upon the plate, and it will be seen that it is well worth while going to the trivial expense, and the equally trivial loss of time, involved in varnishing a negative, rather than risk its destruction by the silver paper print adhering to its surface; a silver stain thus produced being, practically, ineradicable. If, however, it be determined to dispense with the use of varnish, the utmost care must be taken to gently heat every negative before placing in the printing frame, and to see that the paper also is well dried; though, here again, excess of caution may cause evil in a contrary direction, paper too thoroughly dried being deficient in printing qualities and incapable of being well toned.

We conclude by saying that it is evident, therefore, that the endeavour to give a special character to winter-made negatives is capable of materially influencing the quality of the work at the same time that it facilitates its production.

RESTORING SOLUTIONS OF PYRO AND SULPHITE.

In our last issue we published a suggestive and useful communication from the pen of Mr. A. P. Higgins on the subject of *The Regeneration of Sulphite-Preserved Pyro Solutions*, and during the few days that have elapsed we have taken the opportunity of testing the method practically.

Solutions of pyro and sulphite are well known to possess excellent keeping qualities, extending, when proper care has been exercised in the first preparation of the solution, to years, but clearly it is unfair to expect that such solutions will remain entirely unchanged for even short periods. Both the pyro itself, as well as its preservative, are unstable compounds prone to oxidation, and, therefore, we must expect some slight change to proceed constantly; but whether the alteration brought about is sufficient to materially affect the developing power of the solution is a question which remains to be answered. We are of opinion that practically it is insufficient to seriously, or even noticeably, interfere with the result, provided, as has already been said, the solution is properly made to commence with; still, in view of the undoubted fact that a change does occur, a method of counteracting any possible ill effects that might accrue must be welcome.

The change brought about by oxidation results, as shown by Mr. Higgins, in the conversion of the sodium sulphite and sulphurous acid employed as preservatives into sodium sulphate and sulphuric acid respectively, the former of which is totally devoid of any preserving power, while both are strong retarders. It is a curious circumstance that so apparently inert or neutral a substance as sodium sulphate should possess such a property, but such is in fact the case, and numerous other salts of a similar character may be included in the same category. The method put forward by Mr. Higgins aims simply at the removal of these newly formed retarding agents, but does not attempt to restore any power that may be lost by the oxidation of the pyro itself; hence we come back again to the proviso that, in order to derive any benefit from the treatment, the solution must have been originally a properly prepared one.

In effecting the removal of the retarding agent, Mr. Higgins avails himself of the well-known affinity of sulphuric acid for

barium, and by treating the solution with barium hydrate converts the acid, both free and in combination, into insoluble, and therefore harmless, barium sulphate, which may be separated by subsidence. Sulphurous acid is then added to reconvert the liberated sodium hydrate into sulphite, and so the solution is restored to its pristine vigour, except for the inevitable oxidation of a small quantity of the original pyro. This, however, is, under favourable conditions, inappreciable.

But an element of danger creeps in in the course of the process, simple though it is, which probably does more permanent injury to the solution—as a keeping solution—than the benefit it confers. The result of the reaction that occurs when barium hydrate is added to the oxidised pyro-sulphite solution is, as Mr. Higgins correctly points out, the formation of barium sulphate, which is probably harmless, and sodium hydrate, which is with equal probability the reverse.

In an editorial article in the *ALMANAC* for 1885, the comparative effects produced upon a solution of pyrogallol by caustic and carbonated alkalies respectively were pointed out. Pyro, we know, in neutral solution oxidises comparatively slowly, the action being retarded in the presence of an acid, and accelerated, on the other hand, by an alkali, the degree of acceleration depending upon the strength of the alkali. In the caustic state the effective strength is naturally far greater; and, as pointed out in the article referred to, while in the presence of a carbonate the pyro solution oxidises slowly, and at the surface only where in contact with the atmosphere, the caustic alkali causes it to oxidise and discolour evenly throughout its entire volume. In fact, in the one case the atmosphere supplies the oxygen, while in the other the solution carries in itself the germs of deterioration.

Now, it is evident that on treating the pyro-sulphite solution in the manner indicated, soda in the caustic state is liberated, and must necessarily remain in contact with the pyro for some considerable time, as the elimination of the sulphate cannot be performed instantaneously, but requires time and care. Consequently we have during a certain period a rapid oxidation of the solution, which, if it only result in the discolouration and enfeeblement of the developer, is bad enough, though we are strongly of opinion that it goes farther. For instance, we know that a properly prepared pyro-sulphite solution—that is, one which is free from colour, or nearly so at first—will remain in that condition for a practically unlimited period; but should any oxidation occur during the mixing, resulting in a discolouration of the liquid, the fault will go on increasing with time, and the more rapidly in proportion to the extent of the original colouring. Thus it would seem that the mere presence of oxidised pyro tends, if not to set up decomposition, at any rate to aid in its continuance; and it is probable that a solution treated on the Higgins's plan, though not seriously deteriorated at the time, would be found upon keeping to rapidly discolour and lose its strength. Absolute destruction of power, it is needless to say, is an infinitely greater evil than the mere holding in check of a force that still remains in existence.

Such were the reflections that induced us to practically test the method as described, and the results obtained have so far fully borne out the theoretical anticipation. Not having at hand a bad sample of pyro-sulphite solution, a fresh one was made, and to it were purposely added a liberal dose of sodium sulphate and sulphuric acid. It was divided into four portions, which were variously treated, as we shall describe. One portion was first treated by Mr. Higgins's method, neutralised, or rather rendered slightly acid with sulphurous acid, and set

aside for the barium sulphate to subside. When clear the "regenerated" solution was, as we had fully anticipated, very considerably deepened in colour.

Upon trying this side by side with the untreated solution in developing a couple of test plates, the treated portion proved the more energetic of the two at the commencement of the development, though, when the other did commence, it appeared to progress as rapidly as its rival, and at the finish exhibited a decidedly more vigorous image. Several repetitions of the experiment gave the same result, from which we draw the conclusion that the treatment does remove the retarding action of the oxidised sulphites, but that either from the removal of that restraining action, or else the weakening of the developing power of the pyro, the regenerated solution gives a more feeble image than the other.

It is true the conditions of this experiment were not such as actually prevail in the case of an oxidised solution of pyro, but it is difficult to see in what respect they materially differ. At any rate, they are such as to give the regenerating system a thoroughly fair trial, if indeed they do not work slightly in its favour. So far sufficient time has not elapsed to enable us to say whether the treated solution is likely to remain without further deterioration.

Arguing from these results that the liberation of sodium hydrate in the solution is objectionable, we varied the experiment in the following manner. A quantity of freshly precipitated and carefully washed barium carbonate was added to another portion of the solution, thoroughly shaken, acidified, and allowed to subside. Here the theoretical interchange that takes place would result in the formation of barium sulphate and sodium carbonate, the latter being subsequently reconverted into sulphite. Here no discolouration of the solution followed the treatment, and so far theory and practice worked together, but when tested for developing power there was far less difference between the treated and untreated solutions than in the previous experiment. The former acted a little more rapidly, and gave a softer image, but the difference in general behaviour was not such as would, under ordinary circumstances, have attracted any attention. This we do not attribute to inefficiency of the method so much as to want of sufficient time for the full reaction to proceed. The carbonate of barium would be more slowly acted upon by the sulphates than the hydrate, and, in addition, a portion of the liberated carbonic acid would also be absorbed and held in solution to act as a restrainer. By allowing more time we anticipate a more favourable result.

The last experiment, and one which holds out the greatest promise of practical utility, consisted in treating the remaining portion of the solution with barium chloride. A good deal has been written during the past year or more with regard to the value and action of chloride of sodium in the developer; not that the base of the chloride is a matter of vital importance, the sodium salt being selected as being the readiest to hand. If, as many believe—ourselves amongst the number—a soluble chloride is, under certain conditions, beneficial in the developer, and produces little or no slowing effect, it seemed feasible that by adding barium chloride we should at once get rid of the obnoxious sulphates without submitting the solution for however brief a period to any influence at all likely to cause or hasten its deterioration, and in the result we found complete justification.

To the remaining portion of pyro solution we added barium chloride in the proportion of three grains to the grain of pyro,

and simply allowed the precipitate to subside. Upon trying this side by side with the untouched solution, it developed with slightly greater rapidity at the start and progressed with far greater energy, giving an image combining with an equal amount of detail decidedly greater "pluck" and brilliancy and cleaner shadows. In fact, the useless retarder, sulphate of soda, was replaced by a restrainer consisting of soluble chlorides (sodium and barium), which possesses beneficial qualities in addition.

The addition of barium chloride to a properly and newly made pyro-sulphite solution causes only a comparatively slight opalescence, with scarcely any precipitate, properly so called. Indeed, added to a solution which had been made nearly twelve months, the deposit formed was not sufficient to interfere in any way with its immediate use. Thus it seems that the real necessity for this remedy is, perhaps, very slight when the preserved solution has been made with care.

If upon extended trial the use of barium chloride should prove to possess no serious disadvantages, we are disposed to claim for it a decidedly beneficial action. Assuming that chloride in the developer is desirable and useful, we may make up our preserved solution of pyro with barium chloride at the outset, and, rejecting the use of restraining bromide, trust entirely to the chloride for the brilliancy and clearness of development. Then, again, as the solution becomes oxidised, the sulphate or sulphuric acid will at once go to the barium, and in the interchange of elements all that will happen will be the very gradual disappearance of the preservative sulphite and the conversion of a portion of the soluble chloride from the barium to the sodium salt, with the simultaneous deposition of insoluble barium sulphate. If free sulphurous acid be present to commence with, of course a corresponding liberation of hydrochloric acid will follow, and this in the free state may probably not be a desirable adjunct to the developer; but if such should prove to be the case, it is easy to dispense with free acid.

In this manner, it will be seen, we secure a solution which is always in the best condition, and which practically undergoes no change, so far as its developing power is concerned. For the gradual disappearance of the sodium sulphite can only be said to affect the keeping qualities of the solution, and as there appears little reason to doubt these the balance would seem to be in favour of barium chloride.

VERY suddenly, on the 21st inst., died Mr. James Ramage, of Edinburgh. He dropped off his seat without any warning. Mr. Ramage was the manager of the art and illustration department of the printing and publishing business of Thomas Nelson & Sons, which important position he had occupied for over thirty years. In this capacity he employed photography extensively, and initiated many applications of it for book illustration purposes. He was one of the five who organized the Edinburgh Photographic Society. After the process of photo-lithography had been divulged by Osborne of Melbourne, Mr. Ramage was the first in this country to produce results which were admittedly of a high class. As an artist he was very skilful with either brush or pencil.

WE note in the list of lectures and lecturers announced for the forthcoming session of the Society of Arts, Sir Howard Grubb will read a paper on *Telescopes for Stellar Photography*, and another name well-known to photographers, Mr. J. Mayall, jun., is set down in connexion with the subject, *The Modern Microscope*. It goes without saying that the two lecturers will be heard with special attention by photographers, and we may anticipate that Sir Howard Grubb's paper will be of especial interest at the present time, when the preparations for making the great stellar map are so far advanced.

WE recently had detailed to us by a well-known correspondent, an instance of a singular failure of perceptive power which had occurred in his own practice. On a certain day he had developed a large number of negatives in, as he thoroughly believes, his usual manner—development, fixing, and washing, done by the aid of a uniform light, all were carried through in his usual manner; but when he came to examine the finished negatives after drying, he was astonished to find that, with scarcely an exception, they were all far too dense, so much so as to be useless until reduced. He could find no satisfactory mode of accounting for his lack of judgment than to ascribe it to a sudden temporary aberration in his power of judging, for every solution was overhauled and found to be in its normal state. This incident was forcibly recalled to our mind in reading an account of a paper on *Colour Blindness*, by Professor W. Ramsay, read before the Bristol Naturalists' Society. Hitherto it has been usually held that the cause of colour blindness lay in some peculiarity of the retina, which was unable to appreciate certain colours of the spectrum, although quite sensitive to all the others. Professor Ramsay says of cases where the ear cannot separate differing tones of sound, that "it must be concluded that in such a case the brain is the defaulter, and it may equally well be the case that the inability to perceive certain colours is not due to a defect in the instrument of sight—the eye—but to the power of interpreting the impressions conveyed to the brain by the optic nerve." If this is the case, the problem is no longer a physical one—it falls among those with which the mental physiologist has to deal. And it further appears to us that as the power of perception is greatly influenced by the condition of the body, it may well be imagined that the case of our correspondent as quoted above and many others, where discordant opinions exist as to matters of sight in the dark room, may be explained by a similar hypothesis.

MOST amateurs in electrical science, be they photographers or otherwise, have been bitten by the mania of economical electric light production by primary batteries on a large scale, in which the by-products shall be of such value as to prevent loss on account of chemicals. But at a meeting of the Society of Engineers held early this month, a paper by Mr. Perry F. Nursey led to a discussion, in which the ideas above alluded to were shown to be fallacious by no less an authority than Mr. Preece, F.R.S. He said there were few men who had had more experience of the behaviour of primary batteries than he had, and he was sure that any attempt to utilise primary batteries for any such extensive purpose as that of lighting mansions or houses must end in disastrous failure. His experience was that the cost of zinc and acids formed an insignificant fraction of the cost of working batteries; the chief expense was in attending them. In the Post-Office they had some five or six hundred thousand batteries, and where they had so many it must naturally follow that the products were very weighty; but they never yet had paid the cost of collection. It does not, however, follow from this, that for such electric illumination an occasional glow lamp for dark room and one or two other purposes might not be arranged at a very slight cost when the photographer undertook all the working arrangements himself.

THE Instantaneous Process is evidently still a matter of profound belief with the press and the public at large; no considerations of light or depth of focus, or special circumstance or condition, entering into their minds. The instantaneous process is a process for taking instantaneously—what could be simpler? The securing of negatives of objects in rapid motion has been considerably facilitated of late years as regards mechanical contrivances, and really rapid plates are more readily obtainable than once was the case; but, fortunately, or unfortunately, the day has not arrived when the photographer can walk out of his premises, regardless of the strength of light or the positions of objects, walk to any scene or assemblage of moving objects, be they human or otherwise, and secure a set of negatives which shall be sharp in all planes and contain all gradations of tones.

SUCH, however, is the idea apparently held by Mr. Mallock in his now famous letter to the *Times*, where he recommends that instantaneous photographs should be secured of the incidents of riots, or the

physical appearance of political prisoners. There is no doubt that an element of value is to be found in his suggestion, but we doubt whether it could be put to practical use, for it generally happens that when the evidence of the camera would be invaluable the conditions governing the circumstances are inimical to instantaneous work.

PROFESSOR HELMHOLTZ has lately been conducting a series of experiments upon the conditions producing the deposition of particles of mist, and they have led him to the deduction that the general accepted theory connected with the name of Aitken affords a partial explanation only. Experimenting with chemically produced mists he showed that a nucleus of some material particle is not a necessity and that the precipitation of mist might be brought about by vibratory influences. It might be thought that long ere now some practical mode of preserving ourselves from the fog and mists so terribly harassing to the photographer might have been discovered, but the boon is still in the future. Possibly prevention and not cure will be the only panacea.

THE Cellerier Syndicate has now developed into The Photographi Company, Limited, the primary object of which is to acquire the patents of Mr. Cellerier and Mr. Parkes, and work the same. Now we are aware that a good deal of dissatisfaction has been expressed by photographers at what they justly considered a misleading statement by the Syndicate named, that theirs was a process of "photographing in natural colours," whereas the colours were actually applied by a brush to each individual print. But on the representations of the photographic press as the deceptive nature of the distinctive phrase it was at once suppressed, and Mr. Parkes and others of the directors said they were far from having any desire to deceive the public as to the real nature of the process. Still, although by a mistake, as Mr. Parkes informs us, the original misleading announcement certainly did appear up to the last in one London weekly newspaper, and in a modified form it is being perpetuated in the advertisements in the daily papers, in the abridged prospectus advertised being found the words, "Cellerier & Parkes' process of photographing in colours." The artistic results are, however, unimpeachably excellent. Mr. George Augustus Sala is chairman of the new Company, and other good names are on the directorate. Mr. Vernon Heath also is attached to the Company.

ON THINGS IN GENERAL.

WHAT an excellent opportunity the daily papers have recently been afforded to show their utter incapacity to write half a dozen consecutive sentences on a scientific topic without showing indications of the curse of smattering, for such a strong word is the only one applicable where an overwhelming torrent of words, written with such arrogance as to suggest their being entirely *ex cathedra*, is used to conceal an amount of crass ignorance that is really pitiable. We should like to look up to our "dailies" as responsible authorities on the topics they dilate upon, whereas, as a matter of fact, we find that their usual mode of treatment of a technical subject indicates knowledge of the English language, but worse than ignorance of the subject that language is made use of apparently to elucidate. Talleyrand said that the use of language was to conceal thoughts; if he lived nowadays he would say it was to conceal want of thought. Look, for example, at the criticism of the *Builder* on Mr. Sawyer's picture in the late Pall Mall Exhibition, of two fond parents playing with their offspring. Any one who ever saw a baby could tell that the baby in the picture was an undersized dummy, yet the critic here anxious to show his knowledge of "art," heaven save the mark! must needs decry the pretty part of the picture, the (assumed) parents' pleasant toying with their baby, and praise the pinned-up, be-shawled bundle doing duty as a human being of immature age, describing it as "capital, and worth the attention of a painter!"

But such a *fiasco* of criticism as this pales into insignificance when compared with the remarks brought about by a letter in the *Times* from Mr. W. H. Mallock, suggesting the use of instantaneous photography at political meetings, &c. We were lately dosed *ad nauseam*

with wonderful treatises upon photography in colours, till the bubble burst, as per usual, and now the instantaneous process is having its turn. The *Daily Telegraph* wishes to know when "the art of focussing will be brought to perfection," and, pending the acquisition of the necessary knowledge, discusses the "purposes of utility to which photography, even as we possess it in its existent infantile form, may be adapted." Photographers of late years have come to look upon photography as a very lusty infant. "The indispensable condition to the graphic success of an instantaneous photograph is the entire immobility of the object focussed." So says this interesting paper. One wonders, in turn, what the use of instantaneous work can be under these conditions. Space is lacking to continue these quotations. I advise all my readers to obtain the original article and read it through, it will well repay perusal. I must make an exception with regard to this present writer and his knowledge of English, he speaks of Mr. Mallock's "inchoate" suggestions, evidently under the impression that the word has some resemblance in meaning as it has in spelling to incoherent. I need not say that the word as used is simply nonsense.

I am driven also to wonder how it is when people begin to write on the "ten per cent. system," they are almost certain to make some absurd mistake or other before they dismiss their subject. The Editors have shown up several mistakes of the kind, and I see in the early part of the month a letter from Manchester from a writer who has been "looking the subject up." He depicts specific gravity "as the weight of a unit of volume;" this really, in a letter bristling with figures, cannot be passed by. Specific gravity is a ratio and not a weight. He evidently has "density" and not specific gravity in his mind, in which case he might have been still more precise, and used the word, "mass" for "weight." Again, in his wonderful exactitude he applies a correction for water at 14° C., stating it to be less than 1.0. In this country, Acts of Parliament dealing with specific gravity recognise 60° Fahr. as the standard temperature at which water is 1.0 s.g., whence it follows that the correction is wrong, unless he shows that Carius took another temperature as his standard.

In penning my remarks upon photo-micrography in my last letter, I was most careful not to allude to the remarks of Mr. F. H. Evans in regard to M. Pasteur. I considered them idle, misleading, and unjust but seeing the Editors have opened their columns to the anti-vaccinationists, I feel there is less need for reserve, though I don't see how photography is to gain by discussing the question, except the Editors, as I shrewdly suspect, intend to close that correspondence by giving it a little "law," and then telling the disputants to go and photograph the various bacilli engaged in the operation, and afterwards to "come again."

I see that at a meeting of the London and Provincial Photographic Association there was a remark made by the chairman that a member desired to call attention to a statement about an alleged rainbow photograph shown at some London photographic society's meeting. There is no doubt that the photograph alluded to was one shown at a previous meeting of this Association. I remember being struck with the droll aspect of the question as to whether it was a rainbow or a rope that was photographed, the difference being so slight between the appearances of the two objects. I could not gather whether doubt was thrown on the possibility of photographing a rainbow at all or not. Perhaps the American paper remembered Professor Tyndall's stating that the reflection of a rainbow could not be seen in the water, and so judged it could not be photographed either. If this was the case he might, by referring to Professor Tyndall's foot-note to the published account of the lecture, have discovered that the Professor explained his statement away by saying it was another rainbow and not the one seen above the water that was reflected in it.

I quite agree with the spirit of the Editors' remarks in regard to the opal plaques now so freely being sold by the stationers and others. Some little time ago, when I was giving my opinion about them to a stationer who sold them, he replied, "Oh, they will wash easily with a little soap and water." It is easy to imagine what they would be like after a few washings with soap and water, especially if followed by a dry rub with a towel.

With regard to the elaborate instructions given on page 731 as to the restoration to its pristine condition of the sulphite of soda changed by the action of air, I am inclined to ask, *Cui bono?* If only the

writer would inform us how to recuperate the pyro of a developer, I think we might be quite content to disregard the possible restraining action of the sulphite converted into sulphate. FREE LANCE.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

HAVING successfully treated the picture so far, we have only the background to finish, and our task will be complete. Many people who do not give the matter sufficient thought may think this a very unimportant point, but I beg to tell such as hold this opinion that it is not so. On the contrary, it is a very difficult portion of a picture, if we are desirous to give it the value that it really deserves. A badly treated background may and will spoil our picture, while a skilfully treated one will undoubtedly enhance our work. Therefore, I recommend giving our attention to a few of the essentials for its successful treatment.

Needless to say the treatment of a background in natural colours demands great judgment as well as artistic skill in its painting. In monochrome our efforts are limited, nevertheless a great deal can be done to enhance the effect of our picture. It is the successful treatment of the background, be it in natural colours or monochrome, which will produce the effect of a harmonious whole in our picture. By its aid we can blend extremes of light and shade, which otherwise would be hard and inartistic, so that they become harmonious, and thus secure the balance necessary to a successful picture. By judicious contrast we can heighten or lessen effects which left to themselves would be glaring defects. Of course in cases where the portraits are what is called *vignetted* there is but little scope for the special treatment of the background, so these remarks will mostly apply to cases where it is desired to make not only a successful *likeness* but a pleasant *picture*. Many of our greatest artists looked upon the painting of a successful background as the most crucial test of ability. Indeed, if I remember rightly, I believe Sir Joshua Reynolds is credited with having declared, "I let my pupils paint draperies and accessories, but the background I paint myself." Thus this great artist, having more or less completed the painting of the *flesh*, allowed his pupils to treat the draperies, &c., but reserved to himself the putting in of the background. If this were the case with Sir Joshua Reynolds, I think we may take it as granted that the backgrounds of our picture are well deserving of our greatest attention.

Whatever relief your figure may require can be amply supplied by a really good background. According to the lighting of your model, you place in contrast a light here and a dark there, which will in every way be complementary to it and heighten its general effect. It should never be too even in tone, and always of a tint in harmony with your subject. The general tone of your background should not be so dark as your deepest shadows, but yet of sufficient depth to enhance the value and effectiveness of your lights. A very great object to be attained in a good background is *atmosphere*; indeed, without this quality you cannot say you have secured a good background. I had a very strange experience some few years ago which will, I feel sure, give a very palpable proof of the powerful influence a background will have on a picture. I gave the painting of two portraits to an artist upon whose work I could thoroughly depend, and who was especially noted for the beauty and effectiveness of his backgrounds. The portraits were on kit-cat canvases, showing head and shoulders life-size. In due course they were completed, and I was invited to see them at his studio. Now, they were most successful in every way as paintings, yet they would never do as a pair of companion portraits. This may seem very strange, after saying that they were successful as paintings. But it is very easy to explain it.

As individual pictures, they were in all ways satisfactory from a painter's point, yet they were perfectly impossible as companions. Why? Well, because they did not appear the same size; and this fact so impressed me that I actually measured the canvases to "make assurance doubly sure." I asked the artist if anything struck him as being strange, but being used to them I suppose he did not see it. I said they would never do, to which he replied that he would like to know what is wrong with them. I replied that they were not the same size. To this, his reply was that "they must be; besides, you

* Continued from page 709.

have only measured them this moment." I then drew his attention to the painting of the backgrounds—that there was much more indication of space and atmosphere in one than there was in the other. The moment I said this he realised the fact, and was astonished at the difference, and offered to at once alter the background, which he did, and made them both match. This shows how much a picture can be influenced by a background. If I sent these pictures away they would never look the same size when against the wall. One really looked double the size of the other. They were both beautifully painted, but one had greater *breadth*, and gave the idea of greater space than the other, and the eye could never be brought to believe them companion pictures.

The general arrangement of a plain background is such as will bring its darker portions against the lighter ones of the figure, and *vice versa*. As you descend towards the lower portions of the picture the general tone will deepen and the outline of the figure will become less distinct, and partly appear to melt into and blend with it. All the outlines must be softened, and care taken so that the figure may not present the most objectionable appearance of being cut out or, as it were, inlaid. It may be laid down as a general rule, that the fewer objects or accessories introduced into a background the better, and when introduced they should be put in very broadly, avoiding too much sharpness or detail.

As the background should always be painted with the object of setting off the figure, the system of treatment should be somewhat of a bolder or broader nature, in order to add to the greater delicacy of touch employed in the face and other parts of the subject. Put in all backgrounds, as far as possible, with washes and broad hatching, studiously avoiding all approach to small or niggling work.

Now, if we carefully examine our picture, we will find that there is a something wanting; in fact, there is a general lack of finish. It is true we have secured more firmly all the features and other markings of our photograph as regards the face, &c.; we have also washed in the draperies, giving them depth and richness, emphasised and strengthened the folds, and secured a certain degree of relief, light, and shade, and a feeling of atmosphere in the background; but still, there is a lack of finish. This is only natural. The face (which appeared completely finished when compared with the untouched background), now that all parts have been advanced to a certain degree of greater finish, will require a little more work to restore its importance and effect. We must, therefore, proceed to soften by stippling, or other means that may appear more suitable, all lines that may appear harsh or otherwise offensive to the eye. The various shadows here and there may require intensity; these, where necessary, must be treated. Lights which at first appeared strong enough, may be found weak; they must be forced into greater prominence, and many half tones may require *picking out*, which may be done by using a clean brush, just slightly moistened to remove the superfluous colour, or in cases where colour may not have been used, the eraser must be employed.

In the first instance we may be said to have worked each part in detail, but having done so our efforts must now be directed to secure a general harmony in our picture. We must now look over every feature or marking in the face, and give it its relative value as a whole, and not as a part as before. We must also treat the lines and markings (landmarks as it were of time) with great care, in order to preserve them sufficiently to secure the character of the face, yet at the same time to keep them subdued, in order to produce a *pleasing* as well as a true portrait.

Having so treated the face, proceed to finish off the draperies and background in like manner, stippling when advantageous, but more generally hatching, and so softening every part until you feel that nothing more is likely to improve your work.

The general rules which must guide us in working upon all the materials I have before mentioned are the same. Of course the different materials used may demand slight modifications of treatment, but the general idea remains unaltered.

For the treatment of Woodburytypes and carbon prints generally, whether on opal or paper, a slight sizing will be found advantageous at starting. If carefully looked over, after this, there will no doubt be many dark spots visible, which must necessarily be removed. This is an easy matter. Take your eraser or scraper (which latter, by-the-

by, must always be very sharp), and remove these blemishes. Great care must be taken not to cut the surface of the paper, but carefully to scrape off the spot, which really only lies on the surface. The sharper your scraper is the more surely and easily it will work, and I advise having a good oilstone constantly by you, so as to keep this useful little instrument in good working order. Naturally with so fine an edge the least thing will spoil it, but a few touches on the stone will restore its edge, and always keep it in an effective state.

In this manner we go ahead with the various features and general strengthening, adhering to the rules laid down. Often we will have to work upon over printed and very dark carbons, but this will not always be a disadvantage. In such a case we must, with the help of some finely-powdered pumice-stone, reduce such shadows as are too heavy. This is done by rubbing the pumice-stone with the finger (adopting a circular motion in so doing) over the places requiring lightening. Should you, however, require any lights more distinctly marked they must be put in with the ink-eraser as before described. The background, if too dark, can also be treated in like manner. Either the scraper or the eraser may be used with great effect, either to secure the appearance of hatching, or even the suggestion of a pattern may be put in. If this should be necessary or advisable it would be best done *before* sizing.

Very beautiful results can be gained, on carbon base, by the use of the scraper, but a good knowledge of drawing is necessary to ensure success. It partakes much of the style and quality of mezzotint engraving, and the best scraper would be one used by engravers, as it is made of best steel, and will take an exceedingly fine edge.

An ordinary carbon has a fairly glossy surface somewhat resembling the ordinary photograph. It will be found, therefore, very advantageous to use a little gum water with the colour, in order to match the natural gloss of the carbon. Let your brush be only moderately filled with colour when working. The size of the brush you use should be to an extent governed by the size of the picture. High lights are best put in with a scraper or eraser rather than by the aid of Chinese white, as the general effect will prove much more harmonious.

REDMOND BARRETT.

(To be continued.)

PINHOLE PHOTOGRAPHY.

[A Communication to the Edinburgh Photographic Society.]

A GOOD deal of interest has been taken of late in pinhole photography, considerable attention having been bestowed upon it in France, and afterwards among photographers in this country. There have been so many and varied opinions about it that, having myself tried it occasionally, I thought it would not be out of place to say a few words about it here, narrating my own experience. I daresay it is needless to explain what is meant by pinhole photography, but as I have met a few who have not only never seen a pinhole photograph, but do not know how they are produced, it may be well to say that pinhole photographs are taken by means of a minute hole in a metal plate without the aid of any lens. There is nothing new in this. It is just an example of another of those things which come to the surface now and again—new, perhaps, to a new generation, but well known to those of larger experience.

I think I have seen it stated that an aperture of one-eightieth of an inch is the smallest which can be used effectively with a lens. With a pinhole, however, the aperture may, I think, be much smaller.

The camera I used is a rough pine box firmly screwed together, with a hinged door at the back. It is large enough to take a 5×4 plate. The plate lies in a rebate, screwed on all round inside about half an inch from the door, and after the plate is put in I place upon it a piece of paper larger than the box and shut down the door, which is held close by two spring clips. The paper effectually prevents the access of light. The camera, as I originally made it, was four and a half inches in length from the pinhole to the plate, and thus gave upon a 5×4 plate an angular image of about 60°. I have, however, shortened the camera to three inches, which now gives me an angular picture of over 70°, and so includes more subject. The front of the camera has a hole bored in it by a one-inch centre bit, and over this hole is screwed a piece of thin zinc about two inches square. In the centre of this zinc plate I countersink by a small drill a portion of the zinc, and then by a gentle tap drive the point of a needle through the thin portion in the centre. A movable piece of zinc swinging on a pin in front acts as a shutter, which can be held in place over the whole

by means of a small screw through its lower end. I pass the camera round that you may all see it.

It has been said that to get good pinhole photographs you must have very excellent apparatus. I have not found it so. You will see that no camera could be simpler or made in a more inexpensive way, and yet you may get good photographs by its means. The pinhole which is in the zinc on the camera you now see is forty-eight one-hundredths of an inch in diameter—much larger than what I should recommend. I measured it only a few days ago, and thought it had been smaller; yet, with a hole of that size, very fair results can be obtained.

The good qualities of a pinhole camera are many:—1. The first and chiefest of all is its cheapness. Anyone with the least ingenuity may make one for a few pence, and produce with it photographs at least equal to the production of many who use expensive apparatus. 2. There is no lens required, no stops to lose, and no glass about it to break, except the sensitive plate, which may be so well-cushioned as to be also well-nigh unbreakable. 3. Another very important quality, and one which is of very great importance, is the fact that there is no distortion in the picture, every line being rendered as straight and true as in nature. The pinhole camera ought in this way to be of very great use to artists and others who wish to paint scenes which embrace architectural subjects. What can be so simple and easy as to place a pinhole camera in front of any building, and by a short exposure and a little trouble obtain a photograph in which every line of the building is rendered by the very best rectilinear lens ever conceived, perfectly straight and true and in true perspective? 4. Another good quality of the pinhole is, that there is no focussing required. Everything which the pinhole sees is in perfect focus—both near objects and distant ones. You may be standing beside a wall which will be rendered as sharp as the pinhole can, and so also will the spire of a distant church, or the sign of a shopkeeper a hundred yards away. 5. Any amount of subject may be got on the plate of a pinhole camera, according to the length of the camera, or the distance of the pinhole from the plate. It is not advisable, however, to shorten this distance too much for the size of plate used. I have mentioned that I used one giving an angle on the plate of about 60°. This appears to be about the best limit, and gives the best results. If this angular aperture is exceeded, the difficulty is increased in getting the margin of the plate sufficiently lighted to develop evenly. You may see this very well exemplified by means of a ring or hoop. Those sitting directly in front can utilise the whole aperture, while those sitting towards the side fail to see the hoop as a circle, but more as an ellipse. Every plate, however thin we may make it, having a hole in it, acts much in the same way, and stops a considerable amount of the marginal rays.

W. FORGAN.

THE PLATINOTYPE PROCESS.

[A Communication to the North London Photographic Society.]

I do not purpose this evening detaining you with a history, interesting though it may be, of the experiments made by noted chemists over half a century ago—experiments which are, I suppose, considered to be the germs from which this process has resulted—but rather to endeavour to give an outline, at least, of the process, and my remarks will be addressed, therefore, more especially to those who are unacquainted with it. I propose, at the close of my paper, to illustrate some of my remarks by practical demonstration. The platinotype process was invented by Mr. William Willis, jun., and is the subject of three patents; but it is with the third and improved patent that I shall deal to-night. These patents are in the hands of the Platinotype Company, and a license is necessary to work the process. I will pass round mine, so that you may see it is not a formidable document.

The ordinary paper supplied by the Platinotype Company is ready-coated or sensitised on one side with a mixture stated to consist of ferric oxalate and chloroplatinite of potassium, and this surface presents prior to exposure to affecting light a lemon-yellow colour. During exposure under a vigorous negative, the parts acted upon by light become a pale, greyish brown tint, and if the action be allowed to continue the colour will gradually change to a dull orange. The ferric oxalate has been reduced to ferrous oxalate by the action of light, carbonic acid being set free. The print can now be developed by flotation, face downwards, upon a hot solution of potassic oxalate, which dissolves the ferrous image, the platinum salt is reduced, and a picture in metallic platinum black remains, a substance most durable, acted upon by aqua regia alone, and quite immutable by atmospheric influence. The print is then immersed in acid baths, followed by a wash in water. Such is an outline of this simple process. Practically speaking, daylight is necessary to print by. Printing has been conducted by other means, such as electric light, at present out of the reach of the ordinary worker. The paper prints

rapidly—it is said, three times as quickly as ordinary silver paper, and the rapidity in comparison with silver is more noticeable at this time of the year, when the light is less rich in the violet rays, which have a great effect upon the silver and but little on the sensitive salts of platinotype paper.

Development of the print should be done in subdued daylight, or by gas or lamp light, and numerous substances in solution can be used for the purpose. It has been pointed out that simple cold water will act upon the ferrous oxalate, of which the printed image is largely composed, and this will reduce slowly and partially the platinum salt; but I have not obtained good results by this method. What is wanted is a substance which will increase the action of the ferrous oxalate, and a hot solution of potassic oxalate has been recommended as the best for this purpose. The stock solution for the bath is made up as follows:—

Potassic oxalate	16 ounces.
Hot water	54 „

The Company state that this solution must not have an acid reaction. I may say that, although I gave the neutral bath a fair trial, I found, as I believe others have done also, that by acidifying it with oxalic acid the results were more brilliant and satisfactory.

The normal temperature for the bath is 170° Fahr., although a higher temperature must be used for under-exposed prints, and a lower one for those over printed; indeed, in the case of a very considerable over exposure, a cool, if not cold, bath is, I think, a necessity, and the only way I know of obtaining a passable result. The higher the temperature of the developer the more rapid will be the action of the platinum and iron salts upon one another. In development upon a cool bath the chemical action is weakened, and before reaction takes place a part of the materials which would have helped to form the picture are dissolved into the developing bath, and a less vigorous, less rich print is the result. I would recommend a beginner in platinotype to fully expose, that is, have all details of the picture visibly printed out, and to develop upon a hot bath. The development in this case will be completed in a very few seconds. I am, however, aware that many experienced workers do not aim at such brilliancy as this will give, but prefer a cooler bath and different, perhaps softer, results. It really must rest with individual experience, judgment, and taste, to determine beforehand, from examination of a negative suitable for printing with the ready prepared paper, what style of print will suit the subject best; exposure and development are then regulated accordingly.

After development of a batch of prints, the solution is poured back into the stock bottle for use again and again; at the same time, I would point out that this solution must not be over worked. It is, therefore, advisable to keep up the bulk by adding fresh solution to make up for evaporation during developing operations. The bottle containing the stock solution should be either kept in the dark or painted with Bates's varnish.

Immediately each of a batch of prints is developed, it is immersed in a bath of hydrochloric acid—one part acid, eighty parts water—for, say, ten minutes, then into a second bath of same strength for another ten minutes, and again into a third. The object of these baths is to remove from the paper all iron and other salts, and leave only the platinum forming the picture, and the operation must be thorough. It will generally be found that after the prints have been passed through these clearing solutions, that the first and second bath will show a yellow tinge, but the colour of the third bath remains unchanged. Should the third bath show any discolouration, a fourth must be used, and so on. The prints are now removed from the final acid bath and washed in changes of water for, say, twenty minutes to eliminate all acid from the paper; they are then dried and can be mounted.

The question is often asked, "Are not very dense negatives required to give best results in platinotype?" My answer is, that the Company offers to the licensee the opportunity of purchasing from them the materials for sensitising purposes, and that the relative proportions of the constituents can be so varied as to give a sensitised surface to suit, I believe, almost any negative. I am told few workers in this country avail themselves of the offer, and it is not advisable for beginners, for obvious reasons, to sensitise for themselves, but rather to use the ready coated paper, which will be found to suit a sparkling negative, one not necessarily intense, but showing nicely graduated contrasts. The negatives I usually print from received full exposure and were developed slowly. It is said that negatives showing really fine gradation should yield prints exhibiting all the range of tone between a deep black and a clean white. At the same time, I would point out that good results are to be got from negatives of a different character.

The sensitised paper is said to keep in its best condition for a period

of about two months; but it must not, therefore, be assumed that paper of greater age will not yield good results, in fact, it has been recommended that better prints are to be obtained on old paper in cases where very dense or hard negatives with great contrasts have to be employed. My own experience corroborates this, working with paper at least six months old, cool developer used. I was lately shown some excellent results obtained by cold development on paper a year old, and recent experiments made lead one to hope that there is a possible future for old, and even light-fogged, paper. But there is at present an uncertainty regarding the behaviour of old paper which renders its use undesirable.

Great attention must be paid to the fact that damp is fatal to platinotype paper. I refer not merely to the dampness which is apparent, but also to that which is present in the atmosphere during our driest weather. The precautions to be taken are these: The paper must be stored in suitable cases; the metal ones supplied by the Company are made with a perforated chamber at one end, containing chloride of calcium, for the purpose of absorbing moisture which may be present, and, further, the joints of the cases are protected by indiarubber bands to prevent the entrance of moist air. The chloride of calcium on becoming damp must be heated over a clear fire until the moisture is driven off, when it is again packed in the chamber. A sheet of indiarubber must be placed on the back of the paper before the printing frame is closed.

In damp weather, I always, prior to printing operations, dry my frames and warm my negatives before a fire. A damp print on development will give an image wanting in vigour, and generally foggy and unpleasant in appearance. I may mention that prints can be obtained of a sepia tone by using the Company's "Special Sepia Paper" and adding a special solution to the developer; also that various substances, such as wood, tiles, and textile fabrics, can be sensitised and printed upon. The more noticeable advantages of the process are—general simplicity of manipulation; the small quantity of apparatus and chemicals required for working; and the great sensitiveness of the paper as compared with silver. Moreover, undoubted permanence is claimed for the results.

The Company will supply full printed instructions for working the process, and containing the explanation of many minor details not mentioned by me; and I would recommend those who wish to dive deeper into the particulars of platinum printing to carefully peruse the interesting little work on Platinotype by Pizzighelli and Hubl, published by Harrison & Sons, Pall Mall. To the above-mentioned excellent publications I am indebted for much of the matter in my paper.

In conclusion, it is scarcely necessary for me to speak of the true charm and beauty of artistic prints in platinotype; this is already well known and appreciated. I cannot help thinking that a large number of photographers, frequenters of the various photographic exhibitions, within quite recent years especially—photographers whose partiality lay in the direction of the colour and glaze of a silver print—have gradually, perhaps sometimes unconsciously, yet surely, been educated in favour of tones, subdued—may I add more refined?—whether in platinum or photographic processes giving tones similar. Whether or not these are now to be counted in the increasing ranks of platinotype printers, I leave you to draw your inferences from the fact that many whose names at least, I venture to say, are familiar to all of us present on account of their artistic photographic achievements, are now exhibiting their choice works done in this process.

FRED. W. COX.

A SIMPLE METHOD OF MAKING INSTANTANEOUS PORTRAITS AND OTHER PHOTOGRAPHS AT NIGHT.

[Read before the Society of Amateur Photographers of New York.]

Portraiture by artificial light resolves itself into the employment of gas, kerosene, electricity, calcium, or magnesium. With an abundance of either gas or kerosene quite satisfactory portraits may be made with an exposure of from one to three minutes, if care be taken in the arrangement of the lights, reflectors, &c. With the electric light exposure may be very much shortened, and portraiture by this means has already been placed on a commercial basis. The calcium light is also capable of being used for portraiture, but the apparatus employed is bulky, expensive, and troublesome, and the results obtained are not sufficiently satisfactory to bring this method into use. Exposure required by the calcium light is longer than in ordinary daylight gallery work.

The intensely actinic light yielded by burning magnesium has been utilised experimentally, but not commercially, and has generally been obtained by the ignition of a small length of magnesium tape, either suspended free or fed from a specially constructed lamp. It usually requires an exposure of fifteen or twenty seconds. This method is

unsatisfactory, owing to the fact that the magnesium tape is apt to break and the light go out before the exposure is completed. Powdered magnesium dropped from a funnel upon a burning lamp or other source of heat has not been found in practice to yield the results that were hoped for.

Quite recently Dr. H. W. Vogel has communicated the results obtained by him with the use of a photographic powder prepared by Gädicke. By this means he obtained an instantaneous flash of extreme brilliancy and actinism, and capable of fully impressing the sensitive plate. In other words, he succeeded in making instantaneous portraits at night, a feat which had not been previously accomplished. The exact composition of Gädicke's powder is, we believe, unknown, except to the inventor, but is supposed to be a mixture of magnesium, chlorate of potash, and sulphide of antimony. Commenting on this mixture, *THE BRITISH JOURNAL OF PHOTOGRAPHY* of August 26 says:—"The statement that it cannot be inflamed by pressure or percussion is difficult to believe, since most dangerous explosions have taken place with such a composition. Of course the materials must be ground separately and mixed gently, but even then, no matter how far the chlorate of potash may be diluted down, so to speak, with the other two substances, the statement that the mixture is safe against pressure and percussion is too serious, as well as too improbable, to be safely accepted on the authority of an anonymous newspaper paragraph." The efficiency of the Gädicke light may be easily conceded, and is sufficiently attested by the eminent Dr. Vogel, and the only drawback to its use appears to be the danger of premature explosion of the powder, a danger that will be fully appreciated by those who are familiar with the behaviour of mixtures containing chlorate of potash.

Experiment has already shown that the light given out by the burning of ten or fifteen grains of magnesium is sufficient to fully expose a sensitive plate, and, with the aid of a quick-acting portrait lens, to yield a satisfactory negative so far as actinic effect is concerned. In using magnesium tape, the ignition takes place gradually, and a time exposure is necessary. For instantaneous exposures it is requisite that the entire quantity of magnesium be ignited simultaneously, so that the full actinism of the light is developed in an instant. This Gädicke has accomplished, but by means which appear to be somewhat hazardous. The problem that remained was to obtain a substance capable of instant combustion, and the heat from which would cause the simultaneous ignition of the magnesium, and which would be free from the dangers incident to the use of chlorate of potash. Such a substance is ordinary gunpowder. If one part of gunpowder be mixed with four parts of magnesium powder, and ignited in an open space, an extremely actinic light is instantly developed. This mixture is absolutely safe, as it cannot be ignited except by the application of fire, and will not explode by concussion.

Another simple method of accomplishing the same end is to take a small tuft of ordinary photographer's cotton, such as is used for making collodion, lay it on a metal plate, and strew over it a small quantity of magnesium powder. The cotton is then lighted with a match, and the heat developed by its combustion ignites the magnesium, and we have an instantaneous blaze sufficiently actinic to effect the desired result, as I will presently demonstrate. It is not for portraits only that the method here described is applicable. Excellent copies of photographs or other objects can be made, and even enlargements on bromide paper. In practice I have found that seven or eight grains of cotton, with from ten to fifteen grains of magnesium, will produce sufficient light for a single portrait or a small group. For copying, lantern slides, or even bromide enlargements, the same quantity may be used.

The methods here described are not the only ones by which the extremely actinic light of magnesium may be safely developed, as I have made several negatives by the flash of a pistol, the weapon being loaded with a mixture of gunpowder and magnesium.

In comparison with other methods of artificial illumination adapted to portraiture, this panactinic light, if I may be permitted so to call it, is characterised by extreme softness, a feature impossible to obtain with either a single electric or calcium light, or with the magnesium tape; due to the fact that with these latter the light emanates from a comparatively small point, while the magnesium-cotton light gives a large diffused blaze.

The prints which I exhibit this evening are from negatives which have been taken simply with a view to the demonstration of the actinic power of the light, and are to be judged from this and not from an artistic standpoint. It remains for the professional photographer, skilled in the use of screens, reflectors, and other accessories, and familiar with the art of posing, to obtain the best results that this means of illumination is capable of producing.

HENRY G. PIFFARD, M.D.

ZINC ETCHING.

A ZINC plate having a smooth, polished surface is taken, and upon it is drawn the required design with an ink composed of asphaltum, turpentine, and oil (enough to keep the composition in a liquid state), and a little lampblack to darken it. Or, if the object to be reproduced be an engraving, either stone, plate, wood, or any other material, it is transferred by the usual mode; that is, by taking an impression from the engraving on "transfer paper," and thence to the zinc plate.

The transfer ink used is a compound of ordinary lithographic printing ink and asphaltum, in the proportion of about one-third of the latter to two-thirds of ink. The drawing or transfer having been completed, and before the ink has become dry, it is covered with a coat of powdered resin or copal, the back of the plate being also coated with asphaltum to render it acid proof. The plate is now ready for the bath, which consists of muriatic acid of about 1.2 specific gravity (or other suitable acids, either in their pure or diluted state, such as nitric acid, &c.), where it is allowed to remain about five seconds. It is then taken out, washed, dried, and when dry, heated only enough to melt the powdered resin or copal, so as to form a crust which will protect the edges of the drawing or transfer which has been formed by the first exposure of the plate to the etching agent. The plate is next returned to the bath of muriatic acid, again allowed to remain about five seconds, and washed and dried once more. Those portions which are high enough to print are then covered with asphaltum, and another coat of powdered resin or copal is added, after which it is replaced in the bath and allowed to remain until sufficient depth is obtained on the exposed parts. These operations of covering the plate and returning to the acid may have to be repeated three or four times, according to the nature of the work. The plates used are, of course, restricted to such metals as are affected similar to zinc.

-Scientific American.

FAILURES IN CARBON PRINTING AND THEIR CAUSES.

FAILURES	CAUSES.
<i>The black gelatine whilst sensitising runs off in streaks.</i>	The sensitising bath was too warm.
<i>The same occurs whilst drying.</i>	The bath was too warm; squeegee the tissue plates on a glass or zinc plate and dry in cooler room.
<i>Particles of dust or fibres of the paper adhere to the tissue after squeegeeing.</i>	The plate was not clean, or the squeegeeing had been done without the rubber cloth.
<i>The tissue does not lay flat in the printing frame.</i>	The paper has been dried too fast and should be allowed to absorb a little dampness.
<i>The tissue sticks to the negative.</i>	The paper was not dry enough, or the negative or pad was damp. Impermeable paper or rubber cloth should be laid between the tissue and the pad.
<i>The wax on the plate cannot be polished.</i>	The plate was too cold, the wax was not pure, or the polishing flannel was damp.
<i>Small air-bells appear after laying the sensitised tissue upon the glass plate.</i>	The paper was not a sufficient time in the cold water, or had not been lowered with enough care upon the plate. Withdraw the tissue, re-moisten and replace it.
<i>The tissue does not stick to the plate, the borders raise.</i>	It had remained too long in the water, was over exposed, or suffered from emanations from kitchen, gas, &c. Apply pressure for ten to fifteen minutes. A prompt way to learn if the paper is still good is to apply hot water to a small piece of unexposed tissue; if the gelatine dissolves it is still good.
<i>The tissue in developing does not separate from the plate, or the picture does not develop, remaining too dark.</i>	The exposure was too long, or the transfer was made too late after the exposure to light. Hotter water, or a bath of two per cent. carbonate of soda, or the addition of a few drops of liquid ammonia may be used; or the paper is not good.
<i>The tissue lifts too quick from the plate and the picture is too light.</i>	The exposure to light was too short. Develop with cooler water.
<i>Air-bells appear on the back of the tissue when immersed in the developing bath.</i>	The water was too warm. Begin with cold water and raise its temperature by degrees. The air-bells often show in the picture.

FAILURES.

The picture lifts on the borders whilst the collodion remains.

The picture, together with collodion, lifts from the plate.

The collodion film breaks.

Dirt or particles of paper between picture and plate.

Air-bells between the picture and the plate or the flexible support.

The picture is full of small fissures.

The picture appears granular or reticulated.

The picture swells up much when immersed in water, and moss-like excrescences appear in the picture.

Reticulation of picture during development on glass plates.

Small brilliant spots or air-bells appear in the picture.

Cloudy appearances, principally in the background of the picture.

The picture shows no half tones.

The transferred and dry picture does not leave the support, or sticks to it in some places.

The double transfer paper leaves the plate without the carbon picture.

The picture is full of brilliant spots, principally in the high lights and around the outlines.

The picture is granular.

CAUSES.

No safe edge has been used, or the paper was spoiled. Too old, or affected by emanations from gases.

The wax contains tallow. A slight addition of resin to the waxing solution is the remedy. The collodion had dried too much before the plate was immersed in water.

It is too soft or too fresh; addition of negative varnish. The film was hurt. The borders of the plates are too sharp.

If they were not on the plate since the beginning, they come from the water. The tissue was not lowered carefully upon the support, or the squeegeeing was not done in the right way.

The paper was too long in the sensitising bath, or the bath was too strong or too warm.

The tissue was not left long enough in contact with the support. Paper which has suffered from emanations of gases, or dried too fast, shows these defects very often.

The sensitised paper is spoiled by emanations from kitchen, stable, gas, or closets.

The exposed paper had not remained a sufficient time in cold water before effecting the transfer.

Same reason as the preceding. They form some minutes after the transfer, and as they are between the paper and the collodion, there is no remedy.

If hotter water does not remove them, then they are due to the alcohol which was still present in the collodion when making the transfer.

The negative was too dense. Expose the tissue before or after printing for a few seconds to daylight; or the paper was dried too fast, and consequently is too soluble.

The proper flexible support or plate was not well waxed; the waxing solution contains too much resin; the waxing was polished off entirely; or the flexible support was dried with too much heat.

It has been dipped in too hot water, or the alum bath was too strong.

The transfer paper was soaked in too cold water.

The second transfer was made too late.
MAX BOELTE in "Anthony's Bulletin."

NOTES FROM ABROAD.

(From our Special Correspondent.)

III.

THE LICHTDRUCK WORKS OF HERR OTTO AT DUSSELDORF.

IN Dusseldorf I have had the pleasure of seeing in operation the lichtdruck process at the works of Herr Wilhelm Otto, 42, Schadowstrasse. These works have belonged to Herr Otto for seven years, but were founded about thirty years before that by J. & R. Overbeck. One of the printing machines in use during my visit, and driven by a gas engine, was constructed by Messrs. Schmiers, Werner, & Stein, of Leipsic.

A solution is first prepared consisting of:—

Silicate of soda	60 grammes.
Water	120 "
The whites of two eggs.	

A well cleaned, thick piece of plate glass is coated with the above solution and dried; it is next washed for half an hour in running water, and dried again. By this means a fine, even, and insoluble grain is given to its surface.

The sensitising solution, which is next applied, consists of:—

Gelatine	20 grammes.
Water	200 "
Bichromate of ammonia	2 "
Bichromate of potash	2 "

The plate is then exposed under a negative. A gelatine negative is never used for the purpose if it can be avoided; in all cases, negatives taken by the wet collodion process are preferred.

In dull weather the printing is effected by the electric light, a suspended arc lamp being made to slowly vibrate like the ball of a pendulum before the printing frame, at a distance from the latter of about ten inches. This printing by artificial light is effected in from ten to forty-five minutes, according to the density and colour of the negative; by sunlight the time of printing is from three to ten minutes, according to circumstances.

After exposure the plate is washed in cold, running water for four hours, then placed upon a rack to dry during the night. It is next placed upon a levelling stand and some of the following solution is poured over it:—

Glycerine.....	1000 grammes.
Water	300 "
Ammonia (0·880).....	100 "
Thiosulphate of soda.....	25 "

This solution, which gives the gelatine the power of taking colour from the printing rollers, is left upon the plate for fifteen minutes or half an hour, then it is wiped off with a sponge. The surface of the plate is next dabbed with a clean, dry cloth, and the plate is ready for the printing machine.

If too much ink, or too strong ink, be applied in the first instance, there is much trouble in getting the plate clean again afterwards, but it must then be cleaned before good prints can be obtained. The back of the plate is cleaned with a knife before it is put upon the machine.

The chief difficulties of the process lie, as in all engraving printing, in the machining; the machine must be a good one, and the proper amount of ink and pressure to give good results must be carefully adjusted. I saw a specimen of lichtdruck work at Herr Otto's which had just been executed for a London photographic firm. It was a vulgar picture, comprising three large heads—a picture which would break the heart of any French, Italian, or, I hope, German artist, did he have to devote his skill to printing the same.

Herr Otto carries on, as well, a general photographic business. He has a portrait studio, and takes likenesses when necessary by the aid of his electric arc lamp; the little dynamo is driven by the gas engine. The same engine, by means of suitable apparatus, produces an air blast, by means of which the gelatine plates are dried, for Herr Otto makes his own plates for portraiture, and by Andra's formula. In photographing by the electric light, the rays from the arc do not, of course, fall directly upon the sitter; they are sent back by a great parabolic reflector made of whitewashed canvas. Herr Otto is agent in Dusseldorf for Stirn's coat-button camera, and from selected pictures taken therewith he has some fair enlargements, about eight inches in diameter.

DR. LIESEGANG'S ESTABLISHMENT AT DUSSELDORF.

Who has not heard of Dr. Edward Liesegang, whose establishment at 13, Cavalleriestrasse, Dusseldorf, is one of the great headquarters of photography in Europe? Externally his establishment is a large private house, built with that solidity which characterises houses in countries where householders are their own ground landlords; internally it has plenty of offices and clerks, for in Dr. Liesegang the man of science and the man of business are combined.

Dr. Liesegang was born in 1838 at Elberfeld, near Dusseldorf, and was educated at Vienna, Berlin, and Giessen Universities; he always devoted special attention to the subjects of chemistry and mathematics. About the year 1853 he bought a collodion positive process of Wulff, of Paris, for one hundred francs, and tried to make collodion; by the process direct positives on glass were transferred to leather, and the pictures were called "panotypes." The photographs looked nice, so the public began to ask him to make collodion for them, which he did, while in business with his father in Elberfeld. Thus he gradually became known in the photographic world. In 1859 he published the first edition of his *Handbuch der Photographie*, and in January, 1860, the first number of his monthly journal, the *Photographisches Archiv*. Next he started *Le Moniteur de la Photographie* in Paris, with M. Lacon as editor. In Dusseldorf he brought out in March, 1877, the *Lanterna Magica*, a monthly journal, which at present is the only one in Europe devoted specially to the optical lantern and allied subjects. Lastly, he issued the first number of the monthly journal *Der Amateur Photograph*, in January, 1887. In 1861 he issued the first *Photographischer Almanach*, the earliest annual volume of the kind. Up to the present time his *Handbuch der Photographie* has been translated into ten different languages. In 1873 Dr. Liesegang moved from Elberfeld to Dusseldorf, and at the present time he has some chemical works at Bilk, near Dusseldorf. He does not allow any stranger to go over any of his works. He has published a large number of books by different authors upon photography, including German editions of some of the best books by English writers upon the subject.

Among the historical curiosities on the premises at Dusseldorf is one of Sutton's panoramic cameras, made by Cox, of Ludgate-hill. Dr. Liesegang took some pictures with it in Jersey, and bought the French and Belgian patent rights for its construction, but he never made one. Its chief objectionable feature is that the curved plates are difficult both to coat and print. The printing was the greatest difficulty; contact had

to be effected by means of indiarubber backs, and to get equal illumination the printing frame had to have a motion of rotation. Dr. Liesegang has a modification of Johnson's pantascopic camera made by himself, and by means of which very large and perfectly sharp pictures can be taken with but a quarter-plate lens.

Another curiosity in the possession of Dr. Liesegang is a positive picture taken about 1864 in America, by the process of the late Wenderoth, of Philadelphia. Wenderoth, in his process, took a Daguerreotype plate, spat upon it, then rubbed it with a toothbrush to give it a dead instead of a polished surface; next he squeezed a positive carbon print down upon it, and afterwards fixed a glass over its face. Such pictures were turned out commercially for several years in the United States, but the process is now extinct. The first lichtdruck pictures were taken by Tessier du Mothay, at Metz, from plates of copper; Dr. Liesegang has some specimens of his work as good now as the day on which they were printed. Tessier du Mothay was a commercially unsuccessful photographic inventor; the last time Dr. Liesegang saw him was at the Hôtel de Ville in Paris, where he had a commission from Napoleon III. to perfect the zirconium light as produced by a method of extracting oxygen from the atmosphere.

About a dozen years ago, Mr. Jabez Hughes took Dr. Liesegang to Oxford, where he had to copy a water-colour painting for Queen Victoria, who examined the image of the picture upon the ground-glass of the camera, and remarked that it was a great pity that photographs could not be taken in natural colours. Dr. Liesegang then informed her that he had seen Niépce de St. Victor taking photographs in natural colours at the Louvre. Niépce could reproduce true greens, such as that of the emerald, but not the green of the leaves of trees; exposures of several hours' duration were necessary.

Dr. Liesegang obtained his degree of "Doctor" at Rostock, in Germany, for proficiency in chemistry. He is ably supported in the work relating to his different journals by his assistant-editor, Herr Hermann Sehnass, son of Dr. Von Julius Schnauss, the author of a valuable book upon photo-mechanical printing.

In my walks about Dusseldorf I chanced to see the house in which Mr. J. Hubert, the well-known London photographer, was born, in the street leading from the Market Place and through an archway to the Bridge of Boats over the Rhine. At the residence of Dr. Liesegang I had the pleasure of meeting Mr. William Lang, jun., who was travelling on the Continent, to make arrangements for the forwarding of interesting photographic works of high art to a forthcoming exhibition in Glasgow.

CELESTIAL PHOTOGRAPHY.

At a joint meeting of the Literary and Philosophical and Astronomical Societies of Liverpool, Mr. Herbert Sadler, F.R.A.S., read a paper on *Celestial Photography*, in which he referred to the great advances which had lately been made in astronomy by the assistance of photography. Starting from the first crude and imperfect pictures of the sun and moon, astronomy and photography had marched hand in hand, until the present methods of manipulation enabled us to photograph objects which the eye can never hope to see. The paper was profusely illustrated by celestial photographs, and in calling attention to a picture of *Capella*, Mr. Sadler explained that the rays which affected the plate started on their errand during the battle of Waterloo. As an illustration of the far-reaching power of the photographic eye, the map of the Pleiades, constructed by M. Wolf, contained 671 stars, and after a careful sounding in this direction with the largest telescope in the Paris Observatory, the author felt assured that all beyond was darkness, and that he had absolutely reached the utmost depths of space. But a photograph of the same district, taken by the Brothers Henry with a much smaller telescope, in one hour showed 1421 stars, against the 671 which had taken M. Wolf three years to map.

Our Editorial Table.

A STUDIO CAMERA.

By PERKEN, SON, & RAYMENT.

In these days of pocket, portable, and detective cameras, one is sometimes apt to forget the studio camera, which has, or ought to have, no claims to be considered as belonging to the featherweight fraternity. Especially is this the case when, as in the one now before us, such camera is constructed for 10 × 8 plates with reversing arrangement, by which the plate can be placed in either a vertical or horizontal position.

The studio camera of Messrs. Perken, Son, & Rayment, although not professedly one of the portable class, does, however, fold up in a wonderfully small bulk, more especially when its various appliances and great length, when fully extended, are taken into consideration. The range of focus capable is from four to twenty-eight inches, which, when a rapid doublet is employed, means a further focal power of

about two inches added to its already considerable range. With this camera, therefore, a lens of thirteen inches focus could be employed in copying a picture on a scale even larger than the original. The value of a great extension of the camera is now universally admitted, and with this instrument a lens may be employed in taking scenes on a telescopic scale. The camera in question has an ingeniously contrived swing back, and the lens is fixed upon a front which is rigidly attached to the baseboard, an advantage when either weighty lenses or those of long focus are employed; for whereas a tremor of the sensitive plate during exposure will only tend to a slight softening of the definition, an equal tremor of the frame, which carries the lens, may cause the image to dance over a large portion of the plate. The camera, however, has both horizontal and vertical sliding motions for the lens. Finished and fitted with singular care, and brass bound wherever necessary, this camera also possesses an easily unshipped division, by which two different pictures may be taken on one plate if desired.

Invited by the makers to say if in our estimation it could be improved in any way whatever for the purpose for which it is intended, we must answer, No.

STEREOSCOPIC APPLIANCES.

Rapid Lenses by WREAT, London. The Kershaw Shutter.

A PAIR of lenses of the very rapid doublet class, and accurately paired for stereoscopic work, is, we were about to say, on the editorial table, but as a matter of fact they are now on the editorial camera.

Dark weather demands rapid lenses, and those which Mr. Wray, of Highgate, London, has sent are certainly very rapid, for they give sharp crisp definition with an aperture much in excess of most lenses of the "rapid" genus, and while purporting to cover a 5×4 plate, we have made them cover (with a small diaphragm in this latter case) an 8×5 plate quite easily. For either instantaneous stereo work, or for a detective camera, they behave nobly—dull though the November weather be. Being symmetrical in construction they project an image with rectilinear accuracy. The equivalent focus of each is about five and a half inches.

Allied with the above is a shutter we have received from Mr. Kershaw. When lately in Manchester we heard much concerning the Kershaw shutter, and saw much good work effected by its aid, and now we have an opportunity of judging of its merits from personal trial. Mr. Kershaw's invention consists in a framework which slips upon the lenses (the one before us is for a binocular camera), the circular apertures in which are covered by an opaque screen, having in it a square opening to admit the light. There are axes at top and bottom, around which this screen winds. One of these axes is fitted with a spring, which is capable of being braced up to impart any desired degree of rapidity of action. The other serves to wind up the curtain; and the liberation of a catch, by pneumatic ball, throws a click out of gear, thus effecting an instantaneous passage of the aperture in the curtain across that of the lens.

CHRISTMAS CARD MOUNTS.

London: MANSELL & Co.

FROM Messrs. Mansell & Co., 271 and 273, Oxford-street, W., we have received samples of photographic mounts specially intended for the Christmas and New Year. The mottoes are seasonable and well selected, while the mounts themselves—elegantly finished in gold—are all that can be desired.

PRACTICAL GUIDE TO PHOTOGRAPHY.

By MARION & Co.

THIS is a reissue of a very useful work which we have lately reviewed. A leading feature in the present edition is the devoting, by way of commercial addendum, of over a hundred pages to a description of the various productions of this enterprising Company.

PATENTS COMPLETED.

[IMPROVEMENTS IN THE MANUFACTURE OF SENSITIVE PHOTOGRAPHIC FILMS AND IN APPARATUS THEREFOR

(A communication from GEORGE EASTMAN, Rochester, New York, United States of America, Manufacturer.)

No. 3530. ALFRED JULIUS BOULT, 323, High Holborn, Middlesex.—*March 8, 1887.*

SINCE the introduction of the article known as bromide paper for photographic positives and negatives, numerous attempts have been made to devise a practicable method of manufacturing the material on a large scale and at less expense, both in time and material, but until the present invention no material progress had been made and the manufacture was conducted by what may be termed the original processes, that is to say, either by laying the sensitised material on the paper with brushes, or the more common method of passing the strip of paper around rollers, uniting the ends of the strip to form an endless band, and by the rotation of the rollers causing the band to travel in contact with a body of emulsion until the entire surface had received a coating, when it was suspended or left hanging until dried.

A moment's consideration of the nature of the sensitised material, the conditions under which it is applied, and the changes to which the paper is subjected, will serve to show why the ordinary processes of coating and the machinery employed are incompetent to perform the operations and at the same time preserve the necessary conditions.

The sensitised emulsions, as ordinarily compounded, contains as the sensitive medium silver salts dissolved or held suspended in a mixture of water and gelatine, the latter serving as the vehicle for carrying and holding the sensitive material upon the paper. The silver salts are a valuable product, hence it is desirable that the minimum quantity capable of producing good work should be employed; and for that and other reasons only sufficient gelatine is mixed in the emulsion to produce, when applied to the paper, a film layer of just sufficient depth to retain the desired or requisite quantity of the sensitised medium.

As is obvious, the layer or film of emulsion deposited on the paper must be as free from spots and irregularities as possible, hence any treatment of the paper or coating before, during, or after the emulsion is applied, which will produce or favour the formation of spots, streaks, or irregularities in the surface or thickness of the film, will result in the production of defective and unsalable paper, involving the loss of much valuable time, labour, and material.

It must also be remembered that the emulsion is in a liquid condition when applied to the surface of the paper, that the paper becomes saturated by the water contained in the mixture, that no opportunity is afforded for a critical examination of the coating nor can the defects in its surface be removed or remedied after the gelatine is once set, and that the entire process has necessarily to be conducted in a photographic dark room; hence, if the finished article contains the irregularities and inequalities mentioned, they cannot readily be discovered or detected even by a critical examination,—the coating is so extremely thin—until the final test,—actual use—has been applied and then, and not before, can the mercantile and practical value of the material be ascertained.

It will be readily understood, therefore, why the ordinary processes employed for coating cloth, paper, and other materials, with paint, glue, paraffine, and other substances and compounds not requiring so even and regular a surface as photographic paper, whose irregularities are measured not by instruments but by the results produced by the action of light alone—why said processes and machines have not, and cannot as ordinarily worked, be used in the manufacture of photographic paper.

As before stated, notwithstanding the many attempts made to produce a successful article of bromide paper by a cheaper and more practicable method, the only process by which it was generally understood it could be made successfully and the only one in practical use at the time of this invention, was that in which a belt or band of paper with its ends united was caused to pass through a bath of emulsion; and when the band had been drawn through the liquid and the coating applied, it was either raised out of the bath and allowed to hang until dry, or, what is the same thing, was removed to a drying frame and suspended thereon.

The use of brushes for applying the coating, although attempted, has not proved successful, owing to the extreme difficulty experienced in applying the emulsion evenly throughout the entire surface of the paper.

After many unsuccessful attempts and the expenditure of much time, labour, and money, my foreign correspondent has succeeded in discovering a method of manipulation whereby, by a continuous process, he has been enabled to produce a commercial article of bromide paper expeditiously and cheaply in sheets of any desired dimensions and with the minimum of waste.

In the following specification and claims, the expression web, web of paper, fabric, paper, &c., is intended to mean the web or band drawn from the roll or other source of supply, whether that web be of paper, muslin, silk, or other material which may be employed; and similarly the expression emulsion, sensitised emulsion and the like, is intended to mean any emulsion solution or photographic substance, salted or unsalted, sensitised or unsensitised. Coating, coated, &c., refer to the coat or film spread upon the web.

This improvement in the method relates more particularly to the treatment of the paper after the coating has been applied, and consists, generally stated, in so conducting the operation that after the paper has been supplied with a thin and uniform coating of the emulsion, and while the layer is still in a fluid state the coated web of paper shall, while under sufficient tension to maintain its surface flat, be drawn or moved continuously in the same direction until the gelatine in the coating has set, after which and as rapidly as the web is delivered, it is hung in loops or deposited upon a frame where it is allowed to remain until the paper has thoroughly dried.

It is of the utmost importance in practising this improved process, that the paper (which is drawn from a roll of any desired dimensions) should receive an even coating of the fluid emulsion, and it has been found that this can best be secured by causing the strip or web of paper to pass into and emerge at an angle from a layer or body of the fluid emulsion, so that the paper as it rises from the level surface of the liquid may carry only so much of the emulsion as adheres to its surface, the surplus flowing back into the receptacle.

The web of paper, as it passes through the emulsion, takes up a large quantity of water which acts to expand and soften it, hence it becomes necessary to apply sufficient tension to draw it flat over the rollers or other supporting devices. The tension on the paper must be, however, so regulated that, while serving to maintain the web flat and move it at a uniform speed, it shall not produce wrinkles by the unequal strain upon the now weakened and expanded paper, for if such wrinkles or other irregularities on the surface occur, the still fluid coating will run irregularly and form in streaks on the paper.

It is to be observed, moreover, that after the coating has been evenly applied to the web, and while the latter bearing the fluid coating is continued in motion to preserve and maintain its uniformity, it is essential that the coated face be unobstructed while the material is setting, that is to say, it must be held and maintained out of contact with any foreign substance, such as pressing rolls, scrapers, or other devices, which, if permitted to so much as touch the coating, would defeat the purpose of the process by destroying the uniform character of the film and render the latter unfit for photographic purposes.

The rate of motion and distance intervening between the coating devices and the hang-up frame vary with the state of the atmosphere and the quality of the emulsion. Ordinarily, in using a machine such as hereinafter described, the rollers are driven at such speed as will advance the paper twenty feet a minute, and with the temperature of the room maintained at about sixty-five degrees, the hang-up is located at about thirty feet distance, that is to say, the paper is maintained in motion for about one to two minutes after leaving the coating bath before it is deposited upon the slat of the drying frame. The time and distance must, of course, be adjusted and regulated according to the temperature and state of the atmosphere, and, if desired, artificial cooling and drying devices may be employed, but under all circumstances, in order to prevent blemishes when practising the continuous process, the coated web must be kept in motion and flat until the gelatine has set so as to be incapable of further movement upon the surface of the paper, and when this stage has been reached, but not before, can it be suspended in loops upon the drying frame and remain there until the moisture has evaporated, without injury to the coating.

The movement of the web after the coating material has been evenly applied, and which is continued until the coating has set or stiffened so as to prevent running, is a progressive movement, the travel being at all times forwards, but in order that the flow of the material may be regulated, and the uniformity of the coating maintained, it is desirable that the direction, *i.e.*, the angle of inclination of the web during its progressive movement, should at times be reversed or altered, so that at one point it will travel upwards and subsequently downwards, or *vice versa*, thereby arresting or changing the direction of flow, if any takes place, of the liquid coating upon the travelling web.

Thus, in the machine illustrated, the web, as it emerges from the coating device, is caused to move first upward, then horizontally, then downwards, then horizontally, and again upward to the delivery roller.

Under certain circumstances, as when it is desired to use a thin emulsion or in warm weather, the setting of the coated film may be facilitated by reducing its temperature as it passes from the coating apparatus to the hang-up machine. This artificial cooling of the coated web may be accomplished by the use of a current of air, or by causing the web to pass over a surface the temperature of which is kept down as by a current of cold air, water, or a cooling mixture or compound. A fan-blower or other suitable device may be employed to produce a current of air, which is cooled by passing over ice or in any other preferred manner, the air being carefully strained from dust.

It is obvious that the process herein described is adapted to the coating of webs or strips of fabric with a surface coating of any material which has a tendency to run and streak after its application, and which possesses the property of setting or stiffening gradually while the web is maintained in motion, to preserve the uniform surface of the coating.

It will be observed that according to the present invention three distinct operations are required to produce the finished article, first, the application of the coating material; second, maintaining the web in motion until the coating thereon has set or stiffened sufficiently to prevent running; and third, depositing the coated web as rapidly as the coating sets or stiffens upon a support to dry, and further that all those operations are performed simultaneously, but upon different portions of the same continuous web or band of paper, so that while at one point in the length of the travelling web, the coating is being applied at another, it is setting or stiffening, and at still another and more advanced stage is delivered or deposited upon the drying frame.

The improved apparatus for manufacturing sensitive photographic films is represented in accompanying drawings.

The claims are:—1. The herein-described process of coating a continuous web with a uniform layer of emulsion, consisting in applying the emulsion to one side of the web as it is passed through the coating device, in artificially cooling the coated web, in keeping the coated web in continuous motion and the coated surface free from damage by contact until it has set, and finally in delivering the web to a suitable rack or frame to dry, substantially as described. 2. The herein-described process of coating a continuous web with a uniform layer of emulsion, consisting in applying the emulsion to the lower side of the web as it is passed through the coating device, in carrying the coated web on suitable supports around the coating apparatus, and keeping it continuously in motion and the coated surface free from damage by contact until the emulsion has set or stiffened sufficiently to prevent flowing, and in subsequently delivering the coated web to a suitable drying frame or rack substantially as and for the purposes set forth. 3. The herein-described

method of producing uniform coatings upon continuous webs which consists in applying the coated material in a fluid condition evenly upon the face of the web, and in changing the flow of the coating upon the web to regulate and maintain its uniformity and maintaining the web in motion and its coated surface free from damage by contact until the coating has set hardened or dried sufficiently to prevent running substantially as described. 4. The herein-described improvement in the art of producing photographic paper which consists in applying to one face of the web a uniform coating or surface of fluid sensitised emulsion, by causing the paper to emerge from the level surface of a body of emulsion, and subsequently maintaining the coated web in motion continuously and uniformly in the same direction and the surface of the coating free from damage by contact until the emulsion has set or stiffened sufficiently to prevent running substantially as and for the purposes set forth. 5. The herein-described process of producing sensitised photographic paper consisting in applying to a moving continuous web a uniform layer of sensitised emulsion, keeping said web in motion and the coated side free from damage by contact until the coating is set or stiffened sufficiently to prevent flowing and finally drying the coating. 6. The herein-described method of producing uniform coatings upon continuous webs which consists in applying the coating material in a fluid condition evenly upon the face of the web, and subsequently maintaining the web in motion and its coated surface free from damage by contact until the coating has set or hardened sufficiently to prevent running substantially as described. 7. The herein-described continuous process of producing sensitised photographic fabric consisting in applying in a suitable non-actinic light to a running continuous web a uniform layer of sensitive fluid emulsion, keeping said web in motion and the coated side free from damage by contact until the coating is set or stiffened sufficiently to prevent flowing, and finally while the web is in motion and the coating being applied depositing that part of the web on which the coating has set or stiffened at rest with relation to its supports to dry. 8. In a machine for coating a continuous web with emulsion the specified arrangement of the rollers about the emulsion trough whereby the coated web is carried around the said trough without the coated side coming in contact with said rollers and space is economised and sufficient time allowed for the coating to set before being transferred to the hang-up apparatus substantially as described and illustrated in the accompanying drawings. 9. The complete apparatus constructed and operating substantially as and for the purpose described and illustrated in the accompanying drawings.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST Tuesday night, at a meeting of the above Society, held at 5A, Pall Mall East, London, Mr. William England, Vice-President, occupied the chair.

Colonel NOVERRE said that after developing some of Eastman's stripping films with ammonia in the solution, a faint negative was left on the insoluble substratum; the sensitive film appeared to be thinner than desirable. He thought the negative itself in such cases to be too granular. What was the cause of the phenomenon?

Mr. ARNOLD SPILLER responded that Mr. Warnerke had discovered that under certain circumstances the film became insoluble where the image was formed; perhaps some of this insoluble matter adhered to the substratum.

Mr. WILLIAM BEDFORD called attention to an important modification of the platinumotype process recently published.

Mr. T. BOLAS knew no more about the new method than had been published.

Mr. G. SCAMELL said that an important question had been asked in THE BRITISH JOURNAL OF PHOTOGRAPHY, and never answered yet—"What is the best method of photographing upon wood?" Could any one give a reply?

Mr. E. COCKINO said that very little water must be used in any such process.

Colonel NOVERRE asked whether the image in brown platinumypes was all of platinum?

Mr. A. COWAN believed such to be the case.

Mr. COCKING stated that he had been erroneously described in the *Daily Telegraph* as "Manager of the Photographic Society of Great Britain," although in his letter to that journal he had correctly styled himself the Assistant Secretary to the Society and Manager of its Photographic Exhibition.

Mr. A. MACKIE said that some persons had been fooling several daily papers into the belief that by a commercial process they were taking photographs in natural colours.

Mr. W. COBB called attention to an advertisement of "The Photographic Company, Limited," in the *Standard* of November 22, which he said would be likely to convey the idea to the public that the Company was taking photographs in natural colours. Could not the Photographic Society take some action in the matter?

MESSRS. DEBENHAM, BOLAS, and others, made some strong remarks about the Cellerier-Parkes's process.

The CHAIRMAN stated that at one of the meetings of the Society in January, the subject of stereoscopy will be brought up; Mr. Donkin intends to bring some reflecting stereoscopes, and he hoped others would bring anything interesting relating to the subject.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, November 17, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. W. M. Ashman presided.

Messrs. F. H. Berry, W. B. Wright, and R. W. Goodden, were elected members of the Association.

The HON. SECRETARY announced that the Liverpool Amateur Photographic Association will hold a photographic exhibition for one fortnight, commencing March 5, 1888, at the Walker Art Gallery, Liverpool.

Mr. F. W. Cox exhibited a simple and very cheap Fletcher's burner, giving a solid flame for heating platinotype solutions.

Mr. F. A. BRIDGE said that it was a burner which consumed little gas.

The CHAIRMAN believed it to be used exclusively now in laboratories for heating small quantities of solutions.

Mr. A. HADDON stated that if it were used with the enamelled iron trays issued by the Platinotype Company the enamel would crack over the burner, because of the local concentration of heat; those trays should be made part of water baths, by placing them in zinc trays containing water, and then heating the water with the burner.

Mr. BRIDGE had had an enamelled dish in use over a bare flame for five or six years and it had not cracked; it was very thinly coated with enamel.

The CHAIRMAN had had one in use for twelve years over a bare flame for boiling down silver solutions; it exhibited no sign of a crack.

Mr. A. P. HIGGINS exhibited an arrangement for keeping emulsion warm while filtering, consisting of the inverted upper part of a bottle; a cork was placed in the inverted neck to let the neck of the funnel pass through, and the outer vessel thus made was filled with hot water. He had cut the bottle with a glass-cutter followed by the application of a hot iron.

The CHAIRMAN cut bottles by means of a string soaked in turpentine tied tightly round them; he then set fire to the turpentine and while the glass was very hot where the string had been, he dipped it in cold water.

Mr. BRIDGE had broken three bottles out of four by that plan.

Mr. W. H. PRIESTWICH had found the plan to work well except when the bottles were thicker upon one side than the other.

Mr. A. COWAN said that Mr. Leon Warnerke cut bottles by first filing a notch in them, and then drawing a crack slowly round each bottle by means of a red hot point of hard charcoal.

Mr. HADDON remarked that Mr. W. J. Wilson and himself had discovered that if they could get a diamond to cut a ring inside a sufficiently large tube, and then applied outside heat from a Bunsen's flame, that tube could be cut into definite lengths with certainty; at least there were but one or two failures in cutting twenty or thirty pieces.

Mr. W. H. HARRISON had read in an American periodical that a bottle could be cut by placing it in a pail of water, with the surface of the water covered by a thin layer of turpentine. The turpentine was then fired, and the flame split to pieces the bottle above the level of the water, but left the rest of the bottle intact, so it was alleged.

The CHAIRMAN exhibited a photograph rather less than life size of the human eye. Such photographs, he thought, would be useful to artists. In the one exhibited he could recognise the expression of Mr. Offord.

Mr. COWAN stated that there was more expression in the human mouth than in the eye.

Mr. A. MACKIE was once working in hospitals with Mr. Francis Galton, classifying the colours of human eyes; he (Mr. Mackie) then concluded that it was necessary to make thirty or forty colour charts and to number them before they could give the idea to others of the particular colour of any particular eye.

The CHAIRMAN exhibited a small photograph of an interior taken by the magnesium light and gaslight combined.

Mr. HARRISON said that *Industries* newspaper, of the week before, contained a statement that magnesium is now being sold by a firm in Antwerp at one shilling and tenpence per pound; it did not state if in powder, or in what form.

The CHAIRMAN said that the powder when burnt in a descending flame after being mixed with sand diffused much more smoke in the room than if burnt as ribbon; in the latter case much of the oxide fell as ash.

Mr. HARRISON responded that German experimenters had found out how to burn the powder without any smoke being liberated in the room, and without the use of a long chimney.

Mr. MACKIE stated that at the Photographic Club recently, a photograph had been taken by means of seven and a half grains of magnesium flashed off upon fifteen grains of guineotton.

Mr. COWAN added that the picture so obtained was well exposed.

Mr. EDGAR CLIFTON said that a friend of his was of opinion that a wick might be thickly charged with magnesium powder, then soaked in alcohol, and fired.

The CHAIRMAN believed that a friend of his would shortly exhibit before the Association a method of burning magnesium upon a blue cylinder made white hot with oxygen.

Mr. W. COBB asked what was the most prolific cause of white spots upon silver prints.

The CHAIRMAN replied that the causes were numberless; one fertile source was the use of albumenised paper kept too long before or after sensitising.

Mr. BRIDGE remarked that a lawsuit was going on about white spots in prints, and that several hundreds of pounds were at stake upon the result.

Mr. W. E. DEBENHAM had known spots to appear upon prints in the hypo or final washings from dust falling upon them from a badly plastered wall near the sink.

Mr. COBB asked how about prints in which white spots appeared several days or weeks after they were mounted.

The CHAIRMAN had known that to occur with prints mounted in a room below the toning and fixing room; small crystals or dust from the solutions which had penetrated the ceiling fell upon the prints.

Mr. BRIDGE had known spots to appear after a long time in prints upon one batch of white enamel mounts, but not upon prints mounted on another batch similar in appearance.

Mr. COBB said that he had found bronze powder to be the most fertile cause of white spots, because of the sulphide of tin therein.

The CHAIRMAN said that mounts of all colours might have bronze powder in them, in consequence of being printed in the works of a man who used bronze powder over other jobs, so that there would be plenty of its dust about the premises and the machinery.

At the meeting of the Association next Thursday, Mr. Bridge will read a paper upon *Spots on Prints*.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

The Committee of this Association met on the 17th inst. The minutes of the previous meeting having been read, the election of Messrs. J. O. Dewey, J. S. Grimshaw, W. C. Smith, and J. Joel was confirmed.

The Committee then considered an application for aid to enable a member to proceed to a situation. The sum of 2*l.* was granted.

The following letter received under date of the 11th inst. :—"Dear Sir,—I am directed to hand you enclosed cheque, value 32*l.* 5*s.*, being the net amount received as entrance fees from ladies and gentlemen (258 in number) who have contributed their productions to our Third Annual International Amateur Photographic Exhibition, 1887. When the pictures are exhibited at our Regent-street Gallery we entertain the hope that the contributions we shall invite from visitors may form an important addition to our present donation.—I am, dear Sir, yours faithfully, S. Clark, Secretary, London Stereoscopic and Photographic Company, Limited."

The Committee passed unanimously the following :—"That the Committee of the Photographers' Benevolent Association tender their best thanks to the Managers of the London Stereoscopic Company for handing to the Benevolent Association the entrance fees of the contributors to their Exhibition."

A letter was then read from the North London Photographic Society, as follows :—"Dear Sir,—I have much pleasure in handing you a cheque for 1*l.* 4*s.*, being the proceeds of an impromptu collection at our dinner last night.—H. M. Smith, Hon. Secretary."

A member of the Committee then stated he was authorised to hand over the sum of twenty guineas to the Association on the conditions that 500*l.* should be obtained within twelve months for the express purpose of forming the nucleus to an orphanage. This generous offer was received with enthusiasm, the Committee pledging themselves to use their utmost endeavours to fulfil the requirements of the conditions. The amount was then handed over in trust, and the meeting terminated.

CAMERA CLUB.

At the lantern evening (Thursday, November 17) there was an unusually excellent and varied show of slides. Amongst the exhibitors were Messrs. C. B. Wright, P. Newman, Fison, P. Evans, Frith, Stainthorpe, Davison, Barclay, and Lionel Cowan.

The first part of the evening was devoted to pictures taken in Norway by Messrs. C. B. Wright and Fison, and to Swiss scenery by Mr. P. Newman. Mr. Fison's series included some interesting slides showing scenes in Norwegian villages, and those of Messrs. Wright and Newman comprised most beautiful and artistic effects of clouds and atmosphere amongst the mountains and lakes of Norway and Switzerland respectively.

After an interval Mr. Evans showed a very fine set of transparencies of cathedral interiors, also country studies; Mr. Frith a set from negatives taken in Egypt, and Mr. Barclay several illustrating work done on Club excursions. The lantern was worked by Messrs. Lionel Clark and E. Ferrero.

The subject for Thursday, December 1, is *Photography as Applied to the Arts and Sciences*, when Mr. T. C. Hepworth will lecture and show illustrations. Meeting at eight p.m.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

At a meeting held at Myddelton Hall on the 15th instant, Mr. E. Traill Hiscock in the chair, Mr. R. S. Allan was elected an honorary member of the Society.

A large number of views of Lisbon and neighbourhood were passed round by Mr. A. P. Higgins, and a selection taken in Holland by Mr. A. C. Cosser followed.

Mr. E. W. PARFITT showed two negatives taken under similar conditions; he desired to know why the difference in quality.

Mr. A. PRINGLE thought one had been slightly fogged.

Mr. F. W. COX then read a paper on *The Platinotype Process* [see page 743], and developed several exposed prints.

Mr. J. TRAILL TAYLOR (President) testified to the permanency of platinotype prints, and referred to some which had been subjected to extremes of temperature for some years and were now as good as when first made. Other prints made in silver at the same time had faded very much.

Mr. W. COBB confirmed the President's remarks as to permanence, and mentioned that he took the first medal given for this class of print.

Mr. PRINGLE said his name had been mentioned in connexion with the question of the permanence of these prints, and he should like to correct a misunderstanding. He had put platinotype prints to a series of tests quite satisfactory to the Company. He found by treating them with sulphuretted hydrogen he could materially reduce the image, but under ordinary conditions he believed them to be absolutely permanent.

Mr. A. COWAN spoke of a difficulty in matching panoramic views by this process. On one occasion when he desired to match a picture four feet long from four negatives it was necessary to produce eighty-four prints in order to get twenty-four alike in tone.

Mr. W. M. ASHMAN alluded to the difficulty of printing in skies from separate negatives, and congratulated the lecturer upon the results shown.

Mr. BISHOP (a visitor) expressed his pleasure at being present to witness the demonstration of the process, being one in which he took a great interest, and thanked the Society for their kindness in inviting non-members to their lectures.

A hearty vote of thanks was accorded to the lecturer.

The next meeting will take place on December 6, when Mr. T. Charters White will lecture on *Photo-micrography*. Visitors are invited.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held at the rooms, 36, George-street, on Wednesday, November 9.—Mr. A. Coventry, Vice-President, in the chair.

The minutes of the previous meeting were read and confirmed.

The ballot was taken and Mr. E. G. Wrigley admitted a member.

Mr. H. SMITH gave an account of some recent experiences in the working of stripping films, and exhibited many stereoscopic transparencies produced on stripping films attached to glass plates. Mr. Smith gave details of his method of printing these stereoscopic pictures, which was briefly as follows. The negative was first measured to the exact requirements, the film was cut to the size required for the two stereoscopic pictures, then folded in two with a piece of opaque paper between, and in an ordinary printing frame the right-hand side of the film was printed from the left side of the negative, then reversed, viz., the left-hand portion of the film printed from the right-hand portion of the negative. He could thus, by correctly masking the negative and adjusting the folded film to lines drawn upon the mask on the negative, print the transparencies at any distance apart, as he wished. When the films were squeezed on to glass, and dried in blotting-paper, they gave a little appearance of ground-glass but not sufficient to dispense with a ground-glass. Mr. Smith replied to many questions from the members, the subject of stereoscopic printing and mounting being one of great interest.

The CHAIRMAN said the name of Mr. Abel Heywood, jun., was on the circular for a paper on *Pumpley's Films*, but this being the last night before the closing of the Royal Jubilee Exhibition, and as Mr. Heywood was a member of the Executive Committee of the Exhibition, he was obliged to attend a very important meeting there.

The HON. SECRETARY (Mr. W. I. Chadwick) said as Mr. Heywood was unable to be present he had himself come forward as a poor substitute, and read a paper on *Transparency Making and Stereoscopic Work*, exhibiting several pieces of apparatus used in that branch of photography. Mr. Chadwick said he had brought the apparatus from home that morning and intended to snatch an hour or so during the day in which to write his paper, but was sorry to say he had found very little time, and had therefore very little to read, but he would "talk" the remainder.

At the conclusion of Mr. Chadwick's communication the formal meeting was adjourned, and the members passed around the room to inspect a series of about one hundred and fifty stereoscopic transparencies, views of the Royal Jubilee Exhibition taken by the Hon. Secretary. About thirty-five to forty stereoscopes were provided and arranged on tables properly illuminated. The admiration of these pictures was universal, and the following is the style of remarks that were passed by the members:—"I've been to the Exhibition twenty or thirty times, but I declare I have never seen so much of it as we have to-night." "Oh, I say, Smith, come and look at this one, isn't it splendid! How much does a stereoscopic kit cost?" "I never thought I should ever go into stereoscopic work again, but I am quite converted to-night." "I tell you what it is, Chadwick, your paper and exhibition to-night will, I am afraid, cost me ten pounds for a stereoscopic camera and lenses."

A vote of thanks was passed to the Hon. Secretary in complimentary terms, and in reply Mr. CHADWICK said he would accept all their compliments not for himself but for the stereoscope.

CHELTENHAM PHOTOGRAPHIC SOCIETY.

ANNUAL general meeting held November 10, at 4, Clarence-street.

The formal business consisted of the election of officers, which resulted in last year's officers retaining their posts.

Certain variations in the rules having been agreed to, the meeting proceeded to examine an exhibit of apparatus sent by Mr. McKellen.

General DAWSON produced and explained Mr. McKellen's camera with all the recent additions, including the new back which enables the operator to dispense with the focussing cloth.

Mr. BEETHAM showed the working of the roller slide of the same maker. This differs in some respects from the Eastman slide, having a means of marking the paper between each two pictures, and also in recording automatically the number of exposures made.

Sergeant's shutter was also on view, notable for its small size and easy working.

The exhibition finished, General DAWSON introduced the subject of stripping films, showing his own negatives and prints, and calling attention to the different effects produced, according as one side or the other of the gelatine skin is placed in contact with the negative, in one case producing a clear negative, in the other a ground-glass effect, very suitable for thin negatives.

It was arranged that at the next meeting Mr. Beetham should demonstrate the process of developing and stripping these films.

A vote of thanks was passed to Mr. McKellen for sending his apparatus.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE following is an abstract of the annual report presented at the meeting on November 2.

In presenting the twenty-eighth annual Report the Council are again pleased to have it in their power to congratulate the members upon the good progress which the Society continues to make. During the session forty-nine new members have been elected, and after making the deductions which a year's vicissitudes bring, in removals, resignations, and deaths, the total presently stands at 425, as against 393 last year. In one instance death deprived the Society of one who has been almost from its beginning a prominent figure in its history. Mr. J. G. Tunny died on September 24, after a protracted and painful illness. He ever took an active interest in the welfare of the Society, and was repeatedly an office-bearer. Nine ordinary and thirteen Council meetings have been held, and besides numerous sub-committee meetings. A number of outdoor excursions took place, which, though not numerously attended, were much enjoyed by those who took part in them. Two popular evenings were given in Queen-street Hall, which was crowded on each occasion. On both evenings vocal and instrumental music was provided by members and friends.

The annual exhibition of members' work took place in December, and was considered a very creditable one. About two hundred and sixty pictures were shown in prints, ceramics, and transparencies. The presentation print for the session was issued in August, from a negative by Mr. H. P. Robinson. The subject is entitled *A Chat with the Miller*. It is executed in colotype, and has been much approved. An interesting feature of the year was the visit to Edinburgh, on July 8, of a large excursion party from the Photographic Convention of the United Kingdom, then meeting at Glasgow. The report alluded to the papers and communications, demonstrations of film-stripping, and apparatus exhibited, all of which have been duly chronicled in these columns.

SOCIETY OF AMATEUR PHOTOGRAPHERS OF NEW YORK.

At the meeting of the 11th ultimo, President Walker in the chair, after some preliminary business,

The CHAIRMAN said, I wish to call your attention to the use of hydrokinone as a developer. It has been used with great satisfaction by some of our members, and with the best results. It does not stain the hands, develops clearly without producing chemical fog, and gives a negative of good colour, with any degree of intensity required. A single mixture may be used for the development of a large number of plates, probably fifty or more, without any addition being made to it. It works more slowly toward the end of the day's use, but may be restored in a measure by a small addition of alkali. If a dozen plates are developed, the developer may be returned to the bottle and kept for another day's use. The only disadvantage thus far discovered is the lack of promptness with which the image appears, making the total time occupied in developing a plate perhaps fifty per cent. longer than would have been the case had pyro been used. But the results are fully equal, if not superior, to those ordinarily obtained by the use of the more familiar agent. In using hydrokinone it does not appear to be as necessary to rock the plate as is usually done with pyro, so a number of plates can be put in a dish and left there for development while other matters are being attended to, an occasional glance at them being all that is necessary until they are ready for removal to the hypo bath. It may also be used for bromide prints, and is especially good for lantern slides. A very good formula would be that adopted by Dr. Piffard; say, for No. 1, make saturated solution of hydrokinone about fifteen grains to the ounce; to each ounce of this add 60 grains crystallised sulphite of soda. For No. 2, make a solution containing 30 grains crystallised carbonate of soda to each ounce of water. For ordinary development mix equal parts of No. 1 and No. 2 to each ounce of water, and after using return developer to bottle and keep to use again. With over exposures a little bromide of potash may be used with advantage, but less than would ordinarily be used with pyro under the same circumstances. For under exposure less of No. 1 and more of No. 2, also plenty of water and patience. Photographers of all classes have long made research for some practical method, simple in manipulation and cheap as to cost, for use in making photographs at night. Electricity is expensive, the magnesium ribbon is too feeble and uncertain, and all have so far proved of no appreciable value for general use. To-night, however, Dr. H. G. Piffard, one of our most active members, will read an article upon a recent method devised by him for the production of such a light, and will exhibit for your instruction the whole operation of using it.

Dr. PIFFARD then read a paper on *A Simple Method of Making Instantaneous Portraits and other Photographs at Night* [see page 744].

Mr. ROCKWOOD: Last evening Dr. Piffard was at my gallery, and I made some negatives interposing a screen between the source of light and the sitter, thus affording an opportunity to soften the light if necessary. This picture of a little child which I have here, and which you can see, will serve to show you how quickly it was taken. I was at the child's side tickling her, and just as she said, "Oh, don't," her picture was taken, and you see her eyes have a very laughing expression. [The speaker then exhibited other photographs taken by agency of the light], and continued: There will be emergencies where it will be of the greatest possible use. I think it is practicable to attach it to an instrument which has got a small camera—a pistol, for instance—which will be uncovered at the moment of the flash, so that the picture will be taken by the light at the same time, and certainly anything within a distance of fifteen or twenty feet will be photographed accurately and quickly. I shall certainly introduce it to supply the light which is necessary for me to take photographs with in the latter part of the day. Very soon we will be in the short days when the light is very poor and insufficient, especially after half-past four or five o'clock, and I shall certainly supplement my day's work to the extent of an hour or so by the use of this light.

The PRESIDENT: I conceive this to be a very useful device for amateurs for taking photographs at home, or where they are spending their evenings out, and desire to take photographs of their family and friends. It will be of inestimable use to them, because the great difficulty of the amateur is want of time during the day to take photographs. This is the general complaint, that they haven't time, and in the evening heretofore they could not take photographs. But the light exhibited this evening affords the means, and if it is all that is claimed for it, will be a great boon for us all.

Mr. ROCKWOOD: It is proper to place a little emphasis on the fact that a screen made of thin material, such as Swiss muslin, should be introduced between the light and the subject. It serves to soften the light very effectually. This is why we get such perfect roundness in the picture which you have observed here.

Dr. H. VALENTINE KNAGGS, of London, was then introduced, and said: With respect to hydrokinone, I have used that a great deal in the development of lantern slides. I find it one of the best developers you can use for that purpose when they are made on bromide instead of on chloride plates. I have used the ordinary slow plates largely for lantern slides, and with this developer too, and I find it is very good for the simple reason that it does not produce fog. If you use the pyro or ferrous oxalate you will find that if you expose your dry plate underneath the negative in the ordinary way that you will get more or less fog. Of course that does not happen with a chloride plate, but when you have an ordinary bromide plate it certainly does.

Mr. BELLSMITH, of the Eastman Dry Plate and Film Company, of Rochester, then gave a demonstration of stripping films.

Mr. F. C. BEACH: I have a shutter here which is intended to go into the place occupied by the diaphragm. It is mounted on a flat piece of brass which forms a back to hold the disc operating the shutter. The shutter is merely a round disc of metal fastened by an arm to a wheel or disc about two inches in diameter. The novelty in this particularly is the escapement or catch for letting off the shutter, and also for adjusting it to make a time exposure. It is very simple and very certain. It is nothing more than the escapement which you see in a clock, and is divided in the centre, the lower knob being fastened to a little lever, and as you move this arm to the right or to the left it allows the lower leg of the escapement to catch the projection on the drum at the back of the disc, in which is a special spring which operates the shutter, and that spring is made strong or weak according as you turn the pointer on the back. To operate the shutter you turn it around as I have indicated, and you will see the movement. It simply goes and returns. To make a time exposure you simply move the upper lever to the further pin and compress the bulb, and then by releasing the bulb the shutter impinges there [indicating]; by again releasing the bulb it closes so that you can make them as rapid or as long as you hold it. There is nothing about it to get out of order, and it has the advantage of working between the lenses, and by a peculiar movement it allows more exposure to the foreground than to the sky. The escapement part is the invention of Mr. Gregg, and that is the main improvement. The other part of the shutter is patterned after the Grinstead shutter which is sold in England.

Mr. Fisk then exhibited a London made camera, remarking,—"There is no doubt at all in my mind but what America can build better yachts, or at least faster ones than England; but certainly England can teach us how to make cameras."

The meeting thereafter adjourned.

Correspondence.

THE HISTORY OF PHOTOGRAPHY.

To the Editors.

GENTLEMEN,—In my forthcoming book on *The History of Photography* I believe Mr. B. J. Sayce will find that I have done full justice to his important discovery of collodio-bromide emulsion in 1861. The title of my article in your issue of November 4 was *The History of the Gelatino-bromide Process*. In anything like a general review of the progress of photography I should have drawn marked attention to Mr. Sayce's claims.

With reference to Mr. W. H. Harrison's inquiry, just at present I am unable to refer to my books, but I believe Gustave le Gray's book was published in France in 1849 (English translation appeared in 1850). Halleur's book was published in Germany a year or two later, and an English edition also appeared (see my *Bibliography of Photography* for details of the English editions).—I am, yours, &c.,

W. JEROME HARRISON.

Science Laboratory, Icknield Street, Birmingham.

DEVELOPING EXPERIENCES.

To the Editors.

GENTLEMEN,—I have been experimenting with the modification of Beach's developer incidentally referred to in your article on the *Responsibilities of Plate Makers* in the JOURNAL for November 4, and as the results may be interesting to yourselves and readers I give them herewith.

I first of all made up a quantity of the solution strictly in accordance with the proportions given, using hot water to expedite the solution of the salts, sufficient being added to make up the bulk to ten ounces. On cooling, the greater portion of the ferrocyanide crystallised out, and I found that the addition of two ounces more water was necessary to redissolve the deposited crystals and to retain them in solution.

I now proceeded to develop two portions of a roll of Eastman's stripping film, which had been exposed on the same subject under identical conditions as to light, stop, and duration of exposure. One I developed with Beach's normal potash developer and the other with the ferrocyanide modification. The amount of pyro solution was the same in both cases—one drachm. Of the normal potash solution I used half a drachm, which was amply sufficient for a rapid development of the picture. Using a similar quantity of the ferrocyanide modification no trace of the picture was visible after five or six minutes immersion, and I found that further additions, amounting in all to one and a half drachms, were necessary to complete development. I can detect no material difference in the colour of the resulting negatives, which I send for your inspection.—I am, yours, &c.,

EXPERTO CREDE.

PHOTO-MICROGRAPHS AT PALL MALL.

To the Editors.

GENTLEMEN,—Mr. Pringle is quite right, your columns are not the place for a discussion on bacteriology; but I should like to say this one word, that at the very pleasant chat with Mr. Pringle all I "admitted" was that I had not read Dr. Klein's book *Micro-organisms*, or Dr. Crookshank's more recent one. I do not admit that I know "nothing whatever about it," for I know very surely from my general (and special) reading that when I read Dr. Klein's book, as I mean at once to do, I shall be familiar with all the arguments he puts forth. If I get converted from the error of my ways, and turn to the light that is with Mr. Pringle and his apostles, I will confess it with alacrity.

By "the beautiful and artistic" I meant *artistic truth to nature*, but when she is ugly or uninteresting I don't want to photograph her. In such objects as I exhibited at Pall Mall I mean, therefore, more than ever to stick to the "artistic and beautiful," or, in other words, "pictorial effect." In physiological work truth to nature may not always, I allow, make "pretty pictures," but I can't believe Mr. Pringle means to limit the meaning of "artistic and beautiful" to "pretty pictures."

I very heartily agree with all of Mr. Procter's letter, and am really obliged to him for it. I only "abandoned the entrenchment" because your columns are hardly the place for its defence. I hope Mr. Pringle enjoyed Mr. Procter's letter, and will—may I say it?—profit by it also.—I am, yours, &c.,

FRED. H. EVANS.

158, Osbaldeston-road, N., November 21, 1887.

¶ P.S.—May I correct a grotesque misprint in my letter of November 4? "Hereditary server" should have been "hereditary sewer."

"ADCOCK" AND "MONITOR."

To the Editors.

GENTLEMEN,—Permit me to notice "Monitor's" criticism of my little paper, read at the Camera Club on October 6. Although adverse to my views it is so kindly and fairly put that I have had pleasure in reading it.

It is, I think, possible, the altered circumstances of Trafalgar-square may somewhat affect "Monitor's" opinion of my advice to amateurs "to go and take the sprawling groups to be found there on a sunny day." I am ready to admit the groups I saw there three weeks ago seemed very unlikely stuff for picture making. It is even possible that, had my later experiences come to me sooner, I might have thought the impressions made on me in July mere fleeting things that had passed, and too unlikely to occur again, to make recommendation of them a strong point. But supposing the things of which I spoke had not taken the turn they have, or that they again occur next summer, would a camera taking either a group on a bench in Trafalgar-square, or the paviers in Regent-street when closed to all but footway traffic, cause an obstruction? I think not. I think I could have taken twenty shots a-day in either place without any complaint of obstruction or inconvenience to man, woman, or vehicle.

I read with much amusement a description of "Monitor's" experiences in a London street. It would be so new to myself that I think I would like another summer to try my hand, even if I incur some chaff in doing so. The clever, witty fellow "Monitor" met with might be absent. This individual is frequently but not always found, and without him the fun caused at "Monitor's" expense might not be forthcoming. If I am wrong in thinking the difficulties of getting shots are less than "Monitor" found I shall be glad next autumn to say so. But even then I shall cling to the opinion long held, that true pathos may be got into a photograph by picking up the models the streets afford, and, after considering what can be done with them, doing it. *Where?* is another question. It is a debatable one. It would be made easier to the members of the Camera Club had it on its premises any den with a top light, large enough to hold a sitter, a camera, and an operator. Assuming one half or more London amateurs live in the suburbs, it seems likely they possess a piece of back-yard or garden. Here is a studio. For twenty years I photographed the figure in nothing better than the shade given by a south wall, and that can be got at most suburban houses. If the figure have any charms, the amateur may study it there; if not, let him pursue view-hunting and put his own value on results.

My aim in another respect, I think rather misunderstood by "Monitor," if, as I suppose, he thinks I would set up a camera and take, under all circumstances, a subject where I found it, he has misjudged my meaning, or I have said what I meant not. There are materials in the streets I would not accept off-hand, focus them, and take them. No; I would rather consider them, negotiate with them, and make them what I wanted. If in the Strand I saw a picturesque flower-girl, would I think it essential I should take her there? Certainly not! Telling her what I wanted, I would induce her to go to one of the quiet by-streets and pose as a flower-vendor there. I would pay her better for doing it than she would get paid by refusing. I would even ask a passer-by to aid a better picture by seeming to be a customer for her flowers—that is, just for the minute necessary to snap the picture.

I am even at issue with "Monitor" as to the impossibility of getting a child, a dog, and a doorstep, into a picture, under such circumstances as would speak a language to the onlooker, if not as powerful as that rendered by the artist, a lesser sermon on the same theme, but not in Seven Dials or the slums.

I am, gentlemen, about to send to you, with the request you will give them to "Monitor," five $7\frac{1}{2} \times 5$ studies, taken last week. I met a poor chap who has often been to me a model, looking pinched and pined. I told him to come to my *atelier* the following morning. In the meantime I thought over a few subjects, put half-a-dozen plates into my dark slides, and on the morrow, in less than an hour, I had exposed five plates, five seconds each, by my Dallmeyer L.A.A. rapid rectilinear (open lens); and my sitter, poor Topey, had filled my water-tank and gone away to get a decent meal. In the evening I had pleasure in developing these plates. They are nothing, have no intrinsic value; but I prefer them to views, and I took them in less time than I should be hunting for one, even if near home. To indicate to your readers the subject of these prints, I send the

titles, I call them by—1, *Enforced Idleness*; 2, *Private Affairs, urgent*; 3, *Brooding*; 4, *Thinking, hardly of others*; 5, *Prospects brightening*.—I am, yours, &c.,

WILLIAM ADCOCK.

Melton Mowbray, November 21, 1887.

Exchange Column.

A 12x12 studio camera in exchange for whole or half-plate tourist camera and slides.—Address, S. GRANT, 419, Kingsland-road, E.
Wanted, whole or half-plate apparatus in exchange for fifty-four-inch bicycle as good as new.—Address, C. HAWKINS, 37, Tunis-road, Shepherd's Bush.
Wanted, whole-plate portrait lens in exchange for a magic lantern, a 7½x7½ camera, and a quarter-plate lens and camera.—Address, JAMES DENTON, 70, Sheffield-road, Barnsley.
A quantity of quarter-plate negatives, mixed subject, suitable for printing lantern slides, in exchange for some slipping slides or quarter-plate negatives of other subjects.—Address, R. J. SHEERMAN, 147, Clarence-road, Lower Clapton.

Answers to Correspondents.

PHOTOGRAPH REGISTERED:—

H. MOWER, Birmingham.—*Photograph of twin children born at Comden-street Birmingham, joined together at the stomach.*

THE THISTLE.—By a mistake, discovered too late to be rectified in time, the illustration we gave last week was entitled *The Thistle*, instead of *Yachts on the Clyde*.

J. LESTER.—The requirements for silvering mirrors may be had at any chemist's.
F. B.—By adding cyanide of potassium the precipitate ought to be dissolved; if not, filter it out and use the clear solution.

J. ADAMS.—In stating that the yacht picture by Mr. Hyslop which we published last week was the *Thistle*, we were unwittingly guilty of an inaccuracy. It was not the *Thistle*.

COLLO.—1. No work specially devoted to the subject of collotype has been published in this country.—2. Either the ordinary lithographic press or that used for letterpress printing may be employed.

LUX.—By inserting a plano-convex lens between the condensers and the light a great addition to the illuminating power will result. Either of the lenses mentioned will answer for enlarging a portrait.

AN OPERATOR suggests that principals and operators in establishments where a number of hands are employed should take up a subscription for the Jennings's Fund. "Photographers," he says, "as a rule, I am afraid, too often forget how much they are indebted to scientific amateurs who freely publish their results."

N. W.—It is by no means uncommon for a difficulty to be experienced in getting the chloride of silver precipitated from the washing waters of ready sensitised paper to subside. If, however, a little nitric acid be added, and the whole *vigorously* stirred up, the silver will then subside quickly. Hydrochloric acid is better than salt for precipitating the silver from washing waters.

WOODVILLE GRAY.—1. We scarcely understand your query, as you do not say the kind of transfer you require. We, however, presume you mean one for photo-lithography; if so, we cannot understand why the lines in the negative, which ought to be black in the transfer, came white on a black ground, and when you used a transparency, still got blacks where there ought to be whites, and *vice versa*. For photo-lithography vigorous negatives with perfectly clear lines are essential. The property of bichromated gelatine, or albumen, after exposure to light is to render it non-absorbent of moisture, hence the fatty ink adheres to those parts while it is rejected where moisture is absorbed. Therefore a positive cannot be used to get a positive image—it must be a negative.—2. The cause of the gelatine splitting off is that the plates were over dried, thus causing a too powerful contraction of the gelatine.

J. R. G. writes: "1. Will you please tell me the best method of mounting prints on calico or other fabrics?—2. I have bought a wooden studio twenty-four feet by nine feet, and seven feet six inches high to the eaves; it has eight feet of glass on top both sides, also eight feet along sides, but it does not come to the bottom by two feet (glass all at one end of the studio), and I would like you to tell whether it will be necessary to have it altered or not. If so, where should glass be placed?"—Reply: 1. Strain the calico on a wooden frame, damp it, and then mount the print upon it with starch in the same way as you would on cardboard.—2. The glass need not be lower than it is. We should, however, advise you to alter the position of the glass, bringing it more towards the centre of the building, starting it, say, about four feet or four feet six inches from the end, as you will require about this to be opaque over the sitter. Perhaps the simplest plan will be to add about this space on to the length of the studio, making it opaque. The glass will then be in the right position.

EMBW VALE.—[But that we know that the following is genuine we should have treated it as an attempted joke.]—"Will you kindly give me your opinion on the following in your next 'Answers to Correspondents' under the *nom de plume* 'Ebbw Vale'! A friend who possessed six unopened rolls of Eastman negative paper (7½x5) for which she had no use, and which she could not otherwise dispose of, sent them to a refiner, together with ten unused glass plates of the same size, the original cost being, six rolls at 8s., 2l. 8s.; plates, say, 4s. 6d.; total, 2l. 12s. 6d. She paid carriage, and received from the refiner 2s. After hearing so much of the way in which competition has reduced the price of plates, &c., to within a fraction of their cost price, does not this look as if the refiner was making too good a thing of it?"—We wonder, if our correspondent had sent his lenses to the nearest metal founder to be utilised as old brass, would he complain that the sum received bore an astonishing disproportion to the cost price? We are truly surprised that so much as 2s. was realised after the expense of reducing.

J. H.—Mr. Hyslop employed a single landscape lens. We are unaware of the nature of his camera, but bear in mind it is the *man*, not the *camera*.

CITIZEN wishes to know how to write on the negative.—We presume he means so that the inscription appears white on the print, the same as in the case of the titles on the published photographs of scenery. This is done by writing in the names neatly with a sable pencil charged with black varnish. To increase the opacity of the varnish it is sometimes exposed to the air in an open vessel for a day or so, for a portion of the solvents to evaporate before using; or a little lampblack may be added to thicken it.

PIERRE REYON (Banquier à Gray) asks: "1. What would be the best way to revive prints with the silver salts turned completely yellow—(a), on the supposition that they can be removed from the Bristol boards upon which they are mounted; (b), in the event of not being able to remove them from the cards on which they are mounted?—2. For enlargements not exceeding 10x12 (English measurement), what would be the best paper to use, 1 or 2? and which of the three sorts that they sell would be preferable?"—In reply: 1. There is no satisfactory method of restoring faded prints. The yellowness may, however, be removed by immersing the prints in a dilute solution of bichloride of mercury. For this treatment the prints should be removed from their mounts. If this cannot be done a pad of blotting-paper moistened with the mercurial solution may be laid on the print and the whole put under pressure till the tint is removed, then fresh blotting-paper wetted with clean water must be applied to remove the free bichloride. But this treatment is not to be recommended.—2. There is not much to choose between them. Perhaps No. 1 has the largest sale. The kind selected is much a matter of taste; the rough surface yields the most artistic results. The others have a glossy surface.

ROBT. STEWART asks: "Might I ask you to answer the following queries?—1. What is a fair price for a business with a turnover of 300% per year?—2. Does the price include any apparatus or fixtures or negatives?—3. In strengthening the acetate of soda toning bath, what proportion of acetate to gold do you add?—4. What lens would you recommend for 20x16 direct portraits in the studio—a Voigtlander's Euryscope, a rapid rectilinear or symmetrical, or a portrait lens pure and simple? Of course, if an equally good lens for portraiture could be had that would also take a view, so much the better, but I should not care to sacrifice quality of portrait for this."—1. This is a purely business matter, and we can offer no opinion. Perhaps some of our readers, better informed on the subject than we are, will give their ideas.—2. This, of course, is a matter of arrangement between buyer and seller.—3. It is not necessary to add acetate of soda every time gold is added. A little fresh acetate now and then is all that is required.—4. Either of the lenses named will do quite well for portraits, and for views as well. The only advantage possessed by a portrait combination is its large aperture, and, consequently, greater rapidity in working. It will yield no better picture. If a portrait lens be stopped down to the same ratio as a lens of the "rapid" type, it will then only have the same degree of rapidity.

A CORRESPONDENT writes: "I take the liberty of calling your attention to the remarks made on page 723 of this week's issue of the JOURNAL, on the copyright case against Messrs. Tuck & Sons. You there state, in giving the judge's decision, that the plaintiff failed through improper registration. This was so. But, having carefully read the evidence, I apprehend that the plaintiff was non-suited owing to the sitter having erroneously declared Mr. Goodman as the *author* of the photograph, whereas it was proved in evidence that Mr. Goodman's assistant, one Sheidt or Sueti, had actually taken the photograph, and was therefore the *legal author*. It was solely on this point that the judge gave an adverse decision as against the plaintiff, and distinctly stated that he would give no opinion on the other contention as to whether payment or not had been made for the taking of the second negative, and this on account of the conflicting evidence offered. This I think puts a totally different complexion on the result of the trial to that summarised in your article, and in no way interferes with the accepted theory that where payment is made the copyright of a photograph vests in the sitter. In a word, the case in question shows the necessity of a correct declaration being made at the time of copyrighting a photograph. If you agree with my view of the case, perhaps you will kindly refer to it in a future issue of the JOURNAL, as the subject is a most important one."

RECEIVED.—Report of annual dinner of Cardiff Society.

PHOTO-MICROGRAPHY ON THE CONTINENT.—*Errata* in page 727: line 2, read Duboseq for Dubosog; line 48, Nachet for Nechel; line 52, Rafter for Raftio.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—On Thursday next, the 1st proximo, a paper will be read by Mr. F. A. Bridge, subject, *Spots in Silver Prints*.

THE JENNINGS'S FUND.—The following additional sums have been received:—C. H. Evans, 12s. 6d.; Francis Fowke, 1l. 1s.; Professor E. M. Crookshank, 5l. 5s.; A. Rivot, 5s.

PHOTOGRAPHIC CLUB.—Opening lantern night, November 30, 1887. This evening will be devoted to the lantern exhibition, music, &c. There will be no discussion. A limited number of admission tickets. Apply to the Hon. Secretary.

No. 1439. VOL. XXXIV.—DECEMBER 2, 1887.

PHOTOGRAPHERS *VERSUS* REFINERS.

If there be a body of traders with whom photographers do not appear to be on satisfactory terms it seems to be the refiners. Periodically we receive a considerable amount of correspondence complaining that refiners have not remitted such an amount, in return for the residues sent for reduction, as it is supposed they ought to have done. These complaints usually reach us about this season, probably for the reason that as the dark days set in, photographers and their assistants have plenty of leisure for the collection and preparation of the wastes which have accumulated during the more busy part of the year.

Two letters on the subject are now before us: one is from an old and experienced professional who complains that, twenty years ago, he used to receive nearly half as much more for every pound weight of residue he sent than he does now. He adds that at times he has sent them to different houses, but the returns have, in each case, been about the same. Sometimes a statement, which he never understood, has been sent, but not always. The second correspondent says in effect: I sent to a certain refiner, whose name he gives, a large parcel of wastes, consisting of spoilt prints and paper cuttings; also a lot of toned and finished prints which must have contained a considerable quantity of gold, together with a jar full of chloride, as thick as cream, from the washing waters. He adds, the paper alone must have weighed nearly half a hundredweight, and the return was so insignificant that I am thoroughly disgusted. Surely such a quantity should have yielded a handsome sum. Our correspondent asks, Would it not be better for photographers to reduce their own wastes, and thus make sure of obtaining their full value?

From these letters, which are similar to others which often reach us, evidently many who do not give the matter due consideration, are under a misconception with regard to the value of residues. Take the latter case for example. The probable weight of the waste is given, but not the sum received in return. If these were known it would give one no idea as to whether it were fair value or not. Half a hundredweight of paper when reduced to ashes would not weigh much, and the amount of silver they contained would depend entirely upon the strength of bath used for sensitising. It may be taken for granted that the fixed prints contained less than five per cent. of the silver with which the paper was originally sensitised. Had our correspondent burnt the paper, dried the chloride, and then passed the whole through a sieve, he would probably have been greatly surprised at the smallness of the bulk remaining; yet it contained the whole of the silver.

When the residue is in a homogeneous condition, any one

with but an elementary knowledge of chemistry can make a rough assay, so as to arrive, approximately, at the quantity of metal that ought to be recovered. Had this been done the return would, doubtless, have given greater satisfaction. The refiner had, of course, to burn the paper and dry the chloride before it could commence the reduction, and doing all this added to the cost of the work. Our first correspondent we know always does this, and his complaint is that, weight for weight, he gets so much less of late than he did a long time back. This may, however, be satisfactorily accounted for if we consider the conditions then and now.

Twenty years ago the paper, as a rule, was sensitised on a solution at least twenty-five per cent. stronger than is customary now—in the case of the ready sensitised paper the difference is still greater—consequently the ash was proportionately so much richer in metal. But this does not fully account for the wide difference. If we refer back to the market value of standard silver twenty years ago we shall find that it was about five shillings an ounce, but now it is something less than three shillings and eightpence. When these two facts are taken together, it will clearly be seen why the return made for each pound weight of ashes is so very much less now than it was formerly. Some persons, without thinking of the matter, are inclined to estimate their residues—as the correspondent just quoted did—rather by their bulk or weight than by the quantity of the precious metals they contain and their value.

If the bulk of the waste be very large and the proportion of metal very small, it may not actually pay for its recovery. We have before now seen a large sheet of thick, coarse, brown paper thrown amongst the waste simply because it showed several splashes of silver solution. Now, in this case, the paper probably did not contain half a dozen grains of silver, while its ashes most likely, from its common quality, weighed an ounce or more. Clearly, in this instance, it would have been more profitable to have discarded the paper altogether; or, if excessive economy were studied, the stained portions might have been torn out and the remainder rejected. We have also seen large numbers of finished prints, mounted on stout cards, added to the wastes; this is certainly false economy.

Opinions differ somewhat as to whether it pays to recover the metals from toned and finished prints and their cuttings. Some idea on this point may be arrived at from an experiment conducted by Mr. William Bedford a few years back. From half a hundredweight of toned prints he succeeded in recovering thirty-five shillings' worth of the precious metals, and out of this sum the cost of collection and reduction had to be deducted.

As a guide to those about to collect their residues we would

say, Burn the paper as completely as possible, first by burning it in a stove, then collecting the ash and again incinerating it in an iron pot—an old saucepan will answer—for some hours over a brisk fire, so that it is reduced to a compact pale greyish powder. Dry the chloride from the washing waters, and the sulphide from the fixing baths, in the kitchen oven, and rub them up in a mortar. Then pass the whole through a coarse sieve—a cigar box with the bottom removed and replaced by a piece of perforated zinc will serve very well as an extemporary arrangement. When this is done it will be surprising the quantity of heterogeneous matters, in the shape of broken glass, nails, pins, &c., which are arrested on their way to the crucible.

There is no advantage whatever in keeping the different residues apart unless the quantity be large, except in the case of the gold residues—these should always be kept separate. When residues are treated as above, and are sent to a respectable refiner, the return will invariably be satisfactory; such, at least, is our experience.

ON RAPID DEVELOPMENT.

A CORRESPONDENT whose letter will be found in our correspondence columns utters a note of distress which, we doubt not, will be echoed by many another reader of these remarks. He has a large number of dry plates, exposed possibly during a summer tour of prolonged duration, and now he has to face the difficulty of developing them within a reasonable time before his interest in them is gone, or perhaps the time comes round for another tour. To some extent, the presenting this letter for perusal may serve as a warning to those whose constant practice when out photographing is to expose all their plates before the day is over, quite regardless whether or no they are likely to obtain a set of negatives worthy of being printed at all. We have constantly reprobated such a plan of procedure, for if the art be worth practising it is surely worth while to make the production of each negative a subject of some little study and thought. But not to moralise in a direction where a special temptation presents itself, we will discuss possible methods of aiding others besides our overwhelmed correspondent.

In the first case, ten minutes is really an unnecessary length of time to spend over developing a single negative which is assumed to have received about the correct exposure. We will not here enter into the various questions that might at once be raised on our assertion; we merely say that so long a time is not necessary under the circumstances.

It goes without saying that, unless the exposure is practically an assumed success, development will be started with a smaller amount of ammonia in the solution than the plate will bear; but it may be pointed out that it does not follow from this fact that the proportion must necessarily be excessively small. Taking what may be termed a normal developer for a given plate, to contain two grains of pyro and four minims of ammonia, with a little bromide to each ounce of water—and this is an average proportion—it would, unless the exposure was utterly unknown or uncertain, be a throwing away of time to start with less than one-fourth that quantity of ammonia whenever there was a fair number of plates to get through. The better plan would be to use half or one-third the quantity of the normal proportions of ammonia and thus leave ample margin for over-exposed plates while enabling under exposures to be readily combated. A little judgment here may save half

the time that would be needlessly expended under an imperfectly devised method.

We do not, of course, leave out of sight the great variation that is to be found as regards ease of producing density among the different brands of plates now in the market, but most plates properly treated will, nowadays, answer the developer with a fair amount of rapidity. There is, nevertheless, a very great difference even yet in their quality in this direction, and the photographer who, with a large number of negatives before him, finds himself in possession of a batch of plates that will take the maximum time for attaining intensity is truly to be pitied.

A two-grain to the ounce solution of pyro is a very common strength of developer—one leaving sufficient margin either way for reduction or increase; but, where rapid development is needed, this strength may be greatly exceeded without perceptible ill effect with a marvellous shortening of the requisite time. Many plates are now made capable of sustaining without injury the action of developers of six, eight, ten, and even more grains of pyro to the ounce, and the increased rapidity of procedure thus obtained is almost startling. But it must not be lost sight of that an increased expenditure is thus entailed.

The effect of increase of temperature in accelerating development is not sufficiently marked to render it worth while undergoing the risk of frills and blisters in the endeavour to save time. There is, however, another very simple method of encountering the difficulty, involving only the purchase of a few extra dishes and the possession of a quick hand, eye, and judgment. It is merely to develop a large number of plates at once. We have not heard of the practical adoption of any method of developing several dozens at a time in a single grooved trough with a very weak developer—a method we do not see any difficulty in carrying out; but we have seen a large number of plates developed at a time, each in its own dish. Our correspondent's purpose would perhaps be served if we gave him a description of the development of about a hundred half-plates as witnessed by us in the dark room of a well-known professional photographer.

In the first instance ten dishes were laid out side by side over the large sink; then fifty ounces of developer, containing, we understand, two grains of "pyro," one minim of ammonia, and half a grain of bromide of potassium in each ounce, were mixed, and five ounces placed in each dish. On a shelf immediately in front were three bottles containing respectively strong stock pyro solution, mixed ammonia and bromide solution, and ammonia solution the same strength but without the bromide. All being ready the dark-room assistant handed him, one by one, the ten plates, which were then carefully placed in the dishes. The image soon began to appear, and our friend at once became too busy to attend to any conversation. As soon as a plate was considered dense enough it was put under the tap, slightly washed, and immediately transferred to a grooved trough containing a solution of chrome alum and citric acid. A new plate was immediately handed to him, and placed in the empty dish, which was then not allowed to remain where it stood but was placed at the left end of the row. We were surprised to find the negatives develop so uniformly, but soon one appeared which was apparently under exposed. The dish containing it was transferred to the right end of the row, and plain ammonia solution added so as to double the existing quantity. That sufficed to bring the image up completely. Every now and then, as the plates were being passed through, the rule of new plates to the left and underdone

plates to the right being uniformly adhered to, other unexposed plates took the place of the first named, and after a while there were two dishes to the right with stronger ammonia solutions. Ultimately there were three dishes, the third placed to the extreme right and containing four minims of ammonia to two of pyro, that being the limit—with the particular plate—beyond which we were given to understand no gain was experienced by further increments of ammonia. In a very short space of time, comparatively speaking, the whole century of plates was developed, though after an amount of exertion and close attention which we should imagine would be very fatiguing if persisted in for long. There is no need here to follow the plates in their after treatment, it suffices that we have given a thoroughly practical answer to our correspondent's query, and we may say that the narration of the experiences of a few others in a similar direction would be a valuable contribution to practical photography; and we venture to express a hope that we may receive particulars of a few such practical illustrations, which we may print for the benefit of our readers generally.

AGAIN have we to record the death of one who some years ago was well known to photographers. Mr. J. B. Danecr, of Manchester, died on the 24th ult. He was born in London on October 8, 1812, and may thus be said to have attained a good old age. He was born an optician, as both his father and grandfather were makers of optical and scientific instruments. Some account of his career will be found on another page.

In connexion with the alleged dynamite conspiracy, it is reported that one of the incriminated persons was photographed without his being aware of the fact, and that his portrait has been largely circulated and identified. Photographing suspected persons outside the prison walls without their being aware of it, is certainly a novelty to many. It says much for the astuteness and skill of our Criminal Investigation Department if they, unknown to the suspected, can secure portraits of them sufficiently good to serve as a means of identification. Only those who have really attempted to obtain an instantaneous portrait of any particular individual—especially one who was so erratic in his movements as the accused appears to have been—while walking through the streets under the conditions mentioned, can appreciate the difficulties to be encountered. We are of course assuming that the portrait was taken in the street, for it is difficult to conceive that it could be accomplished elsewhere without the knowledge of the "sitter." If the report be correct, which many will doubt, it will be gratifying to find that "detective photography" can be so successfully applied by our detectives.

DURING the past year or two, and prior to the introduction of stripping films, a considerable number of negatives were produced. Now, in printing from these in the ordinary way, the granularity of the paper in most instances does not show to any material extent. But it frequently happens that enlargements are required from them; then the case is different, and the grain of the paper sometimes becomes very palpable in the finished picture. It may not be generally known to amateurs who make their own enlargements that this defect may, to a great extent, if not entirely, be overcome by making the enlargement with the lens a trifle out of focus. It is a curious circumstance, that if the lens be judiciously put just a little out of the actual focus, the distinctness of the granularity of the paper may be destroyed without materially interfering with the apparent definition of the image. A little experience will determine the amount the lens should be put out, because it is manifest if it be too much the finer details of the picture will suffer.

NOTWITHSTANDING the stringent wording of the new Fraudulent Trade Marks Act and its heavy penalties, there can be no doubt that the law is being evaded—ignored would perhaps be the more correct term—and, so far as we are aware, no prosecution has yet been insti-

tuted, certainly not in connexion with matters photographic. We know that foreign made lenses, bearing the names of English houses, are being sold the same as they were formerly. Also, that chemicals, mounts, albumenised paper, and other photographic goods, are still being imported and sold as being of home manufacture, if not upon actual statement, at least by implication. When this Act was first passed it was thought that a severe restriction would be put upon this class of business, but this does not appear to be the case to any great extent. Up to the present, so far as photographic materials are concerned, the Act appears to be, practically, "a dead letter." Still dealers need be on the alert.

AMATEUR photography, that is for outdoor work, may now be considered as over for the season by the majority of workers. Some will, no doubt, obtain a few negatives of winter effects, but tramping about with the camera in snow and wet in search of the picturesque, and when it is found often having to wait for a suitable light, is not an agreeable occupation, even to the most enthusiastic. The majority of the negatives of outdoor subjects that are taken during the next few months will be taken, we surmise, not far from home, and their numbers will be limited. However, there is no reason why amateurs should let their favourite pastime be in abeyance, for there is really plenty of agreeable work that can be done indoors. For example, home portraiture, making lantern slides either by printing direct or by reducing them in the camera from larger negatives. Enlarging or printing on bromide paper; this can as well be done by artificial as by daylight. Photo-micrography is also an interesting occupation, and, for popular objects, requires no very expensive appliances or more skill than is possessed by the average amateur. For the larger objects many of the shorter focus photographic lenses may be successfully employed. Making transparencies for window decoration may also form a winter occupation; this also can be done by artificial light.

COPYING engravings and other works of art, either for scrap-books or for framing, can be done indoors during the winter months. In this work the negatives will prove more suitable if they be developed with ferrous oxalate instead of pyro. Negatives from this class of subject if printed in platinotype or on bromide paper will yield impressions very closely resembling the engravings themselves. In printing subjects of this character, the negatives may be masked so that the prints are obtained with clean margins of suitable width; then, if the picture be framed, no mounting is required, while, at the same time, it will more closely resemble an engraving. Many other directions might be indicated in which photography can be worked during the winter months, but sufficient has been said to show that the amateur need not throw his favourite hobby aside entirely at this season.

THE facts of nature are sometimes too strong for the logic of invention, and a reference to *Symon's Monthly Meteorological Magazine* for October will show the bountiful way in which London has been supplied with atmospheric moisture. Of all the meteorological stations in the British Empire, we learn that the palm for dampness has to be given to the Metropolis of this country.

In his recent paper on *Orthochromatic Photography* (see our issue for November 11), Mr. J. B. B. Wellington mentions that "one great advantage of orthochromatic plates (in conjunction with a yellow screen) is photographing outdoor subjects on a slightly foggy day; the result on an ordinary plate being flat and foggy, on the orthochromatic crisp and brilliant." This experience would indicate that orthochromatic plates should be of great advantage in the studio at this season, especially during a yellow fog. It is seldom during the daytime that the light is so bad that a fairly well exposed negative cannot be obtained, on a rapid dry plate, in a similar time to that which frequently had to be given in the collodion days; but the negative so obtained is, usually, spoilt through a lack of brilliancy arising from the mass of fog intervening between the sitter and the camera. If orthochromatic plates will overcome this difficulty they will prove a still greater acquisition to photographers. Used under these conditions, we presume, the yellow screen will not be required, the colour of the light supplying sufficient yellowness. The thing is well worth trying when sitters have to be taken in a November light.

THE preparation of orthochromatic plates, suitable for the above purpose, by the photographer himself is a very simple affair, all that is necessary being to bath the plates in the "orthochromatising" solution and then rear them up on the dark room shelves to dry. Prepared over night, if the dark room be a tolerably warm and dry apartment, the plate will be dry and ready for use by the following morning. Plates thus prepared will usually remain in a good working condition for several weeks.

PLATE BACKING.

I WAS greatly interested a little time back by the correspondence in these columns with regard to the backing of plates, the subject being one in which I have taken great interest, practically and theoretically, for a long time past. I am aware that a large number of photographers never have seen the need for anything of the sort, and to them, of course, any discussion of the matter would be uninteresting; but it may be safely asserted that every photographer who has any experience of varied subjects has produced some negatives that would have been the better for a backing of some sort. For astronomical photographs it is an essential condition in the production of good work; for landscape pictures some views could not be taken successfully without backed plates, and the same remark is to be made of interiors; while, in portrait work, given a sitter in a very light dress, and under a strong illumination, and taken with the full aperture of the lens, a single trial only is needed to show the inferiority of unprepared plates. A great deal will depend upon the make of plate employed. Some brands have enjoyed an honourable distinction in freedom from halation since the very early days of gelatino-bromide, while others equally have, to those who have given thought to the subject, been known allways for the readiness with which they permit halation. The introduction of iodide into the emulsion was a great improvement in regard to preventing this evil; the introduction of machinery for coating was not an unmixed benefit, for it may be safely asserted that a machine-made plate on the average will, *ceteris paribus*, have a thinner film than one coated by hand. Of course, unless the due quantity of silver be employed it will not be in the film to give opacity, let it be coated by hand or machine.

To avoid halation, or rather to reduce it to a minimum, it is always advisable to choose a plate with a thick coating; the yellower in colour the better, I am inclined to believe. I speak advisedly in saying a "minimum of halation," for the plate is not made nor the backing invented which will, under all circumstances, prevent light action in dark places immediately contiguous to bright lights, as any one can quickly discover by putting a plate, prepared his best to withstand halation, to a crucial trial.

The cases where, in my own practice, I prefer backed plates are, in portraiture, where there is any large mass of white; in landscape or architecture, almost allways; in interiors, invariably. A plate may at times be uselessly backed, but that is as nothing compared with the certainty that whatever the subject no trouble that is capable of prevention will arise from halation.

In portrait work my usual plan was to have a piece of dead black American cloth wetted with glycerine squeezed to each plate put in the slides whenever a sitter made his appearance whose costume had a superabundance of white. The plan was most effectual; but it was messy, and there was danger of the glycerine coming on to the film and causing the plates to become glued together. The glycerined plates were put back to back while they waited development, but there was always danger, and the plan was dropped in favour of another. Captain Abney's collodion of aurine or magenta formed a very handy substitute, and has been of great use on many occasions. Once my assistant placed a number of plates so treated into the dark slides directly after coating, before they had had time to dry; the consequence was serious trouble for some time with the slides. The alcohol vapour had softened the shellac, and dried out again, so that a considerable amount of "ungluing" had to be performed before using the slides again.

The most serious drawback was the getting rid of the collodion before developing. In the first place, if the plate had emulsion on the back it was very difficult to remove the collodion at all; and, in the next, if a piece of collodion were allowed to attach itself to the film it was most

difficult of removal, and if not removed it interfered with development, so that when a dozen or two large negatives, each with collodionised back, had to be developed, the washing away of the collodion was no light undertaking. I tried to develop without regarding the film; but the floating particles of collodion which soon made their appearance were quite in the way, and when a second plate was placed in the same solution it became impracticable to continue development. Hence, all negatives were first placed under the tap to flood away all collodion before developing. It was found necessary to moisten the film first to prevent the pieces of collodion adhering, if by chance they were washed over the edge. But the most serious drawback of any was the readiness with which these collodion skins collected in the sink and caused overflows. Twice over did I experience this, and then I felt it was time to try other backings.

One correspondent a little time ago recommended the old plan of the astronomers—a backing of asphaltum. This would answer well for a few negatives, but would be quite "out of the question" for a professional photographer who had many plates to develop; the time that would be involved in scraping off would be intolerable. Then, again, another correspondent recommended a tube of water-colour paint being purchased, and the contents put to the purpose of backing. A really excellent plan, but exceedingly costly, if, say, a dozen or two eighteen-inch plates had to be treated. The method that yet another gentleman recommended, namely, to take a sketch of a possible window to be included in the view, and to back the plate just there, and there only, is too droll for serious consideration.

The old sienna or lampblack treatment is but a slight palliative, as a small portion only of the particles remain in "optical contact." Any one can easily see for himself the extent to which a pigment touches the plate without an intervening film of air, by backing a piece of clear glass with the pigment to be examined, and, after well drying it, observing the reflection of the sun from the clear surface. There will, of course, be a second image from the back, and the degree of brightness which this image exhibits will be the measure of the imperfection of contact between pigment and glass. Still, a pigment backing appeared to offer most advantages, and a large number were tried.

The backing of pigment mixed into a paste with gum water and glycerine, as described in a leading article in THE BRITISH JOURNAL OF PHOTOGRAPHY a few months ago, has answered my purpose admirably; nothing better could be wished for. It is easily made, easily laid on, and very easily removed. A good plan after making a quantity by rubbing up with a palette knife upon a slab of glass, is to squeeze the paint through a piece of fine muslin: it makes so much pleasanter a paint to lay on, and ensures a greater perfection of optical adhesion.

As a matter of practice, I now always have a number of plates ready backed for any studio work that may require it, and for outdoor work, where it is never known exactly what kind of subject may need to be thrown on the focussing screen, backed plates are always employed. Some may call this excess of precaution, but as the whole operation of backing and removing is performed in so brief a time the slight extra labour is worth undertaking, if only for the peace of mind it entails. The whole backing from a twelve by ten plate may be washed off in a very few seconds without danger to the film, or to sink arrangements, as with collodion.

For all practical purposes of everyday work this gum and glycerine paint is the best it is possible to employ, but, as I said at the outset, perfect prevention of halation, even with this backing and the best plate in the market, is not always possible. If the nearest approach to perfection be looked for the plates must be stained also, but this branch of the subject cannot be now dealt with.

G. WATMOUGH WEBSTER, F.C.S.

"ON PAPER" PHOTOGRAPHY.

EVEN the worm, saith the venerable adage, will turn. This is not correct, but it is well-meaning as we all know. When a man is unfairly ridiculed *coram populo* it is only natural that he should, courteously or not, retort, as witness the case of Mr. L. Sawyer, also that of Mr. Robinson. A great many outside newspapers have "done" this year's

Pall Mall show, but some of them have not got through the task so successfully as one might wish. The *Builder*, in particular, seems to have been strangely maladroit, if not absolutely incomprehensible, in many of its remarks. Mr. Heathcote Statham is, as some of us are aware, a fierce partisan, much prone to making architects and others of that ilk uncomfortable; but in the case under notice he would have done better to have stuck to his T-square. It may be doubted whether his predecessor, Mr. George Godwin, would have penned or passed such butchery.

The esteemed organ of the architectural and building professions, however, sins in reputable company. There is an influential morning paper which sometimes treats its million readers to a photographic "pot boiler." Recently when referring to Mr. W. H. Mallock's suggestion as to the more extended employment of instantaneous photography by the Irish Executive during the present unhappy crisis, this same paper gravely propounded, *inter alia*, the following choice and learned riddle: "Whether the art of focussing will ever be brought to such a degree of perfection as to prevent a gentleman's hat when held in the foreground of a portrait from looking about three times the size of his head!" After a lot more inconsequential padding, *à la* "the art of focussing," it complacently proceeds to assure us that "the very finest instantaneous photographs will only give the general aspect of the scene delineated by the action of the solar rays, and that such a photograph is usually, in parts, so blurred and confused as to require a large amount of touching up before it is fit for public inspection." If the first part of this remarkable enunciation means anything at all, the Gregorian calendar, in the estimation of the practical photographer quoted by the leader writer, is seriously wrong, and instead of this being, as all of us believed, the year of grace one thousand eight hundred and eighty-seven, we must subtract ten, and then we shall be right. As to the amazing indictment that "the very finest instantaneous photographs are . . . usually in parts so blurred that," &c., this is contradictory and nonsensical drivel. One wonders if this amusing leader writer ever uses his eyes when he passes Mr. Spooner's shop or if, when he went to Pall Mall, Mr. Cocking wickedly covered up Mr. England's exquisite little excerpts of Metropolitan animation, or Mr. Cobb's bold transcripts of daily life in the great capital. These prints, so far as I could see, are untouched, and so, I imagine, are the negatives. In any case, and whether they are or not, the wholesale insinuation in a widely circulated daily newspaper, that sharp, well-defined, instantaneous pictures may not be obtained without touching, is as ignorant as it is silly, and deserves to be well laughed at, as no doubt it will be.

Photographers are treated to a deal of scolding and abuse from art journals, and any amount of rightdown misrepresentation and falsification from the general press. Probably nothing is so thoroughly well misunderstood in this country, among outsiders, as photography. The ignorant sit in judgment upon it with delicious self-confidence, the unthinking diagnose and dissect it as if it were some paltry bagatelle well within the comprehension of the meanest capacity. The morning journal referred to is one of many whose recurring photographic blunders make one ask if their general news and politics are of the same cast in point of strict value, and whether the miserable public gets a fair exchange for its matutinal bronze. In the name of the myriad photographers of the community, one protests against the mendacious character of the photographic wisdom that is deposited at our doors with the breakfast milk, and ventures the hope that the time may be at hand when the occupants of these "pulpits," as Thomas Carlyle once called them, will know what they are writing about, or if they don't, will find out; and if it is really necessary for them to preach from a photographic text to the non-photographic public—which some of us take leave to doubt—that they will do so intelligibly, if even they are unable to do so accurately.

MARSTON MOORE.

THE PRESERVATION OF SILVERED PAPER.

In or about the year 1875 I commenced a systematic investigation into that discolouration of silvered paper which results from "keeping." This research, however, was rudely broken off, and the greater portion of my notes, like those on *Phosphorescence and Photography*, have "vanished" in my protracted absence from my "home."

One roll of manuscript, however, has turned up as mysteriously as it disappeared. This I will transcribe, and if my transcription is approved of, it will in due time appear in the pages of THE BRITISH JOURNAL OF PHOTOGRAPHY, and be "lost" no more. There is one great advantage to an experimentalist who adds "globe trotting" to his other avocations, in the publication of his results in such a periodical as THE BRITISH JOURNAL OF PHOTOGRAPHY, and it is this, that he need carry with him only a list of the titles of his articles and the dates of their appearance to enable him to reperuse them in any of the great capitals of the world, if he should happen to have the *entrée* to the libraries of the learned societies which are there located, and this is easily procured by any one who has obtained the fellowship of any of the learned societies here at home.

In my investigation of 1875, I commenced by extracting (from THE BRITISH JOURNAL OF PHOTOGRAPHY) paragraphs relating what others had done in connexion with the matter I have now in hand, and then I proceeded to experiment.

Here are a number of these extracts:—

No. 1.—In THE BRITISH JOURNAL OF PHOTOGRAPHY of July 5, 1867, page 314, Mr. H. J. Newton's paper read before the Photographic Section of the American Institute is given. He says, "Paper sensitised on a strong bath will discolour much quicker than if sensitised on a weak one." *Inference* (the inferences are my own): If true, free argentic nitrate has something to do with the "spontaneous" discolouration which increases with its quantity.

No. 2.—In THE BRITISH JOURNAL OF PHOTOGRAPHY, July 19, 1867, page 344, Mr. Haydon says, "In preparing my paper I have found much of it spoiled by the weather, but by adding a small piece of sugar to each ounce of nitrate solution I could keep it for many days, and however yellow it might have become it will finish up a pure white." *Remarks*: Mr. Haydon gives no evidence that the "weather" spoiled his paper. He wrote in July. The weather probably was hot, and very likely "dry." The addition of sugar would prevent the paper from completely drying. *Inference*: That silvered paper goes "yellow" more readily when dry than damp.

No. 3.—In THE BRITISH JOURNAL OF PHOTOGRAPHY, September 6, 1867, page 429, "J. C." says, "Thoroughly dry sensitised paper rolled up and closely corked in a wide-mouthed bottle may be kept six weeks." The Editor adds, "To keep excited paper it is necessary that it be exposed to neither light nor moisture." *Inference*: That moisture is conducive to "spontaneous discolouration," an inference directly in contradiction to that arrived at from the statements in extract No. 2.

No. 4.—In THE BRITISH JOURNAL OF PHOTOGRAPHY, 1868, page 221, Mr. Bovey says, "Sugar does not prevent the paper turning yellow, but the yellowness is entirely swept away by fixing." *Remark*: This is corroborative of extract No. 2. *Inference*: That in spite of the non-dryness of the paper, sugar does somehow prevent that discolouration which is insoluble in hypo.

No. 5.—In THE BRITISH JOURNAL OF PHOTOGRAPHY, October 29, 1869, the Editor says he "has received a sample of paper prepared by Mr. Henderson, who claims that it will keep indefinitely. The mode of preparation is not given, but it is hinted that the paper undergoes some treatment before silvering, and it is affirmed that in this treatment a salt of tin is used, and, it is alleged, gold also." I fail to deduce any inference from this statement, and have no remarks to make.

No. 6.—Mr. Henderson, in THE BRITISH JOURNAL OF PHOTOGRAPHY, 1869, page 511, says that "putting silvered paper under the receiver of an air-pump and exhausting the air does not prevent discolouration." *Remarks*: I should not think it would. The discolouration (irremovable by hypo) is probably owing to reduction, and I know of no reducing properties in atmospheric air pure and simple.

No. 7.—Mr. Bovey, in THE BRITISH JOURNAL OF PHOTOGRAPHY, 1869, page 591, says, "One of the chief advantages I find in the use of nitrate of soda, is an entire absence of that discolouration which always accompanies the use of nitrate of silver without any adjunct." *Remarks*: Possibly the nitrate of soda is reduced by the presumably existing reducing agent in the paper. But as soda is a more powerful base than silver, why is not the silver salt reduced as well? Is it not reduced? If I remember rightly, when nitrate of soda was introduced weaker silver solutions were employed. Is not the result

obtained in consequence of the weakening of the silver? and is not the inference the same as deduced from extract No. 1? Is it a fact that there is "an entire absence of discolouration?" What is an "entire absence of discolouration?" How long will the paper enjoy that absence? I fail to draw an inference.

No. 8.—Mr. Badai, in *THE BRITISH JOURNAL OF PHOTOGRAPHY*, 1870, pages 29 and 30, says, "Washed paper preserves its whiteness and sensitiveness perfectly for eight weeks after it has been sensitised, and prints thereon may be toned in three or four days, or *weeks* if need be." *Inference*: Substantially the same as that deduced from extract No. 1—viz., the free argentic nitrate has something to do with the "spontaneous" discolouration, which *diminishes* with its quantity.

No. 9.—In *THE BRITISH JOURNAL OF PHOTOGRAPHY*, 1870, page 162, Mr. Antony says, "I have ascertained by careful experiments that the turning brown of albumen paper in hot weather is produced by the penetration of the silver solution through the albumen and into the paper upon which it is spread, the action of the nitrate in a concentrated form causing the brown colour. I have found that merely blotting off the excess of the silver solution has a very material effect in arresting this tendency to turn brown, and it is but reasonable to conclude that washing would be much more effectual." *Remarks*: To my thinking there is more sense in Mr. Antony's observations than in almost any of the others I have quoted. He attributes the reduction of the silver to the paper and not to the albumen. But as he is of opinion that washing would be "much more effectual" than blotting, one is tempted to wonder why he did not try it in the course of those "careful experiments" by means of which he "ascertained" that the turning brown of silvered paper was owing to the penetration of the nitrate "through the albumen and into the paper on which it is spread." *Inference*: That in silvering the paper should not be left upon the nitrate bath long enough for the penetration of the albumen, and that after silvering the paper should be washed.

No. 10.—Colonel Wortley, in *THE BRITISH JOURNAL OF PHOTOGRAPHY*, 1870, page 337, says he uses washed paper fumed (with ammonia?) for his printing operations. He gives a list of its advantages, but does not mention "keeping" as of their number.

No. 11.—"H. T. A." (*THE BRITISH JOURNAL OF PHOTOGRAPHY*, 1870, page 453) says, "Paper sensitised on a solution of silver nitrate containing alum keeps its whiteness in hot weather better than when the simple nitrate only has been used." *Inference*: That hot (and presumably dry) weather is conducive to discolouration, and that alum is an agent which retards it. *Remarks*: Alum seems a curious substance to use in conjunction with argentic nitrate. It would probably oxidise some of the "organic matter" of the paper, and if discolouration is thereby retarded, the inference would be that the organic matter of the paper is a reducing agent, and, *as such*, "develops" the "spontaneous" discolouration. In this event very likely any other oxidising agent mixable with argentic nitrate would have the same effect, and I apprehend that the proper time to use this oxidising agent would be when the paper was in course of manufacture, or, at any rate, before the time of silvering.

No. 12.—Mr. Webster (*THE BRITISH JOURNAL OF PHOTOGRAPHY*, 1870, page 518) says, "Washed paper unfumed will not print in a satisfactory manner, but will if fumed (with ammonia?), and will keep quite white for several days, and at the end of a week be in better printing condition than paper twelve hours old prepared on a summer's day in the usual manner." *Remarks*: The ammonia fumes (I am assuming that ammonia is the "fuming" agent) would, I apprehend, convert a small quantity of the argentic chloride into "argentic ammonia chloride," a soluble, and, if I remember rightly, an explosive salt (I am writing where I have access to no books whatever). My own experience has been the same as Mr. Webster's. I have found when the nitrate has been washed out the prints have had the appearance of being partially washed out too, and that ammonia fuming has rectified all this. *Inference*: That argentic chloride does not print well excepting in the presence of a soluble salt of silver. Why not? I have a hazy remembrance of some photometrical process in which silver chloride was precipitated in a tube with an excess of water in it, and that chlorine gas was evolved by day and reabsorbed by night. Is the unsatisfactory nature of prints obtained on paper washed but unfumed caused by the action

of "nascent" chlorine on the metal which has been reduced, and is it that the function of the soluble silver salt is to absorb the chlorine?

D. WINSTANLEY.

(To be continued.)

COLOURING AS APPLIED TO PHOTOGRAPHY.*

A FEW remarks may not be altogether useless regarding the principal (of the many) materials we may have to work upon. They sometimes demand a special treatment which, although differing one from the other in many points, will nevertheless be conformable to the rules laid down. There will never be excellence in a picture where water colours are used, if *brains* and *judgment* be not employed as often and plentifully as the *water*. I may repeat it, hard-and-fast rules for the treatment of pictures cannot be framed. The principles and the different methods can be laid down for the beginner's study, but without a lavish use of his own brains he can never turn them to advantage.

Carbons upon opal are in very general favour, and can be made very handsome pictures. There are many points which give this class of picture a distinct advantage. The least among them is certainly *not* the beauty, delicacy, and purity of the high lights. On this material the eraser will produce the most delicate lights, while at the same time they are clear and effective. If desired to be made still more prominent than the eraser may have made them, the effect can be heightened by the judicious and careful addition of a little Chinese white.

To begin work on an opal, I would recommend rubbing down with an eraser or the use of pumice-stone (very finely powdered) as a first step. Of course judgment must be used when *rubbing down* to only do so where it is necessary. To touch the shadows which are a proper depth would only be to entail very considerable work, and this would naturally be a very great disadvantage when we consider the prices at which we may be obliged to turn out the work. I have had some experience in this regard, and can therefore speak feelingly as well as give good advice. After so doing we may have a very good surface for working upon, but if not, a wash of a sizing preparation passed over the entire picture will secure it. It will also somewhat help the brilliancy of the shadows as well as give a favourable surface for working upon. We then proceed as already laid down. There is little else to be said as to the treatment of carbon pictures on opal base, save, perhaps, that it is not advisable to use more *gum* than is absolutely necessary, as the same has, if used in quantity, a very great tendency to crack and chip off. Such a calamity as this would necessarily ruin your picture.

We have also collodion pictures upon opal which may require our artistic services to make look at their best. These pictures, when varnished with a water varnish, will present a surface admirably adapted for working upon. There is no material upon which you depend so thoroughly as upon *washes* for your effects. This is a great boon to the artist. Any surface upon which you can safely employ washes for gaining your effects will also enable you by such a treatment to save much time and labour.

It is impossible to use the scraper upon this surface, as the film will not lend itself to such a treatment, therefore it is of the utmost importance that the print should be a proper depth, not too dark. If we do not pay due attention to this we will have our pictures heavy and anything but pleasant to look at. All high lights which may be necessary will have to be put in with Chinese white. The use of gum water, except where extra force is required in the finishing touches, is not at all necessary, nor its use advisable.

The backgrounds of pictures on opals are for the most part vignettised. Indeed, for every twenty pictures done on opal at least eighteen are vignettes. When, however, there is a picture with the background fully printed in, we must treat it just as we would an ordinary picture. In the case of vignettes, many artists depart from the ordinary lines, and rub in their backgrounds with chalk; and I have known some very pretty results to have been obtained in this manner. If we should elect to use this method, we must take a little soft crayon or stumping chalk on the end of our finger, and rub it in with a circular motion, and, of course, doing our best to obtain extreme softness at the outer edges. In backgrounds of this kind our

* Continued from page 742.

efforts are directed to making them appear as nearly as possible like clouds. If it should appear that a light or two (as it were on the edge of a cloud) would be an improvement, we can easily enough secure them. We have only to pick them out with a bit of bread or indiarubber, just as we would in an ordinary crayon drawing.

Plain paper prints, although not often used since the introduction of carbon, which has the very great advantage of being permanent, may sometimes turn up requiring our services. I remember the time when I did a great deal of black-and-white work (so called) upon the plain paper prints, but of late years have very seldom met them. There is not the same facilities for working upon them as upon the carbon tissue. The shadows, for example, if too heavy, must remain so. Therefore we should always have a really good print to work upon. Of course these remarks apply to the use of *photographic* paper only.

There are two kinds of the old-fashioned paper prints—those printed on albumenised paper and those printed upon salted paper. The former gave bright prints, and all we could do was to even them up when they were coarse, and in the cases of enlargements and copies help the drawing as much as we could. This gave us but a limited chance of making a good picture in many cases, as we were powerless, when the print was heavy and black, to lighten the shadows, and in other ways make it more likely to please and give general satisfaction.

Photographs on salted paper were at one time frequently used for water-colour painting, because it afforded such a favourable tooth to the artist to work upon. They were also largely used as a basis for black and coloured crayon work. It is also a good basis for water colour. Washes may be freely used without any danger of disturbing each other. This is more than can be said for its albumenised companion, upon whose surface, if you get one wash successfully, you are lucky, for the rest must be got by stippling, &c. Should the surfaces at any time become rough from any cause whatever, the necessary smoothness can be again attained by the use of what is called a burnisher. These burnishers are made generally of *agate*, and in a great variety of shapes, but I consider the curved one by far the most useful. In order to regain the original smoothness of surface, place a piece of tissue paper over the portion which has become rough, and then with a moderate pressure and circular motion rub the burnisher over it until a sufficient degree of smoothness is obtained.

Photographs printed by the platinotype process will also come under our hand from time to time. These are most delicate and beautiful pictures. They are mostly black in colour, and of course must be worked in a like colour for monochrome. The surface of these beautiful pictures is exceedingly well adapted for the application of colour in any form; indeed, it will take colour as well as any paper generally used for colouring. If not sized it will be found rather absorbent. A print about being worked upon if not sized should be rather well rolled, in order to produce a kind of surface which would be closer and less absorbent than if left in its natural condition. As much rolling tends to lessen and dull the lights, I think it best to give the print a complete wash of some sizing preparation, such as I have before recommended. The shadows may be deepened by the application of gum water, and the lights will be equally benefited by being picked out with Chinese white. The knife and eraser are not much used on these pictures.

Photographs on ivory are generally done in carbon, and the treatment will be the same as on the ordinary carbon prints, whether on opal or paper. It is very seldom that ivories are finished in monochrome, but whenever they should be ordered in that style treat them as though they were opals.

Gelatino-bromide paper is another basis upon which photographs may be produced, and one which lends itself to all the various methods of finishing. It is alike suitable for crayon, water colour, or oils. For working up in crayons there is no necessity for any special preparation, as the plain surface is well adapted to the work. I will not enter into the method of working it up in crayons, but restrict myself to the application of colour.

Before beginning work it will be found necessary to prepare the surface for the reception of the colour. This is done by passing a solution of *alum* over the picture, which happily has the effect of hardening the gelatine to such an extent that almost anything can be done on a surface so prepared. Without this preparation the surface would be

too receptive. Without this preparation it would be impossible to pass a successful wash of colour over the photograph, as each touch would be absolutely held as it were, and all attempts to blend or soften it would only result in pulling up the print from the surface of the paper. After the preparation you can wash in or wash out, and even take out lights as you would on Whatman's paper, by the application of water and rubbing off with a cloth. The alum solution is passed carefully over the print, which is left to dry and is then ready to start working upon.

Some very excellent effects can be gained in putting in the backgrounds of vignettéd pictures by the use of pastel (the half-hard kind), with just enough powdered pumice-stone mixed in it as will give it a gritty feel. This rubbed in with the finger or a stump, as before described, giving a most effective and pleasant result. It will be found advantageous to master the treatment of the gelatino-bromide paper, as it will become very popular. In fact the demand for it increases more and more every day. It is not often one finds a basis so well adapted for *all* kinds of treatment as this paper. It takes crayons like drawing paper, water colour (after alum solution) like a sheet of Whatman's, and oils, after being sized, like an ordinary canvas.

I think the foregoing will be sufficient as regards monochrome as applied to all the principal materials upon which photography is offered to the public. Having mastered these, we will be free to attack the working up in *natural colours*. It must, however, be carefully remembered that all the remarks and principles laid down for monochrome have a distinct bearing upon the whole treatment of photographic painting.

REDMOND BARRETT.

(To be continued.)

MYSTERY GOLD.

In these days, when many photographers prepare their own chloride of gold, and some without the success reasonably expected, the following letter by Mr. Edward Brossey, in the current issue of the *Pawnbrokers' Gazette*, will be useful to all who take an interest in the gold question. He says:—

"Some months since a fetter-link albert marked 15 carat turned out of pledge here. It was sent to the auction rooms, some dealer called it 'mystery,' it did not sell. I assayed the albert and found it contained $6\frac{1}{2}$ carats of gold; I likewise broke it up for old gold, reserving a few links for analysis, feeling sure there was something peculiar about the alloy, as it appeared to me by the ordinary tests much above 6 carat gold (it was pledged for 2*l.* per ounce).

"I have recently analysed a portion and find it is composed of gold, silver, copper, aluminium, and iron. The aluminium, though present in small proportion, helps to make the alloy stand the action of nitric acid much better than one might suppose; the alloy is very malleable, I have passed some links through the flating mill until they are as thin as note paper. Aluminium is a hard, white metal, not so white as silver, and not so blue as zinc. It resists cold nitric acid almost to the same extent as gold or platinum, but dissolves slowly in boiling nitric acid. I have paid from 5*s.* to 8*s.* per ounce for aluminium, but never obtained it pure, it is always contaminated with iron.

"I may here remark that when reporting the presence of iron in an alloy such as the above, or the bright gold brooch in my letter of last week, I do not suggest for one moment that iron is necessary or a desirable element in the mixture, but quite the contrary, it is present as an impurity in ordinary zinc and copper. Pure zinc, free from iron and arsenic, costs 6*s.* per pound, ordinary zinc, I suppose, costs about 3*d.* per pound. With regard to the cost, value, &c., of parting assays, I should be glad to say a few words.

"Parting assays cost 1*s.* 6*d.* The quantity of precious metals contained in the alloy is quoted in ounces, &c., of F.G. and F.S. in 12 ounces troy.

"To convert the quotation into carats of gold multiply the weight of F.G. by 2, and for ounces read carats, and for pennyweight read twentieth part of carat; example—2 ounces 15 pennyweights F.G. in pound troy multiplied by two equals 5 ounces 10 pennyweights, or 5 carats and 10 twentieths, or $5\frac{1}{2}$ carats.

"To find the value take the F.G. at 84*s.* per ounce, the F.S. at 3*s.* 6*d.* (about), divide the total by 12, the product is the value per ounce, example:—

	oz.	dwt.	£	s.	d.
F.G.	2	15.0	11	11	0
F.S.	3	18.0	13	8	
Total, ..£12 4 8					

"Divide by 12—value, 17. 0s. 4½d. per ounce.

"Gold assays cost 1s. and usually quote number of carats worse than 22. Thus—W^o 19 dwts. equals 3 carat gold. Each carat of gold contained in an alloy may be reckoned at 3s. 6d. per carat per ounce, thus—9 carat gold is worth 17. 11s. 6d. per ounce (of course I am speaking of bars of gold sold by assay).

"I need hardly point out parting assays are the proper ones to sell by the example above, 5½ carats would come out at 19s. 3d. per ounce for gold, but by reckoning the silver the value is 17. 0s. 4½d.

"I am not sure that I should have troubled you at such length, but I have seen jewellery factors cover a good size paper with figures to convert the quotation of ounce, &c., in pound troy to carats, that I think the above simple method may be useful to some of your readers.

"EDWARD BRESSEY."

WHAT TO PHOTOGRAPH.

ALMOST everything animate and inanimate has been subjected to the ordeal of being photographed some time or another. Still, it is no uncommon thing to find some difficulty in getting suitable subjects to practice upon. Good pictures and indifferent ones—the latter predominating—are continually being made, and, we may add, a vast aggregation of irredeemably bad ones into the bargain. The difficulty is with those who estimate a photograph principally by its artistic qualities to find sufficient variety. The places and subjects they have tried and found yield satisfactory results lose interest, and the desire for something fresh is not to be satisfied by going over old ground. Here, then, is a striking difference between painting and photography. The same neighbourhood will afford generations of painters ample material for their canvases; variations of light, of colour, and of treatment make so many distinctly new combinations. A most unprepossessing subject to the photographer may be a mine of wealth to the painter. This, however, is perhaps an exaggerated fancy, and the mystery may be possibly referred to a deficiency of artistic perception in the photographer, for it is scarcely probable that any one who has not received a proper artistic training is likely to see the beautiful and picturesque in anything like the same degree with those who have. It stands, therefore, to reason, that not being educated to see, one fails to find those subjects which when rendered in monochrome will afford artistic satisfaction. We all know the refreshing experience of photographing a well-known and possibly uninteresting scene if covered with snow; a new face is put upon it, so to say, and if it were not for the discomfort of working under Arctic conditions we should probably have many more beautiful examples of snow scenery than we have. Snow is, however, an uncertain and unexpected visitor from a photographic point of view—here one hour and gone the next, so far as its pristine sparkle is concerned—and fortunate is the photographer who is fully prepared and in the right neighbourhood at the right time. Trees offer many inducements to the picture maker both in full leaf and when entirely denuded of foliage—beautiful results may be obtained from either; the same view with and without foliage is sufficiently different to merit recording in both conditions.

I think if the illumination of the landscape was made more of a study good would come of it. There might be many new pictures obtained from old familiar places that would be pleasant surprises. Suppose we have found a subject that has given a satisfactory result in the morning; we think that is the best time of day and any other lighting would give an inferior picture. It is well worth while to try it with an opposite effect, not only of lighting but of atmospheric conditions, and very likely the photograph will not only be good, but so entirely different from our first choice that practically it is a different picture. A front light very often supplies beautiful effects, if not the most beautiful; the only precaution is to manage so that the sun does not shine on to the lens by selecting a station point protected by the shadow of some object in front—a tree, building, or what not. The altered appearance of the subject, by nothing more than change of direction of light, is something marvellous, and is worth a most critical examination. A few experiments will convince the most sceptical. Objects that were invisible under one aspect will assume importance under another. Strong, deep shadows will be substituted for gleams of light; in fact, the composition is so altered as to be scarcely recognisable.

In examining a number of photographs taken by various men of the same place, although all may possess equal technical excellence, some will at once arrest attention and others hardly get a second look; and why? Nine times out of ten it will be found the lighting is more effective and the treatment more artistic in one case than the other, or the level uniformity of a foreground is broken up by a shadow or puddle reflecting some bright light that is absent in the rest, or some difference equally trifling in itself, but so important in its effect,

showing that the man who made the picture was fully alive to the value of trifles, which may, perhaps, be light as air or insubstantial as a dream, yet in the photograph are magnified into considerable importance, so much so that it is a reasonable assertion to say that the pictorial value of a photograph depends entirely on trifles. Let any one look over his stock of photographs and see how many he can find that some trifling addition or alteration would not vastly improve. If this or the other was just a *little* different from what it is how much better would the picture be. Another thing, a photograph challenges attention and criticism as much, or more than, any other pictorial effort. The representation of texture, detail, and drawing are, so to speak, effected automatically, with little or no trouble or experience, and in a good photograph are beyond criticism, so that the proper choice of light and arrangement, which qualities are under the control or rather dependent on the judgment of the operator, should receive his most careful attention. If he fails in these respects, it is either owing to his want of care or lack of knowledge, and merits the adverse criticism that will no doubt be awarded.

In the search for subjects to photograph, those presenting strong contrasts are usually the most effective—a bright light in juxtaposition to a deep shadow, such as a *good* moonlight effect for instance, where deep shadow is not represented by unmeaning blackness, or the lights hard and chalky, but where the darkness is full of subtle differences of degree, and the lights with pearly half tones, contrast alone being responsible for brilliancy. Such pictures owe much of their charm to the quality of suggestiveness, the unseen something that excites interest. If we examine a picture of this kind the eye naturally tries to penetrate the obscurity and discover as much as possible of the landscape, the effort creating much more interest than if the whole of the picture was clear and easily discernible at first sight. This quality applies to any other picture. Something left indistinct and indefinite gives value to the parts that are clear and well defined, thus enhancing the importance of both. A slight haze is in most pictures a valuable adjunct to the pictorial effect. In other words it gives the mind a little exercise, for whilst the eyes are occupied in discerning the form, the imagination is busy filling up the gaps that lie hidden or partially obscured. This power of appreciation depends of course on the idiosyncrasy of the observer, and exists in all gradations from an absolute blank to the ultra-refinement that appreciates the slightest variation of a tone or position of an object. The pleasure experienced in the effort of satisfying oneself that one has thoroughly understood the artist has a fascination for some that differently constituted minds can never appreciate—theirs is the loss. The quality of suggestiveness, valuable as it is, is often burlesqued by the substitution of fuzziness; it can be scarcely called going to extremes, for the point of the matter is entirely missed, and instead of something upon which we can pleasantly dwell, we are offered unmeaning blankness, an indistinctness without a purpose. The line between the two is somewhat difficult to define at all times, and is very much dependent on artistic feeling both of artist and observer.

EDWARD DUNMORE.

(To be continued.)

FERROUS MURIATE AND ITS USE IN CONNEXION WITH THE OXALATE DEVELOPER.

Few workers in gelatino-bromide, whether in the case of plates or paper, are aware of the numerous changes that may be rung on the good old-fashioned and well-known oxalate developer. The combination of a solution of oxalate of potassium with protosulphate of iron, in proportions suited to the various formulæ that have from time to time been given to the public through the medium of the journals and reports of societies, is perhaps in a large measure the only one generally known and used. Let it be remembered that oxalate of potassium in combination with any soluble salt of iron forms oxalate of iron, the acids which form the compounds of iron producing various effects according as they are used. In this category we may mention, among others, tartrate of iron, lactate of iron, and muriate of iron, or properly speaking ferrous muriate. While each has characteristics peculiarly its own, which are shown in development, the one which has to my mind seemed to possess qualities of the greatest importance to photography is the last named. Ferrous muriate may be bought of the wholesale druggist at a comparatively low figure, but for experimental purposes a paper of fine tacks and a couple of ounces of muriatic acid mixed at night, well stirred, and left till next day, will be found to be pretty nearly saturated with the iron from the tacks; iron filings would perhaps do better and dissolve somewhat more rapidly. The appearance of the liquid after filtration will be a more brilliant green than that of a solution of sulphate of iron, and

should be tested for acidity. If found to be but slightly acid it is in good condition to be used, and combined in the proportion of one of the iron to three of the saturated solution of oxalate of potassium, will be found to give a developer of extremely powerful character. In some experiments which I have tried this fact has been demonstrated to me very forcibly, and I have been agreeably surprised to find that the ferrous muriate in combination with the oxalate of potassium is a more active reducer than the ordinary form of developer; in fact, I think I may assert the difference in its favour to be almost one-third.

This, I am confident, will be a matter of importance to those who make a specialty of instantaneous work, a small quantity of the ferrous muriate solution being kept for use in special cases of extremely short exposures. I hope that these suggestions will be followed out by those who have more time at their disposal than I can at present afford, to bring out the possibilities that exist in this rather novel form of development.

—Anthony's Bulletin.

THE TESTING OF LENSES.

[A Communication to the Camera Club.]

WE may test photographic lenses in two ways:—First, we may test a lens as to its freedom from faults; and, secondly, we may test a lens not so much to find out whether it is only faulty, but, by focussing the lens on certain definite ruled scales of known size and form, give a definite numerical value for the performance of the lens as regards each quality. Now there is a great difference between these two methods. The first, which is the sole method employed by all lens manufacturers, does not enable them to state how good a lens is—it merely enables them to say, This lens is truly, or untruly, centred. In other words, it simply tells the optician where the fault lies, and whether a lens will perform well or only passably. Now, by the second method, we are enabled to register its performance, and, to use a homely illustration, to award a certain number of marks for each quality, and so to compare each lens in terms of the performance of other lenses, and that for each property it possesses. The first is, so to speak, a qualitative analysis, the second a quantitative one. The first requires special apparatus, and a training which needs years of practice to perfect oneself in, while the second requires only a camera and such apparatus as may be manufactured at home. It is this latter which I intend chiefly to occupy your attention with to-night; but, before doing so, I will allude as briefly as possible to the first, that is, the optician's method of testing lenses. Now, the first thing a workman does is to see that all the lenses are mounted truly, so that all their optical centres are in a straight line. This can be done by chucking the lens carefully on the lathe, and holding a small gas flame in such a position that the whole row of reflected images can be seen in a line with the optical axis of the lenses. The lens is now revolved in the lathe, and the images watched; if they all remain immovable the combinations are all truly centred; if the images wobble, one or other is out of truth. By reversing these in their flanges, it is easy to see which is at fault. After this is done the workman turns the lens in its cell with his finger and thumb, to be sure that it turns freely, so that the contraction and expansion of the amount may not displace the lenses. Before doing this, it will be necessary to see whether the surfaces of the lens are true curves; whether the balsam between the contiguous surfaces is an even homogeneous layer; and, lastly, the curves being right, whether the spherical and chromatic aberration are balanced by the crown and flint lenses. All these tests can be made together and in this way. The lens is screwed on to the camera in the usual way, and a highly-polished silvered or steel ball is placed in the focus of the lens. A beam of light is now thrown on to the bulb from a bright source. The ground-glass is now shifted until the image is perfectly sharp in its centre. The former is now removed, and a Ramsden eye-piece is screwed on a movable arm, and the image is examined in air through it. By the appearance of the image, makers judge of the correction of the lens, whether it is sufficiently corrected for spherical and chromatic aberration, flatness of field, depth of focus, or astigmatism. These are the chief tests used by opticians, and they are of the greatest value; but I will, with your permission, give you my own scheme for testing lenses quantitatively.

Before testing the lens we must first ascertain two points:—(1), The equivalent focal length of the lens; and, (2), its working aperture.

To find the former there are many ways. If a single lens, the best way is undoubtedly to focus on an extremely distant object, such as the moon, or a distant weathercock, and then lift up the ground-glass of the camera and insert a rule; let its end touch the back surface of the lens and then mark where it touches another rule placed across the camera, on a level with the position of the inside of the ground-glass. Next unscrew the lens from its flange, measure its thickness in the middle line, and add half this thickness to the length obtained;

the sum will give the actual focal length of the lens within a very minute fraction, far beyond what is necessary in practice. If we want to find the focal length of a symmetrical or compound set of lenses I think the best way is to take the focal length of each combination separately by the above method, and then to measure accurately the distance between the optical centres of the two combinations, then by the well-known formula:—

$$F = f + f_1 - \frac{a}{f f_1}$$

$$1 = \frac{f + f_1 - a}{f f_1}$$

$$\therefore F = \frac{f + f_1 - a}{f + (f_1 - a)}$$

Thus if focus of one lens $f = 6$ inches and focus of second lens $f_1 = 8$

$$\text{Then } F = \frac{6 + 8 - 2}{6 + 8 - 2} = \frac{12}{12} = 1$$

There are several other methods, but, with one exception, all are laborious and require an optical bench or special apparatus. This exception is by taking a lens whose focal length is known absolutely, and comparing the size of its image with the size of the image thrown by the lens to be tested. Then the focal lengths are directly as the linear dimensions of the images. If the two combinations are of equal focus and symmetrical, the optical centre is obviously midway between them. If not, the position of the optical centre can be at once found by measuring the ascertained focal length from the ground glass to the lens mounts, and there marking it off.

For those gentlemen who wish to arrive at very exact results I recommend them to Glazebrook & Shaw's *Practical Physics*. In comparing lenses it is absolutely necessary to compare them with similar working apertures proportional to their focal length. For the portrait I take $\frac{1}{4}$ rapid doublet, $\frac{1}{4}$ wide-angle triplet, and landscape $\frac{1}{8}$ as the standard. If the stops do not correspond to these apertures I make fresh ones out of cardboard. In the case of compound lenses I check their sizes by Dallmeyer's plan of placing a card with a small hole in the place of the focussing glass, and measuring the image of a candle placed behind the hole as it appears in the front lens of the combination.

I have had a large camera specially constructed for testing lens. When actually testing I remove the focussing glass and substitute my movable magnifier. This consists of two bars of magnetised iron, one on either side of the frame, on the outside of which is a scale divided into millimetres all the way along. Another bar of steel, also divided into millimetres, whose ends rest on these bars, can slide up and down, but is prevented from moving sideways by brass stays. On this a holder slides along bearing a Ramsden's eye-piece, with which I focus, and by the position of the ordinates and abscissae of the two scales I can find instantly any position on my aerial focussing field. Having placed my ruled trial screen, on which a series of concentric circles are ruled each two mm. in width, and the spaces also two mm. in width, I proceed to move my camera until a given number of lines can be counted to the inch or centimetre, and then I proceed to test my lens.

In this method the figure, consisting of concentric circles, is placed in the centre of the focus of view of a camera, the number of inches or centimetres, within which the outlines of the circles can be distinctly defined, being taken as a measure for the defining power of the lens. In comparing difficult lenses, these lines should be reduced.

DR. G. LINDSAY JOHNSON.

(To be continued.)

THE LATE MR. J. B. DANCER.

WE have referred to Mr. Dancer's death on a previous page. For some time Mr. Dancer had been in very delicate health, and to this suffering was added the terrible affliction of total blindness. Mr. Dancer was born in London on October 8, 1812. In 1818 his father, Mr. Josiah Dancer, removed to Liverpool, where he carried on the business of optician and philosophical instrument maker; he was also a public lecturer on science, and was an active promoter of the Mechanics' Institute and Literary and Philosophical Institution of Liverpool. The foundation of Mr. Dancer's optical knowledge was laid in his father's workshop. He also assisted his father in his lectures, and very early in life evidenced a strong bias for mechanical and scientific pursuits. In 1835 the father died, and the business was afterwards carried on by the son.

After a few years Mr. Dancer removed to Manchester, where we find him in 1842 elected a member of the Literary and Philosophical Society, his diploma being signed by Dr. Dalton. In 1845 he became a Fellow of the Royal Astronomical Society. In the successful exhibitions which were held many years ago at the Mechanics' Institution, both in Cooper-street and (after its removal) in David-street, Mr. Dancer took a very important part. It was he who suggested the application of photography to the magic lantern, and who, by the use of limelight, made such application possible. The exhibition of photography on so colossal a scale took the world by surprise, and this grand application of a marvellous art, which has now become so familiar to us, was received with the admiration it deserved. Mr. Dancer's services to the lantern did not end with the application of photography to it; he also improved the arrangement of the optical parts, producing a clearer image and a flatter field than had before been obtainable.

In 1839 he introduced photography to Liverpool, working Daguerre's process, and in 1841 he was the first to do the same for Manchester, which had not yet seen a photographic camera. In the same year he commenced microscope photography on Daguerreotype plates, and this wonderful art he perfected in 1852, when the introduction of the collodion process much simplified this and every other photographic process. These tiny examples of photography excited the warmest admiration and commendation of Sir David Brewster and other distinguished men. Mr. Dancer's diffidence prevented him from claiming for himself in this, as in other discoveries, the acknowledgment that was his due. The invention of micro-photographs was claimed elsewhere, but after a full inquiry by Mr. Joseph Sidebotham, Mr. Edward W. Binney, and the Manchester Photographic Society, Mr. Dancer's claim was allowed. In his record Mr. Sidebotham wrote in 1859: "Mr. Dancer's modesty will not allow him to speak of his own discoveries, but I am sure you all join in the annoyance I have felt in seeing persons coolly claim as their *own new discoveries* what our respected townsman has accomplished so many years ago." In 1853 Mr. Dancer invented the twin-lens stereoscopic camera; that is, a camera with two lenses, placed side by side, at a short distance apart. Before Mr. Dancer took the matter in hand photographers had disagreed as to the distance the camera should be moved for the second picture. In order to give in the stereoscope the proper relief effect some advocated eight inches distance, and some so much as twenty-four. Mr. Dancer was convinced that the proper separation was the ordinary distance between the eyes of a human being, and made his camera under this idea: for the purpose no other camera is used now. Writing in April last to a friend, Mr. Dancer says on the subject of stereoscopic photography: "Whoever undertakes the photographing of the articles collected in the Jubilee Exhibition, which may possibly not be excelled by any collection for many years to come, will, I sincerely hope, freely use the stereoscopic camera. In my humble opinion, based on thirty years' experience, stereoscopic photography is the only process suitable for photographing the solid objects contained in such exhibitions. There is one advantage connected with it which is very little known, or otherwise stereoscopic photography would never have fallen into such disuse as it has done of late years. The advantage is this: if the lenses used are of the same focus as those used in the stereoscope through which the pictures are viewed, the objects represented appear of the same size as the real objects did to the human eye when viewed from the place where the camera was situated." It is to be regretted that such a series of pictures as Mr. Dancer hoped would be made was not undertaken at the Exhibition.

After recounting numerous inventions and improvements in the realms of science, particularly in microscopy and electricity, the *Manchester Guardian*, to which we are indebted for the foregoing particulars, says:—

"Any scientific man finding himself confronted by a difficulty has gone, all through the last forty years, to Mr. Dancer as to an encyclopædia. Days absorbed in this way had to be made up by nights spent over the microscope, and in the end Mr. Dancer lost his most precious possession—his eyesight—not suddenly, but little by little. His knowledge of his own state even enabled him to make diagrams of the destruction of the retina, and to show the surgeon how it was slowly becoming unserviceable. Blindness to such a man was a terrible infliction indeed. With the failure of his sight business also began to fail, and a few years ago the old shop, known to every Manchester man, had to be shut up. Then a few gentlemen came together, an appeal for subscriptions was issued through the papers, and very quickly a few hundred pounds were raised. From that time the small income that has come from this fund has been Mr. Dancer's only means of living. The story is one of the saddest it has ever been our lot to chronicle.

"His active mind never lost its interest in the studies and discoveries

of his earlier years. By his numerous friends his society was to the last highly appreciated, and his modest and kindly disposition greatly enhanced the pleasure and advantage of his conversation."

THE PHOTOGRAPHIC COMPANY, LIMITED.

WITH a great flourish of trumpets the prospectus is published of the Photographic Company, Limited (proprietors of the Cellier-Parkes Colour Process). Although the Company also takes over the business of a photographer (Mr. Vernon Heath), the chief feature of the new venture is the above-mentioned process of so-called photography in colours, and considering the enormous purchase consideration demanded—42,000*l.* in cash and 25,000*l.* in deferred shares—it would be absurd to suppose that an ordinary photographic business could produce anything but a mere fraction of the income required to earn a dividend on the capital of the new Company of 100,000*l.*

All, therefore, depends on the value of the Cellier-Parkes process, and the investor will do well to ponder whether this invention is such as to promise a lasting income. We have not ourselves been given an opportunity of investigating the merits of the process, although we offered to do so, but our photographic contemporaries have expressed themselves unfavourably on the same, and, as we stated in our issue of 18th June, the *Photographic News* considered this process "to be merely the placing of coloured materials or pigments at the back of a photograph, a thing which has been done so often by Woodbury, Vidal, and others before them. Colouring at the back has hitherto found its most popular expression in the 'Crystoleum' pictures which are still sold in Regent-street and elsewhere." As far as we are aware this opinion has not been contradicted, and speaking, therefore, from the opinions which our photographic contemporaries have been able to form, we should say that the novelty of the process does not appear to be established, while its value is more than doubtful.

There is, moreover, a most formidable rival in the field in the "Mayall process," which approaches much nearer (although it does not, of course, realise) the ideal of photography in natural colours, and is of incalculably greater value than the Cellier-Parkes system. Under these circumstances and unless the Company have some different process than that criticised in our photographic contemporaries, we are afraid that the results must fall greatly short of the results promised by the prospectus. It is very strange that no particulars should be furnished in the prospectus of the patents sold to the Company by the Cellier Syndicate, Limited, but we have taken the trouble to unearth the same from the agreement, and are able to inform our readers that the patents therein stated as purchased by the Company are No. 5052, of 1885, for improvements in the production of pictures with the aid of photography, and No. 14,120, of 1886, for improvements in the production of coloured photographic pictures. As we have received various inquiries from correspondents on this point, we shall fully report on the patents in our next issue. In the meanwhile we have to complain that no copy of the other agreement set out in the prospectus as concluded between the Photographic Company, Limited, and the London Scottish Mercantile Investment Trust and Agency, Limited, was to be seen at the offices of the solicitor of the Company, an omission which is contrary to the Companies' Law. From the information furnished it is impossible to glean what amount has been paid for Mr. Vernon Heath's business and what sum for the patents, and we can conceive no valid reason why these particulars should be withheld.—*Invention.*

[Thus far *Invention*. We are, however, quite at a loss to discover the nature of the "formidable rivalry" hinted at in connexion with the Mayall process, unless Mr. Mayall has discovered some process of colouring photographs *other* than that which has been so mercilessly annihilated upon by the press and by technical photographers ever since its introduction last summer.—*Ens.*]

A NEW GRIMSTON SHUTTER.

WE have been favoured by Messrs. Wratten & Wainwright with an opportunity of examining a new Grimston shutter, which is regulated by a cylinder and piston. The action is altogether unlike any other, inasmuch as the mere raising and lowering of the shutter is effected with the greatest possible rapidity, but there is a regulated delay of action when it reaches the top, the lens being then open. But we allow the specification of patent to speak for itself:—

"This shutter has been designed to obviate a defect common to all time shutters, namely, that when slow exposures are required the opening and closing is as a rule performed slowly also.

"In this new patent the opening and closing are always effected with the full rapidity of the shutter, whilst any slowing that may be required is performed when the shutter is fully open. The slowing is done by the attachment of a dashpot or cylinder to the upper part of the shutter, which comes into action only when the aperture is fully open. The opening and closing are regulated by a cam, and the slowing by a small screw valve on the top of the dashpot. This method of regulating time shutters by an air buffer or dashpot was first applied to the Grimston

shutter in June 1885. In the present patent an improvement has been made whereby the releasing and timing are done by the same dashpot or cylinder. The former arrangement for working in the diaphragm slot has been retained. The shutter is also supplied with the usual pneumatic ball.

"In operation, on pressing the pneumatic ball the shutter opens to the full extent as rapidly as a strong coiled spring can make it; the cam at the moment that the aperture is fully open forces the piston to the top of the cylinder with a rapid movement, giving the required slowing motion, varying in degree according to the regulation of the screw valve, and when the crank has just turned its highest position the cam releases itself entirely from any further action of the air cylinder, and the shutter drops as rapidly as it opened. The whole of the mechanism, which is extremely simple, is enclosed in a small air-tight case, there being no holes for dirt or dust to enter. The exposures can be varied from the most rapid to several seconds."

NOTES FROM ABROAD.

(From our Special Correspondent.)

IV.

THE BAGGAGE OF PHOTOGRAPHIC TOURISTS.

THERE are two classes of tourist photographers; the one class is represented by a man who takes with him more baggage than he can lift, or than he can conveniently carry, the other takes no more baggage than he can easily carry himself, far from railways and the busy haunts of men. The latter plan is the best for health or for exploring districts new to him, and involves the necessity of carrying but a quarter-plate camera, or one still smaller, unless he be of considerable muscular development. With knapsack on back, containing his small camera and a few clothes, he is independent of cabs, railways, and porters; he can go ahead over hill and dale, learning the unsophisticated manners and customs of the country, talking with the peasants in their rural homes, or sojourning in the hospices of the monks in mountain fastnesses. On an expedition of this kind he can gain a general idea of the country visited, and decide upon some place as his headquarters when upon a future excursion he can quietly settle down therein for a time armed with heavier apparatus. The late Albert Smith defined the true tourist as the one who roamed in this lightfooted manner, and who carried but two shirts, both of flannel, one of which he would wash himself, if necessary, in a mountain stream, and dry in the sun, weighted down by a stone or two when there is wind.

The travellers who know least about the countries they visit are these who are "put through" by some tourists' agency; they stop at Anglicised hotels abroad, they are attended by servitors who humour their insular customs and prejudices, and who do not forget to charge them at not less than English rates. They travel shut up in an English glass case, metaphorically speaking, and on their return know not so very much more of the real thoughts and social condition of the countries they have visited than if they had been looking at a series of dissolving views in London, and listening to the description thereof by a popular lecturer.

For a tourist who intends to carry all his own baggage, including photographic apparatus, a handbag or small portmanteau is out of the pale of consideration; it would soon become a weariness to the flesh. He has no resource but a knapsack.

A knapsack, however, is rarely sufficiently rigid when it becomes a question of carrying optical apparatus of any delicacy, although some are made of indiarubber over a gridiron-like wicker framework, and others are made of some pasteboard material. Remembering what Mr. England once published about the advantages of a basket for lightness and for carrying anything of a breakable nature, I searched about shops near Covent Garden for a portmanteau-shaped basket, and at last found an exceedingly elegant one of French make. The next step was to discover an actual maker of knapsacks, and one was found in the person of Mr. Price, of Great Marylebone-street, London. He fitted up the basket with two sets of straps, the one set permanently fixed to it, to keep it well closed by straps and buckles; the other, or shoulder set of straps, was removable, and could be detached and stored away inside when in towns. The only fastening to the original portmanteau consisted of two wooden pegs passing through two loops. For these pegs a thin rod of brass with a ring at one end was substituted; through a hole at the other end went a little padlock. Here, then, was an arrangement which served as a portmanteau in towns and as a knapsack beyond their limits; it was light in weight, its contents were under lock and key, and it was so rigid that little fear was entertained of injury to apparatus placed therein, did it get no more than a fair amount of knocking about at railway stations and elsewhere. The knapsack tourist does not want a weight, however light, always tied to his back, and in towns it is often a convenient thing to leave it at the hotel or in a railway cloak-room for a day. Rain was kept from the contents of the basket knapsack by wrapping them in an amply large sheet of mackintosh, which indiarubber fabric, by the way, makes the best of all focussing cloths, it being perfectly impermeable to light and possessing little weight. Once for all, it may be mentioned that in testing this knapsack over long distances it was found to answer every purpose anticipated. Man, by taking thought, cannot add a cubit to his stature, but by taking thought he can wonderfully adapt the knapsack principle to the requirements of the tourist photographer. The straps just where they come over the top and front of the shoulders should

be broad, say, two and a half inches; the knapsack should be carried high up on the shoulders, not down in the small of the back—in the latter place the weight drags, and is more uncomfortable. All Swiss mountaineers and schoolboys carry their knapsacks high up. In two small things if we, in England, imitated the Swiss, comfort would be increased. Few persons in Switzerland wear chimney-pot hats, which are considered an abomination. In some towns they are never seen at all except upon the heads of foreigners, who are gaped at by children as London street boys would stare at a Welshwoman in her Mother Shipton hat. The other thing is, that the Swiss as much as possible abjure handbags and substitute knapsacks for carrying purposes. By combination among individuals these customs should be made more fashionable in this country. Aristocracies care nothing for public opinion, and allow plenty of freedom of thought and action to their own members; the more uncultured the people, the more do they take the liberty of criticising those of their number who depart from commonplace uniformity in dress or anything else; what they deem best for themselves they think best for their neighbours, and exercise uninvited pressure upon their fellows to an extent antagonistic to freedom. The food, dress, education, or religion which is best for one individual is not necessarily the best for another.

English photographers who make but an occasional day's excursion from home with the camera, do not know the wants of the real tourist who means to carry all his baggage for several weeks at a stretch, and who wants its weight kept down as close to, say, eight or ten pounds as possible. Given three ounces unnecessary weight in too heavy mounts of lenses, and five ounces unnecessary weight in too thick paper and covers of guide-books, we have half a pound to be carried uselessly for hundreds of miles, so that the man who does not speak out to manufacturers on these items is an idiot. On critically examining the whole of his baggage, he may be able to see how various manufacturers might together have lightened it by a whole pound. Quite recently, at one of the London photographic societies, two or three of the members thought it to be such a funny thing that anyone should propose to weigh lenses, because conditions in which a few ounces of baggage more or less are of importance had not come within their personal experience.

BELGIUM AS A FIELD FOR THE CAMERA.

Armed for a journey of many hundreds of miles with the light baggage just described, I left London in the middle of September, the best time of year for continuous pedestrian feats, because the great heats of summer have gone, and foliage has but begun to assume its autumn tints. Leaving Liverpool-street by the boat train at eight o'clock, one is on board ship at Harwich by half-past nine; at ten the start is made, and by eleven o'clock the open sea is reached, far from the filthy air of London. The comfortable boats, so late in the tourist season, are not much crowded on the outward journey, the general stream of tourists flowing in the opposite direction. On the following morning, gazing at the porthole of my cabin, I saw as set in a circular frame the weather-beaten countenance of a British sailor, his locks streaming in the wind, forming a good subject for an artist, but the puzzle remained how his face chanced to be there—was he standing upon the briny ocean? Gradually my waking senses realised that I was the sole occupant of a deck cabin, and that he was upon the deck outside. After four or five hours smooth steaming up the Scheldt, the lace-like spires of Antwerp Cathedral are seen over the flat country long before the city is reached, and at ten o'clock the landing is effected. Here a new virtue was discovered in the portmanteau knapsack; the Custom House officers, in passing baggage, put their initials or other hieroglyphics upon it, and trying to make marks upon the blackboard of the Photographic Society is child's play to attempting to write upon such a basket with a piece of soft chalk. The official having failed once, gave up the hopeless attempt with a grin.

It was a Sunday morning, and I found my way straight to Dr. Van Heurck, the Director of the Botanical Gardens, and after a kindly welcome inspected his more recent achievements in photo-micrography, including his latest prints of *Amphipleura pellucida*, which recently have been so much criticised at the Royal Microscopical Society in London. He presented me with an instantaneous photograph of himself and of M. Naquet, son and partner of the celebrated optician of that name in Paris; it was taken by the flashing magnesium light, and is additionally interesting because it includes part of Dr. Van Heurck's laboratory, and some of the microscopes with which so much good work has been done. After leaving him I found a military band enlivening the Place Verte alongside the Cathedral. Then with drum and trumpet, and flying banners, a procession approached. In its centre was a man on horseback, dressed in black velvet, with low velvet cap and a heavy black plume, a broad collar of white lace adorned his neck, and over the high tops of his buff-coloured boots were hanging circlets of white lace. He bore aloft a gorgeous banner, and by his jovial glance appeared to enjoy his position. Here was a subject, indeed, for a photograph. It was the procession in honour of the tercentenary of Joost van den Vondel, the Dutch poet, and I presume that the banner-bearing hero was supposed to represent Van Vondel himself. Had time permitted I should have been glad to have called upon M. Storms, and to have visited some of the officials of the new branch of the Belgian Photographic Association in Antwerp, but the object of the trip was to get the freshest air, and to leave large towns behind as quickly as possible.

That evening I reached Louvain and remained there for the night. In the morning another procession with band and colours came along; a

number of children in dresses of brilliant colours, like the kings and queens of a pack of cards out for a walk. In their hands they carried bunches of flowers—some of the bouquets were gilt all over. One of these fairy queens, aged perhaps twelve, entered the *café* from which I observed the procession, and was treated by the landlady to about a pint of ale, which she swallowed with two or three pulls as if it had been mother's milk. Lonyain is noted for brewing the best beer in all Belgium, and perhaps the children are brought up on it. In the centre of the procession was an open carriage containing an old man and woman, who surveyed everything with nonchalance, as if wishing it were all over; opposite them sat two grown up members of their family. All four carried extra-large bouquets fully gilt. Here was an un-English scene for an orthochromatic photographer; but what did it all mean? It was the fiftieth anniversary of the marriage day of the old couple. They were driven, accompanied by martial music, to the ancient City Hall, where probably they went through some time-honoured ceremony in the presence of the Burgo-master. In the vestibule of this Hall are three statues representing the three most highly-prized foundation principles of Belgian liberty, namely, free education, a free press, and freedom of religious opinion. This *Hôtel de Ville* is one of the most elaborate Gothic buildings in the world, the whole of its exterior being carefully carved by the chisel; the artists worked upon a soft stone brought from France and soaked with oil, the whole subsequently hardened. I called at the University, which in the sixteenth century was considered the best in Europe, to see one of the Professors, but it was in the vacation season, and the place was deserted with the exception of the doorkeeper and family. Autumn visits to Belgium are disappointing to strangers, in the circumstance that most of its chief and university libraries are either closed altogether or open only until midday. The people do not seem to have realised the benefit of keeping their best libraries open every evening all the year round.

The chief attraction to the photographer in Belgium is the rich variety of specimens of old Gothic architecture, not alone in churches but in civil buildings. There is infinite variety in the churches, which are frequently vast enough to deserve to rank as cathedrals, and all these eligible subjects for the camera are congregated within short distances. France has magnificent specimens of Gothic architecture, and Rheims Cathedral is perhaps the finest specimen of such, north of the Alps. In France, however, the distances for the tourist are greater. Even little villages in Belgium have magnificent ecclesiastical piles, out of all proportion in grandeur to the density of the surrounding population.

Our Editorial Table.

ELEMENTARY MICROSCOPICAL MANIPULATION.

By T. CHARTERS WHITE, F.R.M.S.

Now that so many are directing their attention to the fascinations of enlarging microscopic subjects by the agency of photography, a manual intended for beginners in microscopy by such an experienced microscopist as Mr. Charters White, comes in at a most seasonable time.

Designed with the aim of instructing the tyro in the preparation of objects of interest and instruction in an elementary yet complete manner, Mr. White's manual takes the neophyte in hand *ab initio*, and describes the nature of the various apparatus required in language the youngest student would find it hard to misunderstand.

The preparation and mounting of both opaque and transparent objects; the cutting of sections; insect anatomy; infusoria and the numerous other things, a knowledge of which go to the making of a microscopist—all come in for as lucid and full treatment as the limits of the work permit; while, as might have been anticipated, a chapter is devoted to photo-micrography.

The manual will prove useful to the class for which it is mainly intended. It is published by Roper & Drowley.

PHOTOGRAPHS OF YACHTS.

By W. H. HYSLOP.

To take from the deck of a steamer in motion direct instantaneous pictures of yachts under full speed in a stiff breeze, on plates 18×14 inches, is evidently no easy matter, and the one who achieves this task well is entitled to great credit.

Two photographs of this class before us, not merely photographs but *pictures*, attest the skill attained by the artist, Mr. W. H. Hyslop. They were taken on the Clyde at or about the time of the Photographic Convention of the United Kingdom at Glasgow, when so many crack yachts were disporting themselves in the Clyde. In one we have the *Ariel* and the *Roma* tearing away as if life or fortune depended upon their efforts; in the other we have the *Thistle*. The attitudes, so to speak, are singularly graceful, and their beauty is enhanced by fine cloudy skies. They are printed in platinum with rich warm tones.

PATENTS COMPLETED.

IMPROVEMENTS IN HOLDERS, CLIPS, OR EASELS, FOR PHOTOGRAPHS, MIRRORS, PHOTOGRAPH FRAMES, CARDS, AND OTHER ARTICLES.

No. 5488. HARRY WHITFIELD, 68, Broad-street, Birmingham.—*April 15, 1887.*

My invention is primarily a metal holder or clip constructed to hold or clip a glass plate, behind which is held a photograph, picture, or card. It is also constructed to hold or clip a mirror, photograph, card, or other article.

My invention is formed of two flat or round strips of metal or other suitable material. These two strips are rivetted or in some other way fastened together loosely at their centres so as to form a cross. Each end of each strip is formed as a hook. A spring which exerts an outward pressure is attached, one end of it, to each of the two strips at a position above or below the centre of each strip. On this spring being compressed the cross assumes a lengthened shape, and when the spring is released the cross is shortened and clips the article which it is required to hold. Thus, when it is desired to release the article held it is only necessary to compress the spring, and the cross lengthening looses the hooks from the article held.

I make the spring in my invention in such a way that it can be used as an easel leg, but any suitably formed spring would actuate the cross in my invention in the manner desired.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, November 24, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. W. Cobb presided.

Mr. J. B. B. Wellington exhibited plates which he had received from an acquaintance in the country who made his own emulsions; the plates had scum-like markings upon them.

Mr. A. COWAN believed the effect to be due to the method of coating; the emulsion had been poured on in too small a pool and the plate too slowly drained.

Mr. WELLINGTON had had similar marks after attempting to remove air-bubbles with the finger.

Mr. C. HEINRICH TRINKS had seen similar marks when the emulsion was applied too hot.

The CHAIRMAN remarked that too much spirit in the emulsion would produce a similar result, which was more likely to be seen when the precipitation method was employed.

Mr. WILLIAM ENGLAND said that such markings were usually due to carelessness of some kind.

Mr. A. P. HIGGINS exhibited his method of fitting the cork of a large bottle with tubes for use when the water supply is limited and the operator cannot work near a tap or sink. When the water has to pass through a smallish tube he is likely to use less of it than when pouring from a jug. Mr. Higgins then drew attention to a part of the money article in the *Daily Telegraph* of the preceding Tuesday in relation to the Cellerier-Parkes process, which stated about the Photographic Company, Limited, that 67,000*l.* were to be paid to the founders, of which 25,000*l.* would be in deferred shares. The capital of the Company was put at 100,000*l.*

The reading of these figures was received with great laughter, and various censorious remarks were made about them by different speakers.

Two questions in the box asked, "Is there any rule for determining the distance between the lamp and the condenser in the lantern for enlarging purposes?" "At what distance should a five-inch double condenser stand from a four-wick paraffin lamp?"

Mr. FRESHWATER replied that the distances depended entirely upon the focal lengths of the front lenses used.

Mr. A. HADDOX said that to get the best effect the rays from the condenser should be made to intersect at the place of the diaphragm of the front combination of the lantern.

Mr. ENGLAND remarked that a small portrait lens formed a much better objective for the lantern than the ordinary objective supplied therewith.

Another question was, "What is the best developer for gelatino-bromide plates for lantern transparencies?"

Mr. J. J. BRIGNSHAW could recommend the ordinary washing soda and pyrogallol developer without sulphite; it gave warm tones and plenty of density with those plates prepared specially for photo-micrographic work; the proportions were—

Washing soda	4 ounces.
Bromide of potassium	40 grains.
Water	40 ounces.

Poured into the developing dish, after which about one grain of pyrogallol was added to each ounce. He used old washing soda which had gone quite white and contained no crystals of visible dimensions.

Mr. HADDOX remarked that when carbonate of soda was recommended in formulae it should always mean the pure dry salt, otherwise the operator would be using an uncertain mixture.

Mr. W. Few was elected a member of the Association.

The rest of the evening was devoted to the exhibition of lantern slides, including some by Mr. William England representing statuary at the late Paris Exhibition and elsewhere; Mr. Atkinson, views in Killybeg; Mr. Cooke, rural English views; Mr. L. Medland, views in Northern Europe; Mr. H. M. Hastings, views at Brighton; Mr. J. B. B. Wellington, landscapes and sea views, many with natural clouds, which in most cases were printed upon the covering glass, and in all greatly improved the pictures; and Mr. A. P. Higgins, views in Portugal.

CAMERA CLUB.

THE subject on Thursday, November 24, was *Enlarging*, opened by a paper read by Mr. D. P. Rodgers, Mr. E. Ferrero in the chair. There was an unusually large attendance of members and friends, over seventy being present.

The screens and walls of the Club were hung with enlargements to illustrate the subject of the evening.

In his paper Mr. RODGERS treated chiefly of enlarging by means of a lantern from quarter-plate to whole-plate size, and described his method for obtaining the best illumination. In going over the advantages of enlarging he held that the detail in a quarter-plate was too fine to be visible, but that all this detail was seen in the enlargement. Further, lenses of short focus—the smaller lenses—gave more intense pictures and greater depth than were obtained in large direct work. He preferred the limelight as an illuminator, as he found it gave more vigorous tones.

Mr. VALENTINE BLANCHARD then described his method of making enlarged paper negatives.

Mr. HEFORTH pointed out that the mixed gases gave a sharper image than the blow-through because of the larger flame of the safety jet.

The discussion was carried on until a late hour by Messrs. Bolden, Walker, Davison, Foulerton, Adeock, Sage, Beck, and the Chairman.

On Thursday, December 8, Mr. Andrew Pringle will read a paper on *Amateurs' Residues*. Meeting at eight p.m.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

THE annual meeting of the above Society was held in the Technical Schools, Bridge-street, Birmingham, on November 24, 1887.—Mr. R. H. Norris, M.D., President, in the chair.

Messrs. C. Mantell and A. Robinson were elected members.

THE PRESIDENT, before calling for the annual report to be read, said, an annual meeting is dear to every Englishman; it is the occasion when we render the report of the past session, and we are your humble servants and have again to solicit your suffrages. It is an occasion when you on your parts are perfectly at liberty to re-elect us, and we should all be encouraged to air any grievance which you may have, or which you may think you have, during the past session. It is encouraging at least the principle of amity amongst us, and the contrary is always a bad thing; it is like a volcano which always has a tendency to upburst, and we do not want in this country social or intellectual problems to be solved by a chemical solution. Now I say that when a Society like this looks to air its grievances, or any grievance which a member thinks he has, then he should be entitled to state his case. We should be like men, and have a little forethought, and our little grievances should be got rid of, and if we manage matters in this way we shall have constant health and make sure that we shall be a flourishing body.

The annual report was then read, from which we make a few extracts.

Deducting resignations and those struck off the roll for non-payment of subscriptions, the register shows a total number of members and associates of 144 against 108 last year.

The average attendance at seventeen meetings has been forty-nine.

Among the papers read were the following:—*The Humorous Side of Photography*, Mr. W. D. Welford; *On Enlargements*, Mr. E. H. Jaques; *Printing by Artificial Light*, Mr. F. Birkett; *Retouching*, Mr. A. Nock; *Photography and Reminiscences of Birmingham Photographers of Bygone Days*, Mr. W. R. Osborn; *Outdoor Photography*, Mr. S. Delicate; *Stripping Films*, Mr. E. H. Jaques; and *Collotype or Practical Lithography*, Mr. E. C. Middleton.

On October 13 an exhibition (which is intended to be annual) was given of photographs taken by the members. This proved a great success, over four hundred pictures and transparencies being shown, upwards of one hundred and sixty being for competition in the nine classes for which prizes had been

offered. The whole of the pictures showed a decided advance, and the friendly rivalry should serve to stimulate the members to strive for still better work and to attain the goal of every good student of the art, "success." The Judges were Messrs. Walter Breiden, John Collier, and Harold Baker. The successful pictures and winners' names were:—Class A, "Best photograph of the successful pictures in Classes B to H," J. C. Huxley, M.D.; Class B, "Home portrait," E. Underwood; Class C, "Best instantaneous picture," W. J. Harrison; Class D, "Best landscape taken in 1887," W. D. Welford; Class E, "Best photograph from paper negative," F. Dutton; Class F, "Best contact print produced by development," J. C. Huxley, M.D.; Class G, "Best enlargement," J. Heaton; Class H, "Best transparency on glass or opal," J. Heaton.

During the year several excursions have been made and were well attended. During the year Mr. B. Karleese was compelled, owing to ill-health, to resign the co-Secretaryship, and the best thanks of the Society were given to him for his great assiduity in promoting the interests of the Society.

The Council recommend that the Exhibition for 1888 be held towards the close of the year, and have great pleasure in announcing that they have already received several offers of prizes for competition.

The papers promised are:—*Saunshine and Shadow*, E. C. Townshend; *Lantern and Slides*, J. Place; *Don't* (a paper for beginners), R. Godfrey; *Double Contact Printing for Lantern Slides*, W. Tylar; *The Land of the Midnight Sun*, E. H. Jaques; *Photographic Humours*, W. D. Welford.

During next year the Photographic Convention of Great Britain, having been invited by this Society, will favour Birmingham with a visit, and the Council trust that each individual member will assist with hearty good-will, so that the success of the Convention may be assured.

A summary of the income and expenditure of the Society is appended to this report, and the Treasurer's accounts show a balance in hand of 18*l.* 0*s.* 2*d.*, as compared with 12*l.* 5*s.* 6*d.* last year.

After passing new rules and alterations, the election of officers and Council was proceeded with, and the result was as follows:—*President*: Mr. R. H. Norris, M.D.; *Vice-Presidents*: Messrs. W. Septimus Harding, J.P., J. C. Huxley, M.D., and E. H. Jaques; *Council*: Messrs. J. A. Button, James P. Heaton, E. C. Middleton, W. B. Osborn, J. Place, G. A. Thomason, W. D. Welford, and G. M. Bliff; *Librarian*: Mr. S. J. Holliday; *Hon. Treasurer*: Mr. Thomas Taylor; *Hon. Secretaries*: Messrs. J. H. Pickard and William Rooke.

In consequence of the lateness of the hour, the President postponed his address to next meeting, and a vote of thanks was carried unanimously.

THE CHAIRMAN, in returning thanks, said, My little box must remain unopened to-night as time is short, but I will give you its contents later on. I think I have studied photography to some extent for the last forty years, and I still remain, as ever, attached to the art and science of photography. In this life a man who follows a public career, as many do in such a variety of ways, finds it almost impossible to devote any particular amount of time to one thing. It is perfectly true when your Secretaries called upon me I felt great hesitation in again becoming your President, because I knew I could not possibly give the time to it if it ought to receive, I can well understand that if your President came more amongst you it would be conducive to the interests and progress of your Society, and I cannot readily understand why you continue to elect me as your President, seeing I am so deficient in what is so essential. From the kind feeling and recognition received at your hands I have tried to develop our mutual study. A man, too, must be remembered who gives himself up to expositions but cannot find time for research. The past three years of my election as President of this Society have created quite a diversion in my studies. It is a singular thing in connexion with the human mind that it runs in grooves for years, and if it is compelled to pass from one groove to another it continues to run in the old groove for a time, so that it has happened that many researches have only been partial. Since I have been elected your President photography has come in for the lion's share. Though I am not with you in body I am in thought, and I am working for the interests of this Society. Of that which I am doing for you at home this may be one day expounded to you here; that is the only justification I have in allowing myself again to be elected your President. I consider the position one of considerable honour, and I appreciate your kindness in electing me. At the same time, at the end of my term of office, if you will allow me, I should again be glad to retire into private life from this position, and let some younger blood and more energetic material take my place.

Votes of thanks were accorded to the Treasurer, the Librarian, the Auditors, and to the Secretaries, and the meeting terminated.

Dr. Norris's address and paper will be given early in the session.

CHESTER SOCIETY OF NATURAL SCIENCE. PHOTOGRAPHIC SECTION.

THE first winter meeting was held in the Dark Room, Grosvenor Museum, on November 9, when Mr. F. Evans, of Birkenhead, gave a demonstration of the preparation of lantern slides, at the close of which a number of slides were shown on the screen, eliciting a very warm discussion.

WALLASEY PHOTOGRAPHIC ASSOCIATION.

THE first annual supper and distribution of prizes in connexion with the above Association was held on Wednesday evening, the 23rd ultimo, at Seacombe, Dr. Cannell presiding.

At the conclusion of the repast the PRESIDENT proposed the toast, "The welfare of the Wallasey Photographic Association," and in doing so he descended in pleasing terms upon the work of the Association since its inauguration, which had evidently consisted not only of "talk," but also of hard work, as was clearly evidenced by the results before them. He hoped that at the next annual supper the number of members (twenty-seven) might be considerably increased.

Mr. WILKINSON, in responding to the toast, confirmed the President's remark regarding the Association's work, and joined with him in the hope that many of the residents in the district who practised the art would come forward and join them.

The prizes were then distributed to the successful competitors by Dr. Cannell,

In response to the toast of "The Judges," Mr. JOSEPH EARP remarked that the adjudication had been a pleasant task, the work put forward being exceedingly creditable to the Association.

After other toasts the remainder of the evening was spent pleasantly.

CARDIFF AMATEUR PHOTOGRAPHIC SOCIETY.

THE second annual dinner of the Cardiff Amateur Photographic Society came off at the Angel Hotel, on the 17th ultimo. About forty gentlemen participated in doing justice to an excellent repast provided by Host and Hostess Bland. The President (Mr. Alexander Kellar) occupied the chair.

After the customary loyal and other toasts,

In responding to the toast of "Our Late President," Mr. ALLEN said that being chosen first President of the Cardiff Society was to him a source of great pleasure and pride, knowing, as he did, the very important part played by photography in all matters of modern science. Speaking as an engineer, he felt that the art was one that no engineering establishment of any importance could afford to ignore, and that most large firms now felt this so much that they are obliged to add a photographic department to their business in order to secure accurate delineations of their manufactures, as well as to duplicate their drawings and plans—the latter being generally done by the ferro-prussiate process. No matter how complicated the drawing or tracing might be, the photographic copies might be multiplied to any extent and in the merest fraction of time, thus rendering it easy to duplicate working drawings in a manner that was utterly impossible before adopting this invention. Photo-printing processes were now superseding lithographic drawing and wood-engraving to a very large extent, and scarcely an illustrated journal now goes to press without blocks thus produced being employed. We are thus enabled to see in print copies of original drawings direct from the hand of the artist—a matter of immense importance from an artistic point of view, and of no less importance when looked upon with an eye to its scientific usefulness, as by its means we can obtain correct data of progress of works, such as that immense triumph of modern engineering skill, the bridge now building over the Firth of Forth, so splendidly illustrated in the pages of *Engineering* recently, wherein the whole of the plates were executed by means of photography in such a way that for accuracy and artistic effect could not be equalled by any other art. Photo-lithography is now the only process employed in the large illustrations of the architectural papers, whilst the various forms of photogravure are so well known to most of you that you cannot fail to appreciate the splendid copies now to be obtained of original paintings taken direct by photography and translated into monochrome and sold at a comparatively small cost which as works of art can well hold their own with the best line engravings. He felt that the art of photography was much misunderstood by the general public, the majority of whom are satisfied with the most crude productions, and look upon it with a very indifferent eye; some artists even imagine that it is capable of doing much more than it is really capable of. For instance, photographers are blamed for their want of art knowledge when a landscape photograph is being criticised, because the values are not correct and the tender greys of the distant hills are completely lost, and the foreground and middle distance are a mass of black. Now, it is here where chemistry plays such an important part in the production of a picture, and scientific development should go hand-in-hand with our artistic knowledge to produce a pleasing result. He hoped the time had arrived when we might venture to extend the aims of our Society, and that the amateurs, &c. of Wales would join them in making the Society a truly national institute, and thought that such a title as the Photographic Association of Wales would be a very appropriate one.

Mr. VICE-PRESIDENT DYER then gave "The Scientific, Artistic, and Literary Institutions of the Town," which was responded to by Mr. SEWARD, who, in the course of his remarks, said it was appropriate to bear in mind that that toast was first proposed in a public manner in Cardiff at the first dinner of the Photographic Society last year, and it was worth remarking that at the municipal banquet just past the same toast took an important place on the list. Not only in that respect had the Corporation of Cardiff had an eye in the direction of their Society, but on the previous day an influential Corporation Committee, with Sir Morgan Morgan, Knight, at its head, had been placed in charge of the scheme for a National Institute for Wales, which was also first publicly mentioned at the Photographic Society's dinner before referred to, and with which their Society and several others were affiliated.

The toast, "Kindred Photographic Societies," was coupled with the name of Mr. H. J. Gifford, who, in replying, stated that the societies in London sprang from the Photographic Society of Great Britain, which could rank with the Royal and Chemical Societies, but that for amateurs he thought the less formal societies or clubs were preferable. Two years ago a new departure was taken in the way of photographic clubs when the Camera Club was opened. It was a social club as well as a scientific one, and had its own rooms, which included a dark room for the use of its own members and those of affiliated societies.

Mr. PARKER HAGERTY, in replying to the toast of "The Visitors," admitted that several of his brother artists did not put that value upon photography as an aid to their own art that the science was entitled to; speaking for himself, however, he must acknowledge he appreciated its work from practical experience.

Several gentlemen favoured the company with songs and recitations, and altogether a most enjoyable evening was spent.

YORKSHIRE COLLEGE PHOTOGRAPHIC CLUB.

THE second meeting of the session was held in the College on Thursday, November 24, when Mr. C. H. BOTHAMLEY, F.I.C., F.C.S., delivered his Presidential address. He reviewed the progress of the past year with special reference to orthochromatic processes, the permanence of prints, and Carey Lea's researches. A concise summary of the present artistic and industrial position of photography was then given, and the address concluded with a discussion of the claims of photography to rank as a fine art.

There was a very good attendance. The address was illustrated by a large collection of specimens, including Tolley's *On the Lundy Shore*, Sutcliffe's later *Studies*, Hollyer's portrait of Miss Terry, platinotypes by Keene, photogravures by Annan & Swan and the Berlin Photographic Company, collotypes

by Wagner & Co. and Waterlow & Sons, block prints by Waterlow & Sons, and typogravure by Bousset, Valadon, & Co.

The next meeting, on Tuesday, December 13, will be devoted to a discussion on *Methods of Enlarging*.

Correspondence.

PHOTOGRAPHIC HERESIES.

To the Editors.

GENTLEMEN,—Your correspondents "Monitor" and "Free Lance" having pronounced their opinions on the paper I had the misfortune to read on the above subject, perhaps you would kindly allow me a brief reply. If professional critics would take the trouble to read twice (or even once in a generous spirit), I think they would avoid much misrepresentation and distortion; but then their occupation might be more than half gone.

Your correspondents appear to think that every paper read before a society should be learned and elaborate, forgetting that very useful class, written expressly to provoke discussion (not distortion), which may be fragmentary, disconnected, and incomplete.

"Free Lance" says, "It is all sheer nonsense to say that a good rapid plate is capable of doing all that a slow plate is, and much more beside." You will notice, gentlemen, he does not say he has not made the acquaintance of such a plate, or that such plates are not on the English market, but in effect, that such plates never have, or can be made. Let me remind him it was once "sheer nonsense" to say that steam could be made to exert a gigantic power.

I assert that plates are on the American market capable of making fully exposed negatives of any ordinary well lighted landscape or architectural subject with diaphragm $\frac{1}{16}$ in the $\frac{1}{16}$ part of a second, and of a quality equal to any slow plate of my acquaintance, and I am ready to take part in any friendly contest to decide this point. I may be wrong, but in this country am entitled to my opinion, even if an heresy. Either "Free Lance's" standard of a good negative is higher than mine, or my standard of "a good rapid plate" is higher than his. My experience is that the good rapid plate of to-day is not the coarse-grained plate incapable of rendering a wide range of tones without solarising, or giving vigour readily, as was the case two years ago, but a plate answering to the helm readily in development, and good for copying portraiture or landscape work. Copying with an automatic exposé is not such a ridiculous thing as "Monitor" supposes.

"Free Lance" denies that photographers generally are afraid to use rapid plates for general work; but it is a fact nevertheless, and may arise from a lack of experience with rapid plates, and also for want of proper appliances to accurately gauge short exposures. The signs of the times are, that as plates are being made more rapid and of better quality every year, the "good photographer" of the future will have no use for slow plates unless they are orthochromatic, your correspondent's unscientific intolerance to the contrary notwithstanding.

With reference to J. Traill Taylor's single lens corrector, it has no effect in my hands. No one will be better pleased than myself to make it succeed. If that gentleman, or any other, will give additional information, I shall be obliged. Is it possible that my lenses neutralised each other too perfectly?—I am, yours, &c.,

CHAS. TRUSCOTT.

U. S. America.

It is a pity that, for the sake of his own reputation, Mr. Truscott had not thought it worth his while to make himself in some degree acquainted with the subjects about which he descanted so confidently in his paper; for example, what he designates the single lens corrector. Had he made inquiry of even any tyro in historical knowledge of lenses, he would have been told that many lenses had long since been made, publicly described with drawings, and even patented, the essential features in which consisted of a concave and a convex lens which, as a pair, possessed practically neither magnifying nor diminishing power, but yet gave such an amount of displacement as, when used with a third lens, to neutralise its tendency to give distortion. Probably he has never heard of the influence of correcting lenses employed by Sutton, Goddard, Ross, Dallmeyer, Grubb, Furnell, and several others, in the various non-distorting lenses introduced by these opticians. But let Mr. Truscott study the productions or the writings of these men, and he will be wiser in future. He is not the only young tyro who, with closed eyes, has struck his head against photographic rocks. Meanwhile, let him separate the component parts of his correcting lenses by a much wider ring.—Eds.]

DEFERRED DEVELOPMENT.

To the Editors.

GENTLEMEN,—I should be much obliged for a little assistance in developing. I have made a large number of exposures of various subjects (on half-plates) which I feel sure are about right for time, but as every negative takes me five to ten minutes, I don't know, with the limited time now at my disposal, when I shall have finished them. Is there any way of pushing the plates through quickly without spoiling them? Your reply will greatly oblige.—I am, yours, &c.,

J. C. HOLMES.

[See leading article upon the subject in present number.—Eds.]

THE HISTORY OF THE GELATINO-BROMIDE PROCESS.

To the Editors.

GENTLEMEN,—Gustave Legray's book had been examined by me before asking Mr. Jerome Harrison for the source of his statements, and I could find nothing about gelatine therein, so he would oblige by, as soon as convenient, giving exact references to his authority for his record.

Among the very early gelatine processes not mentioned by him, was a celebrated one by Poitevin. Excellent prints by a gelatine process on paper were obtained in primitive days by Baldus. The few gelatine processes other than Gaudin's before 1868 I will examine to see if they contain anything about the use of an emulsion.

The broad facts appear so far to be that there were two classes of gelatine processes. In the one, in the endeavour to find a substitute for collodion, excess of nitrate of silver was used and acid development. Gaudin, in 1861, went beyond this, by using an emulsion from which all alkaline nitrates were washed away. He, however, then added excess of nitrate of silver, and used acid development. Gaudin was probably the first who used a washed gelatine emulsion. The other class, the precursors of the present dry plates, contained an emulsion with no excess of nitrate of silver, and included alkaline development.

The first class was found to be exceedingly slow in the camera; it was almost exclusively used and promulgated for positive printing, and sometimes without development. So far as anything before the public in the recent utterances is concerned, the first plate of the second order of processes was made in January, 1868. In Mr. Jerome Harrison's recent historical articles, he does not state who devised the system of washing the gelatine emulsion made without excess of nitrate of silver. It was a vital step in the process, so it would be interesting if he would furnish the particulars.

W. H. HARRISON.

REMOVAL OF SULPHATES FROM PYRO SOLUTIONS.

To the Editors.

GENTLEMEN,—Referring to your leading article of this week on the removal of sulphates from pyro solutions by means of chloride of barium, I fear it will not be found that this substance is a desirable, or even innocuous, constituent of the developer. In the course of a research which I once had occasion to make on the reactions of the tannin group, I found that many of these bodies, including pyrogallol, though without action alone on barium and calcium chlorides, yet gave on addition of ammonia the reactions peculiar to baryta and lime, and not those produced by ammonia alone. It has been shown that these alkaline earths do not satisfactorily replace the alkalies in development, but rapidly give turbid solutions. It is possible, however, that in presence of sufficient sulphite, this reaction may not occur, since I have found that the use of even five per cent. of bisulphite of soda in a ten per cent. pyro solution enabled me to use an excessively hard water without injurious results in the developer.

The reaction is very curious from a chemical point of view, since ammonia alone cannot displace baryta from its chloride, but is enabled to do so by the added affinity of the tannin or pyrogallol for the baryta. It is analogous to the fact that while caustic ammonia will not precipitate baric and calcic salts, carbonate of ammonia does so completely.

It seems rather dubious whether it would not be wiser not to keep the pyro so long, rather than to try to revive it when spoiled, or to use acid sulphates instead of neutral ones, since the former are more stable compounds, and have beside a far greater preservative action on the pyro. If, however, "the game is worth the candle," I would suggest the use of neutral sulphite of baryta, which is insoluble itself, and would simply restore the original sulphite of soda, and form insoluble sulphate of baryta. It could easily be obtained sufficiently pure by precipitating baric chloride with sulphite of soda and slightly washing on a filter.—I am, yours, &c.,

HENRY R. PROCTER.

Tynemouth, November 26, 1887.

THE PLATINOTYPE PROCESS.

To the Editors.

GENTLEMEN,—If Mr. A. Pringle's statement made at a recent meeting of the North London Photographic Society is correctly reported, may I beg Mr. Pringle to be so kind as to send to the Platinotype Company a portion of a print or of prints of which he has succeeded in materially reducing the image, together with some of the solution of sulphuretted hydrogen (if he has used a solution of it) with which he has so acted upon them. In the absence of the latter, perhaps he will describe the method of production of the preparation he used. Some prints so acted upon would also interest.

In reference to Mr. F. W. Cox's useful paper on *The Platinotype Process*, may I be permitted to explain the reason why the Platinotype Company recommend the use of "neutral" potassic oxalate? The reason is that the "neutral" salt causes the image to adhere better to the paper at the time of development, while, if the acidified salt is used there is no tendency to precipitation of the iron salt, but a powerful solvent is formed having what amounts to a restraining action upon the developing or reducing power, so that the metallic platinum falls away irregularly from the surface, being reduced to some extent while its salt is in process of removal from the surface of the paper.

In this way, and by worn out acid developing solutions, many cold,

coarse, grey, and abominably uneven and patchy and even streaky prints have been and are being turned out. It is not far wrong to say that an acid bath has much in common with a cold bath. I do not think it well, with the Platinotype Company's present papers (which are different in behaviour to those made by Captain Pizzighelli), to use an acidified bath. But, as Mr. Cox states, the appearance of a print is so much a matter of taste.

Mr. Cox is quite correct in stating that an acid bath gives "brilliance" (if by "brilliance" we then mean purer "whites" or less half tone); but the "blacks" are generally damaged by it, as well as the otherwise even fineness of the print. If, however, the paper is old, and the "whites" are degraded on development, an acid bath might effect an improvement; for with old paper there is a firmer hold of the platinum and iron salts.

I trust that these few remarks may be useful to some of your readers; otherwise they should not blame the paper for certain defects, but the bath.

I may add that the instructions of the Company are compiled with a view to the best technical results; any one may use other plans to suit his taste or requirements, but it should be borne in mind that only by adhering to the Company's directions can the results they state their papers will give be achieved.—I am, yours, &c.,

November 28, 1887.

HERBERT B. BEKELEY.

"FREE LANCE" ON SPECIFIC GRAVITY.

To the Editors.

GENTLEMEN,—In the battle of the standards, "Free Lance" singles me out for a combatant. Allow me to parry his thrust as best I may.

He is displeased with my "wonderful exactitude," and says that my correction for temperature is wrong unless I can show that Carius took a temperature other than 60° Fahr. as his standard. This roundabout expression makes me suspect that "Free Lance" is himself uncertain as to the standard temperature used by Carius. I do not know, but presume he was or is a foreigner, through the peculiar name and his use of centigrade units of temperature. If the correction be wrong, then is the expansion of ammonia on further dilution much more manifest. Will somebody who knows kindly say who Mr. Carius was, and what was his standard?

Had I omitted the correction, somebody would have pointed out my glaring error, and without himself applying it would have said that my figures proved nothing.

For my own part, I much prefer a mean temperature, as 60° Fahr., to the wintry standard of our neighbours. I am waiting for a developing formula from France, normal at 0° C., with corrections for temperature.

The definition of specific gravity as the weight of a unit of volume is too awful to be passed by, says "Free Lance;" it is nevertheless correct. The fact is that specific gravity is defined in two ways, either definition being used as may be found convenient. Similar instances are common: Euclid's definition of proportion is unlike Colenso's; Hutton, Drew, and Clifford define an ellipse in different ways. These definitions are not incongruous, and we may use which we like. Similarly with specific gravity, it may be defined as a weight or a ratio. I did not make the definition, but use what I have to hand.

Clearly "Free Lance" is not Professor Donkin, or he would not have quarrelled with the definition. Neither is he Webster, or he would not talk about depicting in place of defining, as if synonymous. Neither is he a leisurely reader, or he would not misquote "looking the subject up" for "looking into the matter."

Who is he, "At all at all, I tell you?"

Once more: "Free Lance" suggests that I might have said "density is the mass of a unit of volume." Quite right; now, multiply by gravity (32.2 feet per second) and we have at once "specific gravity is the weight of a unit of volume!" If this statement seem a puzzle, I would suggest that "Free Lance" "look the subject up."—I am, yours, &c.,

4, Camp-street, Lower Broughton, Manchester,

R. C. PHILLIPS.

THE PHOTOGRAPHIC COMPANY, LIMITED, AND THE CELLERIER-PARKES PROCESS.

To the Editors.

GENTLEMEN,—I am much obliged for your remarks in connexion with this process. I have done my best to prevent the insertion of any misleading heading or statement, and, again, I am surprised and annoyed to find that the agent who abridged and published the amended prospectus should not have followed the wording of the prospectus settled by me on behalf of the Directors of the Photographic Company, Limited, who are most anxious that no misdescription should appear. From the prospectus you will see that no such words as "photographing in colours" or "photography in colours" are used, and the processes are plainly described as "for improvements in the production of coloured photographic pictures." As soon as attention was drawn to the error, instructions were given to the advertising agents to withdraw all such advertisements, and to give correct definitions in accordance with the prospectus approved by the Board. This was forthwith done. You will kindly note that the press notices sent with the prospectuses also define the true character of the processes. The Directors much regret the mistake, feeling assured that the patents will succeed on their own merits.—I am, yours, &c.,

E. W. PARKES.

3, Salters Hall-court (opposite Cannon-street Station), London E.C., November 29, 1887.

CUTTING A BOTTLE.

To the Editors.

GENTLEMEN,—I notice in your report of the meeting of the London and Provincial Photographic Association that the members who took part in the discussion seemed to be "at sea" as to the best means of cutting a bottle in two. A very simple but effectual plan is to take a piece of twine about one and a half yards long, wrap it twice round the bottle, let one person take hold of one end of the twine and get another to take hold of the other end. Then with a sort of see-sawing motion the part becomes so heated that when the bottle is dipped into water the parts fall asunder. If it is desired that the bottle should be cut in a certain place, I usually cut a round hole in a piece of wood large enough to admit the bottle; the string working on the glass and against the board ensures the cut being a clean one. If, however, the see-sawing motion is continued long enough the parts will fall asunder, thus rendering the dipping in water unnecessary. If time is no consideration this is by far the best plan, as I sometimes find that hock bottles are thicker on one side than the other, and invariably where they are so the water bath starts a crack up the bottle.

I have cut a large number of hock bottles in this way and converted them into lamps, and have found them useful when enlarging or using bromide paper, affording a safe light.—I am, yours, &c., AMATEUR.

BOYCOTTED MEDALLISTS.

To the Editors.

GENTLEMEN,—I have just received a prospectus of an exhibition to be held in the spring at Liverpool, under the auspices of the Amateur Association. This document contains a rule which seems intended to exclude most of the best work that has been done during the year. It runs thus:—"No picture shall be eligible for competition which has taken a prize at any public competition, the Council being desirous of encouraging the exhibition of new work." It is very praiseworthy of the Council to endeavour to promote the production of novelties, but what new work does it expect to have done between now and the middle of next February? The best recent work has already been medalled at London, Falmouth, or Dublin; the Liverpool exhibition, therefore, will have to fall back on the refuse of these exhibitions to make their show attractive. It will be a great chance for the second rate—the millennium of the mediocre, as a friend who read the paper over with me called it.

Of course, no producer of a medalled picture who respects himself and his art would think of sending pictures which he is so pointedly told are not wanted.

If medals are to be given at exhibitions it seems only fair that the best exhibits shall have the same chance of winning them as the worst, and, as pretty well all the available good work of this year has been rewarded, there will be nothing left to compete for the Liverpool medals but inferior productions, thus bringing medals even lower down than they have already got, and that is indeed low, now that trading firms and struggling journals have to purchase their customers by offering them medals through amateur societies.—I am, yours, &c., A MEDALLIST.

APOLOGY.

To the Editors.

GENTLEMEN,—I desire to tender my unreserved apologies to Mr. W. H. Hyslop for my letter published in the *Photographic News* of the 21st ult., relative to his photographs of the *Thistle*, as the statements or insinuations made therein imputing dishonourable conduct to Mr. Hyslop are, I find, without the slightest foundation in fact.—I am, yours, &c., A. J. WEST.

Southsea, November 25, 1887.

Answers to Correspondents.

NOTICE.—Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a NOM DE PLUME as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

E. J. R.—The maker will supply all particulars.

NOVICE.—No notice taken of queries not endorsed by name of sender.

P. C. S.—Nothing to prevent you from opening such a business as suggested. See answer to "Photo."

W. MOULT.—Remove the spirit lamp by drawing it back a little after ignition of the magnesium has taken place.

J. W. DOLLAR.—Not having seen any lenses by the maker named, we cannot advise, but we prefer the "rapid" to the other.

E. W. M.—Much warmer tones can be obtained on wet collodion transparencies by immersing them in a solution of sulphide of potassium than in one of platinum.

E. D. SKELTON.—It is impossible to predicate the degree of success that may attend the venture. Everything depends upon personal skill, business tact, and a fitting locality.

A. Z. (Durham).—Enamelled paper suitable for the purpose may be had from most wholesale stationers. Messrs. Spicer Brothers, Bridge-street, E.C., will supply your wants.

R. R. C.—Pine will do very well for making a camera, but, to secure the same stability as with mahogany, a greater thickness will be required, so that the advantage in weight will not be so great as you imagine.

PHOTO inquires: "Can a person who is not a certified chemist carry on a business in photographic materials and sell all the necessary chemicals?"—Yes, except in those cases in which the Poisons Bill is operative.

J. MARES.—Any good paper coated with plain gelatine will do for transfer paper for double transfer in carbon printing, provided it be soaked in a solution of alum before it is applied. This was the plan employed by the late Mr. Jabez Hughes in his daily practice.

S. ALDUS.—Several practical articles on albumenising paper appeared in our volume for 1884; you cannot do better than refer to them. Any information we could give you in this column would not be of much service in enabling you to prepare the paper on a commercial scale.

C. J. SOMMERS.—A lens of the "rapid" type will do quite well for enlarging with; indeed, it is one of the best forms that can be employed. It is always a good plan to use a lens for enlarging that will cover a size or two larger than the picture to be enlarged. The focal length of the lens is governed not by the size the picture is to be but by that of the original.

S. A.—The preparation of canvas as sold by the artists' colourmen is not easily done on a small scale. Unless your consumption is much larger than your letter leads us to surmise you will find it more to your advantage to purchase it ready prepared. Then you will get an uniform and reliable article. If it would be more economical in your case, you can purchase the canvas in rolls of various widths.

X. Y. Z.—1. Simply cement the two glasses together with paper round the edges.—2. The light will be sufficient if the exposure is long enough to suit the aperture of the lens.—3. No mountant will really prevent the print from cockling, but one of a solution of gelatine in which a large proportion of alcohol takes the place of water will reduce it to a minimum.—4. No doubt the deposit or stain is silver. Try a solution of cyanide of potassium; possibly that may take it off.

W. N. writes: "I should be much obliged if you would tell me what is the best battery for my purpose. I use a small incandescent lamp in my dark room, not continuously, but I turn it on now and again for judging density (as I use daylight for developing), so a battery that polarises and recovers itself will do; but I do not want anything like a bichromate or chromic acid battery, where the carbon and zinc have to be lifted out, as it must stand out of reach; nor do I want a battery which gives off fumes, as it must stand in the dark room. My lamp, I should say, is about two or three candles."—We should recommend either Schenck's battery or one supplied by Mawson & Swan.

RECEIVED.—Liverpool Amateur Photographic Association.—In our next.

NORTH LONDON PHOTOGRAPHIC SOCIETY.—The next meeting will take place on Tuesday, December 6, when Mr. T. Charters White will lecture on *Photomicrography*. Visitors are invited.

THE JENNINGS'S FUND.—The following additional contributions have been received by Dr. Maddox, Greenbank, Park-road, Portsmouth, Southampton, and Mr. Andrew Pringle, Cromwell House, Bexley Heath, Kent:—Edward C. Bousfield, 10s. 6d.; B. Vivian, 10s. 6d.; J. Thomson, 1l. 1s.; *Employees* of J. Thomson, 9s. 3d.; Mrs. H. B. Pritchard, 5l. 5s.

FORTHCOMING EXHIBITION.—The Dundee and East of Scotland Photographic Association purpose having an exhibition of photographs and photographic apparatus in the Art Galleries, Albert Institute, Dundee, commencing on February 16, 1888. There is to be a liberal donation of gold, silver, and bronze medals. Prospectuses from the Hon. Secretary, Mr. James Hattray, 82, High-street, Dundee. Entries close in January.

PHOTOGRAPHY IN COURT.—At the Bow County Court, before Mr. Registrar Hore, the case of Wright v. Wright was heard. The plaintiff is a clerk, living at 32, Percy-street, Forest Gate, the defendant a photographer, of 1, Sebert-road, Forest Gate, and the claim was for 5s. 6d., for balance of money paid for goods not delivered. It appeared that the plaintiff had the family group taken at the defendant's studio in Forest Gate; there were to be a dozen cards for 15s. 6d., and the plaintiff paid the money, but when the cards had been finished he refused to accept them, saying they were not satisfactory, and they were left on the defendant's hands; for that reason the defendant gave him back 10s., and he now sought to recover the difference of 5s. 6d., as balance of money paid for goods not delivered. The defendant maintained that the photograph was very correct, and produced one for the Registrar to look at. The learned Registrar, having looked at the plaintiff and at the photograph, observed, "I think I never saw a more exact likeness or a better picture, and I must give judgment for the defendant. No costs."

HOMemade STRIPPING FILMS.

In view of the apparently established position now filled by paper as a negative support, and of the additional fact that there still remain a few who take pride in the preparation of their own sensitive films, not improbably the subject of home-made stripping films may possess an interest for some of our readers. At any rate, we may venture to give the results of some experiments in that direction we were recently led to make as a digression from another branch of work.

Stripping films are by no means new, either in principle or in detail, so there is no fear of infringing any patent rights, even if our methods be followed by other than amateurs. But the principle has been variously applied, as by the late Mr. Woodbury, who stripped his negatives *after development* and retransferred them to glass when desired for printing purposes; while Warnerke's sensitive films were prepared upon a temporary paper support, upon which they were exposed and developed, to be afterwards stripped and used as translucent "film" negatives or transferred to glass, as might be preferred.

Woodbury's method, by means of which he produced the exquisite series of Italian views exhibited by him some ten or twelve years ago, was devised for the purpose of lessening the trouble of the travelling photographer, and is specially applicable to collodion negatives. In Mr. Woodbury's case, he employed collodion emulsion, and, travelling with a bottle of emulsion, a dozen or so glass plates, and a supply of prepared transfer paper, he was equipped for the production of as many negatives as if he had been hampered with innumerable packages of extra plates.

His *modus operandi* was simplicity itself, and our recollection of a first trial of the transfer paper sent to us by Mr. Woodbury is that we experienced not the slightest difficulty in operating successfully, even upon negatives that had not been specially prepared for stripping; indeed, there is hardly any need of such preparation. The glass is cleaned in the ordinary manner, and preferably polished, either with a solution of wax in ether or benzole or with powdered talc; this is not absolutely necessary, but it facilitates the subsequent stripping. It is then coated with collodion or emulsion and exposed, either wet or dry, the whole process being conducted in precisely the same manner as for an ordinary glass negative.

After fixing and washing, the preparations for stripping the film are commenced. A sheet of the transfer paper is cut to size—about three-sixteenths or a quarter of an inch smaller each way than the glass—and soaked in water until soft. There is no mystery or difficulty in the preparation of the transfer paper; it is merely ordinary paper of moderately

smooth texture coated with plain gelatine and allowed to dry. This, when softened by soaking in cold water, is squeezed into intimate contact with the negative and permitted to dry spontaneously, or, at least, without the application of any considerable heat. When quite dry, the edges of the paper are cut round in the usual manner, and the paper, bearing with it the negative image, slips readily from the glass, leaving the latter ready to be cleaned and recoated with emulsion for another exposure.

If a suitable paper have been selected at first, the negative may be allowed to remain attached to its new support, which may be rendered translucent by any of the well-known methods if desired. Or the paper may be used merely as a temporary support until such time as it may be convenient to retransfer the images to glass or other permanent support, when the collodion side of the flexible negative having been cemented to the new surface by means of indiarubber solution, the paper is easily removed, soaking first in cold and eventually in warm water.

This method varies very considerably from the more modern stripping films, but chiefly in the fact that with the latter glass does not necessarily play a part. Warnerke's films more nearly realised the modern idea, consisting as they did of a translucent film—itsself spread upon paper—which formed the support for the image throughout the whole of the operations it had to undergo. But this was unnecessarily troublesome in preparation and not likely to meet the requirements of the amateur manufacturer.

It has long appeared to us that with certain precautions the simple transfer paper of Woodbury would answer all moderate requirements. That is to say that any one who wished to prepare his own films either with gelatine or collodion emulsion, would find gelatinised paper a convenient and suitable support. Of course the difference, physically and chemically, between collodion and gelatine has to be borne in mind, but, as we shall show, the gelatine transfer paper is equally applicable to both purposes.

First as regards the preparation of the transfer paper, as we shall continue to call it, though it may be used as the final support. If it is to be used merely as a temporary support, the nature and quality of the paper are of very little moment, provided it be fairly even in surface and of sufficient strength to bear handling when wet. If, however, it is intended that it shall form the final support, attention must be given to its thickness and texture, in order that the translucency of the finished negative may meet the printing requirements, and its definition not be materially interfered with by unevenness of grain or fibre. Where *paper negatives* are intended to be made

we should in all cases advise a proper "photographic" paper to be employed, but for other purposes any fair ordinary quality of paper will answer perfectly well.

The strength of the gelatine solution, too, is a matter for some consideration, and may be varied in accordance with the particular purpose to which the transfer is to be applied. If a simple transfer paper for collodion films, either for stripping them after exposure *à la* Woodbury, or for holding them during exposure and development only, a simple twenty or thirty-grain solution, with a few grains of sugar to each ounce will answer well. If the paper is to be used in connexion with *gelatine* negatives a stouter layer of soluble gelatine is desirable in order to lessen the risk of the negative becoming permanently attached to the paper support. When the paper is to remain as the final support, too, it is advisable to resort to a stronger solution of gelatine, in order that it may remain more completely upon the surface and not sink in and fill the pores of the paper so as to prevent its being subsequently rendered translucent. For these purposes a strength of forty or even sixty grains to the ounce will not be too much, and the addition of from fifteen minims to half a drachm of glycerine to each ounce will improve the flexibility of the paper and prevent its becoming brittle on drying.

The coating of the paper with gelatine presents no difficulties beyond those of keeping the solution at a proper temperature and preserving the coated paper from dust during drying. It must be borne in mind that the extreme care necessary in preparing sensitive films, or films of emulsion, is entirely wanting here, all that is needed being a tolerably smooth and even surface. The fluidity of the gelatine must be kept up by immersing the dish containing it in a deeper one holding hot water, or by other means that will commend themselves according to circumstances. With regard to the avoidance of dust, we find no better plan than to coat the paper at night and to allow it to hang in a warm room during the still hours when no one is moving to stir up the dust. Two or three hours will suffice to complete the drying under such circumstances.

The papers if cut to sizes may be simply floated on the warm gelatine until limp, drained for a few seconds, and laid upon blotting paper until set, after which they are hung up to dry. If very large sheets, or continuous lengths, are required they may be managed without a great amount of trouble as follows:—Let the dish or trough of gelatine be placed on a shelf or platform at one end and about a foot below the level of a table of convenient length; take the sheet or length of paper and float one end of it upon the dish of gelatine, placing upon it a light wooden roller of sufficient weight to ensure that the paper comes in contact with the gelatine without sinking below the surface. If when this has been done the end of the paper is carefully raised to the level of the table and then slowly drawn along its surface, it will be found that a smooth and even coating is given which sets very shortly after leaving the trough, and enables the coater to hang it in "festoons" to dry at the opposite end of the table. It is scarcely possible to perform this single handed, but we have seen a length of nearly twenty feet perfectly coated and hung in a small room by a couple of operators.

In coating large sheets or widths it is not necessary to provide large porcelain dishes, nor, indeed, to employ dishes at all. There is nothing to prevent the use of metal as the material out of which to construct the gelatine holder, and in order to avoid a large bulk of solution the receptacle may be made in the form of a trough sufficiently long to accommodate

the width of the paper to be coated, which is drawn through it in the manner described.

The paper, if freely exposed to the air in a room which has been warmed during the day, will dry as we have said in two or three hours, and if the material used be of proper quality will give no trouble in curling or cockling, especially if a due quantity of glycerine be used. If, however, it be attempted to utilise extremely thin paper, except for sheets of the smallest size, it will be found necessary to roll and smooth the paper after drying, and to preserve it constantly under pressure. An ordinarily stout paper coated with a forty-grain gelatine solution when completely dry simply requires rolling up, when it will quickly rid itself of any chance inequalities or irregularities formed in drying, and may be kept indefinitely if preserved from damp.

In this manner an amateur or small consumer may prepare in a single evening sufficient transfer paper to fulfil his negative and other requirements for a season, and at the same time feel certain that there is no chance of its deterioration, as in the case of the sensitive films. Nor does it occupy the space of glass nor require to be cleaned and polished, but there it is ready for coating when required.

Next week we shall speak of the methods of applying this transfer paper to photographic purposes in connexion both with collodion and gelatine films.

PHOTO-MICROSCOPIC STEREOGRAPHS.

ON the occasion of Mr. Charters White delivering a lecture on photo-micrography before the North London Photographic Society on Tuesday evening, a conversation which ensued gravitated in the direction of photographing microscopic objects in duplicate, and under such conditions as to enable them to be examined in a stereoscope, showing the same degree of relief or rotundity as that experienced when employing a binocular microscope.

This is a department in photo-microscopic science which does not appear to receive any attention at present, and yet there are few of the cognates of the science more worthy of notice or which will bestow greater pleasure or profit than this.

There are innumerable bodies in the world of small things which can only be properly observed, so as to realise their configuration, by a binocular microscope; and in the case of such objects, no matter how much they may be enlarged by photography in the usual way or with what perfection their detail may be rendered, they still afford a very inadequate idea of their form.

Our object at present is to point out, briefly, some methods by which the possessor of an ordinary monocular microscope may be enabled to photograph any suitable object with all the relief as seen in the finest binocular instruments, and this, too, without incurring much expenditure for costly appliances. Premising that the method to be described is intended for employment with low powers, we shall explain its principle of action by a simile we employed many years since, when we had occasion to introduce it to the notice of our readers of those days. Let a bust or statuette be placed on a table at a distance of a few feet from a single fixed camera and a negative be taken. Now, without moving the camera, rotate the statuette on its axis in the slightest degree, and then take a second negative. Prints from these two negatives will, when mounted side by side on a stereoscopic card mount and examined in the stereoscope, show the image in all the solidity

that could be desired, the amount of relief being determined by the extent to which the original object was rotated previous to the second negative being taken. Reasoning from analogy we now proceed to apply this system to the production of micro-stereographs.

The object slide must not be placed flat down directly on the stage of the microscope, but upon a secondary or super-stage so constructed as to allow of the small platform upon which rests the object slide to oscillate from right to left within a limited sphere. The one we constructed for the purpose is made of thin brass pivoted at its two sides into guiding side pieces, the axis of motion being adjusted so as to coincide with the object to be photographed. Having focussed the object, and using a diaphragm in front of the objective so as to increase its penetration, the first photograph is taken, when the little see-saw slide holder is tilted to one side, after which it is tilted to the opposite side preparatory to making the second exposure. The amount to which the tilting takes place must be only very slight, else will the apparent solidity of the image when subsequently examined in the stereoscope be exaggerated.

Success in this is ensured by employing an objective of small angular aperture, or, should it be too wide, limiting this otherwise excellent quality by a diaphragm cap being slipped over the end.

Another way by which stereoscopic photo-micrographs can be obtained by a monocular microscope is to employ an objective having an effectively large front lens and covering it with an easy-fitting cap, having in it an aperture so much at one side as to cover up one half of the lens. When making the first exposure the cap is turned so as to uncover one side of the lens, and is rotated half a turn before taking the second negative. The resulting pair of pictures will be stereoscopic.

There are several other methods which may be employed, and which are more especially adapted for the higher powers; this article is, however, mainly intended for the photo-microscopic aspirant with limited appliances.

On another page will be found a letter from Mr. Samuel Fry, indicating what, in his opinion, will remove the annual vexatious squabbles about the distribution of medals at the Exhibition of the Photographic Society. It is simply to make the awarding of medals the great popular function of the members of the Society, in which every one not only has a right but should feel it his duty to personally participate. The larger proportion of members are perfectly competent to form a just and reliable opinion on the matter, and as Royal Academicians and Members of the Water Colour Society have, as jurors, equally failed to give satisfaction, it seems very reasonable to hope that the system proposed by Mr. Fry, and which is understood to be favoured by many members, may with advantage be now given a careful trial.

RUMOUR has it that a gentleman who applied for, and received, 500 shares in a certain Company recently formed, has instructed his solicitor to demand an immediate return of his money, failing which recourse will be had to legal proceedings.

SCIENTIFIC journals have lately contained descriptions of several new processes involving the use of pyroxyline. Not the least singular is the one for the production of artificial silk, a process for which is described in *Comptes Rendus* by M. Chardonnet. He makes a collodion of just about the strength of the photographic preparation, and adds to it one per cent. of a ten per cent. solution of chloride of iron, and about half that quantity of tannic acid. The whole is then

filtered in a closed apparatus, and the liquid discharged through a fine glass or platinum nozzle into water acidulated with one half per cent. of nitric acid. The thread so produced is then rapidly dried and wound up.

A STILL more remarkable use for the neglected chemical, however, is to be found in the coating of ships' bottoms with celluloid, the main base of the manufacture of which, as our readers are aware, is pyroxyline. It is stated that experiments have been made with this substance lasting over six months, and that in the places where it was used its preventive action was complete—fouling was entirely prevented—while other parts of the vessel unprotected during the same period were freely covered with marine vegetation. The celluloid is produced for the purpose by a French Company, who offer it at the price of nine francs per square metre (that is less than one shilling per square foot) one millimetre thick.

OUR readers will remember the great interest caused by the announcement, now some years old, that oxygen had been spectroscopically discovered in the sun. Dr. Henry Draper had convinced himself that there were bright lines in the solar spectrum corresponding to the bright lines of oxygen, whilst his brother, Professor J. C. Draper, had identified the oxygen with faint dark lines. But Messrs. Trowbridge and Hutchins have been working with the huge concave grating of Professor Rowland (which has been already described by us in connexion with the large solar map he is producing by photographic aid), and they state that they "have photographed the sun's spectrum every day that the sun has shone for nearly five months without finding a line that could with certainty be pronounced brighter than its neighbours." The bright bands have vanished, and the above two observers say further that there is no real correspondence between the oxygen lines and the dark lines Professor J. C. Draper identified with them. Thus by means of increased instrumental power, aided by photographic methods, the discoveries of a decade ago are shown to be figments.

PROFESSOR PRITCHARD has by the same means been able so to simplify some processes of observational astronomy as to greatly reduce the time hitherto involved in their application. One most interesting and difficultly worked of astronomical operations is the ascertaining the parallax of certain stars. It is not desirable here to do more than allude to the laborious and time-absorbing process as ordinarily conducted. Professor Pritchard took four negatives, on each of eighty-nine nights, of a certain star, and obtained results of a gratifying nature, the photographic parallax being the mean of those obtained by micrometrical measurements of other observers. He next made a certain theoretical selection of the negatives, reducing them to those taken on ten nights. The mean results did not differ from those obtained in the eighty-nine nights, and he has henceforth determined to confine the observation to five nights on each of four periods of the year. It is thus evident that a far greater number of parallaxes will be able to be ascertained in a twelvemonth—perhaps those of ten to fifteen stars. His detailed results are not yet published, but incidentally his paper—read at the Royal Astronomical Society's meeting—states that three per cent. of the plates were found to be injured and unsuitable for the inquiry, and also that he should economise both time and labour in the future by taking two impressions on the same plate.

OUR readers have been made aware, from time to time, of the remarkable results obtained by M. Marey in his instantaneous photographs of various animals when progressing from place to place. A large number of photographs of men in the act of walking, running, and jumping, have been given, and also, *à la* Muybridge, of horses in motion in various kinds of gaits. But, perhaps, the most interesting series of the whole is that relating to the flight of birds. In *La Nature* (in last week's issue) a number of illustrations taken from M. Marey's negatives are given, and they show a most remarkable and interesting set of positions. M. Muybridge's pictures were

a great source of wonderment and amusement, when first introduced, on account of the very strange shapes into which the limbs of his horses seemed to be contorted; and here, instead of those beautiful pictures of birds with their pinions extended above the body as is wont to characterise the Western representations of bird-motion (the Chinese and the Japanese draw their flying birds indifferently with wings either depressed or raised) we see their pinions in as many and as remarkable positions as those of the celebrated horses above alluded to. In some the wing tips are high in air, in others quite low and beneath, and, indeed, in front of the body; while, again, in still different views of the same bird we seem to see nothing but wings apparently extended to imitate an umbrella. The pictures of the pelican are particularly ludicrous. It is desirable again to point out with regard to such photographs that their value is not for artistic but for physiological uses.

PHOTO-CHROMATIC PROPERTIES OF SILVER CHLORIDE.

WHEN a well polished plate of silver is dipped into a five per cent. solution of iron chloride it acquires a slate colour. The plate is taken out of the solution after ten seconds, dried quickly (without heating), and covered with red, emerald, orange, and cornflower-blue glass. In sunshine the colours appear on the plate after a few minutes. Over-exposed plates, especially blue ones, are brownish. The colours dissolve readily in aqueous ammonia. If the plate is heated before exposure, it acquires first a violet and then a red colour, and at the same time partly loses its sensitiveness to yellow and green light. The experiment is suggested as suitable for a lecture experiment.

G. STAATS (*Berichte*, 20, 2322-2323).

—*The Journal of the Chemical Society.*

ECHOES FROM THE SOCIETIES.

I HAVE had frequent occasion in this column to comment on the performances of reporters, and I cannot help opening this communication by a further reference to one of their vagaries. At a meeting of the Walthamstow Photographic Club a changing box was exhibited which, we are told by the reporter, called "for more than passing notice." Then follows the "more than passing notice"—"Combining several novel features," the reporter says, "with a considerable amount of ingenuity in its construction which should render it a really useful and efficient accessory to the photographic tourist." That appears to me a passing—very rapidly passing—notice without the something more.

That sort of reporting is all very well for filling the pages of the minute-book, or as an exercise in a style of composition which spreads an infinitely small amount of information over a vast area of paper, but it is hardly up to the requirements of a public journal. If we had been told what the "several novel features" consisted in, and precisely where the "considerable amount of ingenuity" had been displayed, we could have dispensed with the reporter's own opinion, which involves a palpable truism, and judged for ourselves. As it is, we are as well posted up in the "points" of Mr. F. Houghton's changing box as if the Walthamstow Club possessed no reporter.

I know it is extremely difficult sometimes to condense the account of a discussion without spoiling it, and therefore I would let *published* reports consist only of important matter that will bear treating at some length, leaving the catalogue of exhibits and of namby-pamby speeches for the private minute-book of the Society. As an instance of how the too severe curtailment of a discussion may work I would point to a meeting of the Birmingham Photographic Society, at which the question of toning and fixing in one bath was discussed. Mr. Middleton is reported to have said, "Chief objection, sulphur; use a little common salt in the bath." Now, owing to the extreme brevity of the wording, I am quite at a loss to know in what way Mr. Middleton finds the sulphur make itself objectionable; whether it is deposited in the bath or on the prints, or whether the latter become sulphurised at a subsequent period. But there can be little doubt, as the report reads, that salt is a remedy, which I very much question. If the speaker's remarks had been a little more fully given the context would have assisted me, perhaps. Then Mr. Pumphrey is not made very clear as to whether he speaks in favour of the system or not.

"Not used by professionals" would, perhaps, be a recommendation in the eyes of some of our "exclusive" amateurs; so, perhaps, would "costs more" if they happen to possess means as well as exclusiveness; but, "can take straight from printing frames and put into bath" remains unexplained. Mr. Tylar's evidence alone reads intelligibly, and I gather from that that he has used the process with success, and that the prints have stood the test of time so far as he has applied it. But that particular subject would bear much fuller reporting at the present day, when gelatino-chloride, and similar papers, offer a chance of going back to the gold and hypo bath, if its results will stand.

Nothing in connexion with photography has struck me as so forcibly emphasising its rapid spread in a purely scientific direction as the application mentioned by the Chairman, Mr. C. H. Trinks, at one of the meetings of the London and Provincial Photographic Association. The idea of instantaneous photographs in the microscope would have taken away the breath of a photographer of ten years ago, but now, thanks to the rapid progress not only in photographic methods but in other sciences, that, and other feats apparently equally impossible but a short time ago, are now looked upon with comparative unconcern.

I am no advocate of indiscriminate drop-shutter work, considering that the artistic results would be infinitely improved if nine-tenths of the shutters now in use were put behind the fire. But there are, of course, cases where infinitesimally short exposures are absolutely necessary. I can conceive no more interesting application of rapid photography than to the rendering of the contents of the live cage under the microscope. The task, however, is one so surrounded by difficulties that it is not likely to attract a large number of experimentalists; there will, therefore, be all the more credit to be divided amongst the few who may enter the limited field.

I have to thank Mr. Adcock for the pictures duly forwarded to me by the Editors, but they scarcely affect the argument in any way. Making figure studies from selected subjects, who attend by appointment at the artist's studio, is a very different thing from securing picture studies by chance "shots" in the streets. My argument was that the production of *pictures* from materials to be picked up in the London streets is not the easy task Mr. Adcock appeared to deem it; but now that he himself disclaims any idea of exposing haphazard upon anything that presents itself, we find ourselves on the same side of the argument. It is not every photographer, however, who possesses the necessary amount of "pluck," and the feeling of being sufficiently above suspicion to make a practice of enticing "picturesque flower-girls" into "quiet by-streets." Little considerations of this sort combine to prove what I originally said, namely, that street photography is not the easy task it appears on the surface, while the question remains as to whether the results are worth the trouble artistically.

My contention is that such photographs may be technically excellent, may be good and useful studies of grouping, and all that, and as such invaluable to the painter; but that if the painter-artist actually made use of them he would, even though adhering slavishly to the pose and grouping, and what I may term mechanical construction, infuse into the picture a feeling and meaning quite beyond the power of the photographer. The painter, in addition to his technical skill and artistic perception, must be an actor capable of *feeling* the character he desires to depict on his canvas. The photographer must be more; he must not only possess the dramatic perception, but also the power of imparting it to his subject, in order that the latter may assist him in completing his conception. If the subject fail him in this, he is no better than the painter's lay figure, and the photographer's best effort will be as devoid of artistic merit as a rendering of the expressionless block of wood robed in the property finery of the artist's studio.

I do not wish to deery the class of work Mr. Adcock loves, nor to deny to photographers the possible capability for really artistic work. Rather, I desire to show how the photographer is sufficiently handicapped in the race and how to produce artistic work is more difficult, and consequently more meritorious, than in the case of the painter. This brings me back to the starting-point—is it worth the while of the ordinary photographer to adopt so high an aim; to forsake landscape work or "rustic scene hunting," for a class of work in which his chances of attaining even mediocrity are but scant?

Your correspondent, Charles Truscott, in last week's issue stands up for, but scarcely succeeds in defending, his photographic heresies to which I alluded some time ago. I have nothing to say against papers being read for the purpose of provoking discussion, but I do object to such papers taking the form of a string of "distortions" (Mr. Truscott's own expression), and that is what I complain of in his case. Perhaps when Mr. Truscott has lived and learned a few years longer he will discover a few more "heresies;" but if he shall have really learned, he will scarcely again lay himself open to such a well-deserved rap on the knuckles as that applied to him by the Editor last week.

MONITOR.

THE TESTING OF LENSES.*

I HAVE now to describe my method of testing the relative value of lenses for each quality, viz.:—1. Defining power and flatness of field. 2. Astigmatism. 3. Achromatism. 4. Depth of focus. 5. Distortion. For this purpose I use a long table which supports my optical bench. This bench consists, first, of a framework five feet six inches long, with a finely-divided scale running along each side from end to end. Secondly, of two supports capable of being propelled by separate screw niches to any distance required. To one of these supports my ordinary camera is clamped, to the other is a large bellows and focussing screen. This bellows can be fastened on to the rear of the small camera so as to make a large camera of four and a half feet extension, the large focussing screen being twenty-eight inches in diameter, which is sufficient to include the diameter, or half the diameter, of the circle thrown by any ordinary lens used in photography at not less than five times its focal length. On the wall opposite, in a well and evenly lighted position, I place the various test objects in a line with, and at right angles to, the axis of the lens to be tested. By means of a soft composition (chiefly wax and paraffin) used by dentists, I am enabled to fix any lens accurately, and at a moment's notice, to the front of the camera, thus dispensing with the flange. Let us suppose that the camera is in position, and the lens to be tested adjusted, we can proceed to test it as follows for flatness of field:—A cardboard figure is prepared consisting of a number of concentric circles drawn with Indian ink on a white ground, the intervals between each being one millimetre and the lines of similar thickness. For reference, every tenth line starting from the centre is numbered. This figure should now be placed in the axis of the lens, and parallel to the plane of the focussing screen, and the object carefully focussed on the latter. Now, in comparing different lenses these lines should be reduced in the same proportion. For it is clearly easier to compare accurately the definition of two lenses when they are of the same breadth than when they are of different breadths. The thicker a line is, the greater breadth of indistinctness there must be round it for it to appear indistinct. It is clearly easier to compare the qualities of two things when they resemble each other in all qualities outside those in which we compare them. Thus it is easier to observe whether the illuminating power of two sources of light are alike when the light is of the same colour from each than when it is of a different colour. Hence, in comparing different lenses, the lines must be reduced to the same size.

Now, it is necessary for us to contrive a formula to enable us to show at what distance the circles must be placed so as to set the lines the same size in each case:—

Let O be the size of an object, I the size of its image; (a), the distance between the object and the lens; (b), the distance between the image and the lens; (f), the focal length of the lens.

$$\text{Then: } \frac{1}{b} + \frac{1}{a} = \frac{1}{f} \text{ i.e., } \frac{1}{b} = \frac{1}{f} - \frac{1}{a}$$

$$\therefore b = \frac{af}{a-f}$$

$$\text{Again: } \frac{I}{O} = \frac{b}{a} = \frac{af}{a-f}$$

If, then, O be the system of circles, or any fraction of that system, and the arrangement be such that the image is *always the same size* for any lens, we must choose a (i.e., the distance of the lens from the object), so that $\frac{f}{a-f}$ is the same for all lenses used.

If we were to place the object several feet away, a would be very much greater than O , and f might be neglected in comparison with a . Hence $\frac{f}{a}$ would be the same for all lenses used, i.e., we should have to

* Concluded from page 761.

view the object at distances from the lens proportional to the focal length. The objection, however, to having a very much greater than f is, that the figure viewed would have to be increased to an enormous size. Hence this simplification is not in general convenient. Practically, it will be found best to choose a about five times the focal length, and as the lines in the image should be only just so large as to be distinctly visible, i.e., $\frac{1}{100}$ inch broad, we should have the breadth of lines in the object:

$$= \frac{a-f}{f} \times \frac{1}{100} \text{ inch} = \frac{4}{100} \text{ inch,}$$

i.e., one millimetre, or, rather, they should be of this order of magnitude, and not less than this.

An objection to this method of comparing lenses will be that a lens has different defining powers, according to the distance of the object viewed. The defining power of the lens ought, therefore, to be taken when viewing an object at a fixed distance. But the objection can easily be removed; for, from the defining power of a lens at any distance, that at any other distance can be calculated. Practically it would be best to choose for the absolute measure of the defining power of the lens the defining power at an infinite distance, and this can be calculated from our observations by means of a "correction for infinity." Now we can show mathematically that this correction for infinity is a

constant, and that it can be represented by the formula $\sqrt{\frac{a}{a-f}}$.

To show how easily it is applied, let us suppose our lens is one of four-inch focus, and that the series of circles is placed at five times the focal length of the lens, then A being distance of the lens from the object, and f being the focal length of the lens, then

$$\sqrt{\frac{a}{a-f}} = \sqrt{\frac{5}{4}} = \frac{2.236}{2} = 1.118$$

It can be proved that the defining power of a lens

$$\sqrt{\frac{a}{a-f}}$$

Now, when the lens is used to view an object at an infinite distance,

$A = \infty$, and $\frac{A}{a-f}$ tends to the limit unity for $\frac{a+f}{a-f} = \frac{1}{1-f/a} = 1$ if

$a = \infty$. Hence the defining power for an infinite distance = defining

power for distance $a + \sqrt{\frac{a-f}{a}}$, and the correction to our observa-

tion for an infinite distance is $\sqrt{\frac{a-f}{a}}$.

Now, let M be the number of millimetres, within which the lines can be distinctly defined, which is the best measure of defining the power of the lens M or $\frac{M}{f}$ or some other function of M ? Suppose we have two lenses of different focal length, but whose measure of definition is equal according to the first system. These two lenses will give an equal amount of haziness at equal distances from the centre of the focussing screen. They will take equally clear photographs of the same size of plate, although the shorter focus lens will contain smaller images and more subject matter than the other. Suppose we have two lenses of different focal length, but of equal measure of definition according to the second system. These two lenses will give equal amounts of haziness in the focussing screen at distances from the centre proportional to their focal length. They will, therefore, have equally well defined photographs if the size of the photographs be proportional to their focal length. Now, the size of the photograph is proportional to the distance to which the camera is drawn out, and cameras are usually made similar, i.e., the distance to which the camera can be drawn out is proportional to the general dimensions of the camera. Hence these two lenses will give equally good photographs, provided they are used in cameras whose dimensions are proportional to their focal lengths—i.e., a "quarter-plate lens" will give as good a definition at the edges of a "quarter-plate" focussing screen as a "whole-plate lens" at the edges of a whole-plate screen, if the two lenses are in all other respects equal. A little reflection will convince every one that we must adopt the formula

$$\frac{M}{f} \sqrt{\frac{a-f}{A}}$$

in preference to the former method, and that is what I adopt, as it is a quantity independent of the unit of length adopted. This method of comparing lenses, as above described, has been in a modified form

adopted by the foreign opticians in testing microscopic objectives, although I believe it has never previously been adopted for photographic purposes. Indeed, Professor Naegeli, in his work on the *Microscope*, says (page 127): "The images of wire gauze are recommended as test objects preferably to all others, because, in the first place, for every range of amplification they present one and the same object, and wire gauze may be substituted for the test circles above described, if any one wishes, although the latter are easier to read off."

2. Measurement of defining power. The defining power of a lens is quite an independent property from the last. In this case the centre of the field must be first chosen (and afterwards other points at variable distances if deemed necessary), and the test circles or squares removed, and in their place a silvered ball or convex mirror of very short radius (one inch to three inches) is substituted. Cowell's test types* are now placed at a definite distance from the ball or mirror (the distance bearing a constant ratio to the radius of curvature of the reflector), and the letters are well illuminated by a lamp, the lamp and the types being so adjusted that the image is seen in the centre of the screen of the camera and in a line with the lens axis. An extremely small image of the type is projected on to the reflector, and the smallest type is noted that can be read off with the eye-piece in mid-air. This is the index of definition for this particular lens. This should be done first with full aperture, and then with all the other stops in turn until the best result is arrived at; by this means we arrive at another result, viz., the penetrating power of the lens. This latter is a different quality from the defining power, and in telescopes and microscopes it is of great importance. To make my meaning clear it is as well to define these two terms. By the term penetrating power we imply the power which a lens has to render clearly and sharply fine details. By the term definition we mean the capacity of exhibiting clearly and distinctly in the image the form and outlines of the object. Thus good penetrating power shows up the markings and striæ of diatoms, and shows up obscure comets and nebulae, and is largely dependent on the size of the aperture or stop used; while good definition will show a clear, sharp marginal outline to the diatoms, or in the telescope will resolve double stars, &c. Herschel, who first applied the term penetrating power, showed that it is dependent on the size of the aperture, not the defining, or outline power, upon the optical perfection of the instrument (Naegeli & Schwendener). *I believe that it is due to the combined effect of these two properties which enable the portrait lens to excel every other form of lens in the perfection of the image of a flat surface over a limited area.*

Besides these tests, which are the chief ones, it will be necessary to examine for achromatism, depth of focus, and distortion to complete our task. I will not examine them in detail, reserving this for another opportunity. I may say, however, that achromatic aberration is best tested either by the optician's method of examining the colour circles, and the coincidence of the chemical and visual rays (i.e., of the photographically actinic with those rays most visible to the eye on the focussing screen) is best tested by the apparatus described and figured in Monekhoven's *Optics*. This consists of seven pieces of wood inserted in spiral form along a cylinder of wood about two feet long. These are painted black, and each is numbered with a white figure in order from 1 to 7. The cylinder is placed at about five or ten feet from the lens, with its long axis pointing to the centre of the lens. In this way each of the figures is clearly seen. We now focus carefully for the central figure 4, and expose and develop a plate. If this figure is quite sharp, the chemical and visual foci may be said to coincide; if not, according as the lower and higher in figures come out clearest, so the lens is over or under corrected.

To test the depth of focus of a lens, I think the best way is to adjust the camera first of all to infinity—a distant weathercock or chimney will do perfectly to mark the position on the camera front, or the back, if that travels. Then focus for the test squares at five times the focal length of the lens and mark again. The distance which the camera has been racked out (as shown by the two marks) will give us data for calculating the depths of focus.

DR. G. LINDSAY JOHNSON.

DISCUSSION.

Mr. J. Traill Taylor, while admiring the learning displayed by Dr. Lindsay Johnson in his lecture, would have preferred that a somewhat more practical turn had been given to the testing of lenses.

* Cowell's test types are merely an improvement of Professor Snellen's "Schriftproben," in which a number of sentences are printed in types of varying but definite size, so that the letters of each series subtend an angle of five minutes at a distance of 1, 1½, 2, 2½, 3, 3½ (and so on) metres measured from the observer's eye. They may be had of Harrison, printer, in St. Martin's-lane.

Concerning the method described by the lecturer for ascertaining the focus of a single or landscape lens, viz., measuring the distance between the ground-glass and the nearest surface of the lens, and adding thereto half the thickness of the lens, this could only apply to a lens of double convex form—a class that was never employed in photography. Photographic landscape lenses were either of a plano-convex or meniscus form; and in the case of the former of these, the point from which the focus had to be measured was one practically adjoining the optical centre which was at the convex surface of the lens, while in a meniscus lens the focus was measurable from a point altogether outside of the lens, and which, if the meniscus shape was very pronounced and deep, might be situated some considerable distance outside the convex surface. One of the best and simplest tests for spherical aberration in a combination was to cut a disc of opaque paper the size of the front lens, and in that cut a hole seven-tenths its diameter, measuring the central portion thus removed. Attaching the first portion to the lens, let a photograph be taken of any well-defined object, focussed with the utmost care, and then, having removed this temporary diaphragm, let the piece that was cut from it be affixed to the front lens, and a second photograph be taken without disturbing the camera. Both negatives would be equally illuminated, as the areas of aperture would in both cases be alike. If the second picture were equally sharp with the first one, the lens would be free from spherical aberrations. A watch dial placed at a little distance formed a good test for definition in a lens; while its condition with regard to chromatic aberration might be ascertained from examining an artificial star conveniently made by illuminating a thermometer bulb illuminated by an adjacent lamp.

Mr. Conrad Beck said that opticians had to deal with a great inconvenience in that all optical books in English up to within the last few years in treating of lenses have omitted in their calculations the effect of the thickness of a lens, and the means of correcting for rays traversing it obliquely. The focus should not be measured from the centre of a lens, but should be measured from two "principal planes," which were situated in different positions, according to the formation of the lens. In a biconvex lens they were situated within the lens, each plane being about one-sixth of the total thickness on either side the centre of the lens. In a plano-convex lens one plane was about two-thirds through the lens, the other on the convex surface, while on a meniscus both planes were outside the lens. In a case which he had in his mind of a twenty-four inch focus meniscus landscape lens the planes were situated at a distance from one inch to one and a half inch outside the lens, so that if the focus had been measured from the centre of the lens it would have been about twenty-three inches one side and about twenty-five inches the other. He then mentioned that in a symmetrical these planes were often situated at some distance from each other, and showed that it was not correct to measure from the centre of a symmetrical lens to obtain the focus. He recommended, in order to obtain the equivalent focus, the method that was mentioned by Mr. Traill Taylor in his lecture on lenses. He then stated that the optician had not only in making his lenses to correct them for spherical aberration, but that he had to throw his image on to a flat instead of a spherical plate, and in order to do this certain special corrections became necessary. If the lenses were accurately corrected for one aberration, another correction was often disturbed, and the whole system of correcting photographic lenses was a system of balancing corrections against each other, so that the best final compromise was effected. He then stated that if an amateur examined a mercury bulb in the way that Mr. Taylor suggested, he would find a very different correction to what would be used in a telescope object glass. If a photographic lens were corrected in the same manner as a telescope there would be what is commonly called a chemical focus—that is to say, the rays which do the most work in taking a photograph would not come to the same focus as the visual rays, and a special correction has to be made for this purpose. He concluded by saying he believed the best method for amateurs to test their lenses was by taking photographs with similar lenses and judging of their working qualities on the subjects they were sold to photograph. He stated that in optical tests there were so many points to be considered, that one who had not had an optical training was very apt to be misled.

Mr. Lionel Clark said it was of course impossible to criticise the learned Doctor's paper, seeing that it was in an unfinished state, but he thought that what were the particular defects and faults inherent to lenses might perhaps have been more fully dealt with by the lecturer. There were five great sources of error in lenses; Monekhoven called them five aberrations. The first was spherical aberration; this form of aberration is caused by the fact that the rays of light falling on the edge of a spherical lens were not refracted to the same point as were those rays which fell on or near the centre of the lens. Now

since the image was formed by the accurate consequence of the several rays of light, of which it was formed to a single point, it naturally followed that when they did not meet it resulted; this was the cause of the so-called depth of focus being greater in one lens than in another. The second aberration is known as chromatic aberration, when the lens refracts the light it also breaks it up into its component colours, and the image is seen surrounded with coloured rings. The third aberration, commonly called roundness of field, was often confounded with spherical aberration, but could easily be distinguished by the fact that with roundness of field by racking the camera in a place could be found where the marginal definition was improved, whereas when the fault lay at the door of spherical aberration there was no point at which the definition improved. Aberration No. 4, commonly called distortion, was the bending in or out of the marginal lines of any rectilinear object, and was called either barrel or pin-cushion distortion, according to the shape the image took; it was entirely absent in lenses of the symmetrical type. Its cause was easy to see. If a square were cut out of a plano-convex lens, the extreme edges of the square will be of thinner glass than the centre of the sides; so with the rays of light, the corner ones passing through a less thickness of glass than the centre ones, they are differently refracted. Aberration No. 5 is known as astigmatism, and the cause was not quite so easy to see as that of the preceding aberrations. Imagine a cylinder of light falling on the lens obliquely, that is from one side. Now, if a vertical section be taken through this cylinder, the bounding sides will be of equal length, but if a horizontal section be taken they will not be so, but one will be longer than the other. The effect of this was to make one focus for vertical lines and one for horizontal ones, so that in focussing a cross the whole could not be got into sharp focus at once, but either one or the other limb. He believed, however, that this aberration was by no means often met with in modern lenses. In conclusion, he was very pleased to see that Dr. Johnson had taken so much trouble to popularise what had hitherto been considered as beyond the reach of the average amateur.

Captain Abney, in summing up, pointed out one or two errors into which the lecturer had fallen. He also showed that it was easy to obtain parallel rays by the use of a collimator. The whole system of photographic lenses was a matter of compromise, errors being counteracted by errors. Mr. Clark's remarks gave him the greatest cause to blaspheme. His reference to depth of focus was to him like a red rag to a bull. He looked upon it as a matter of aperture. A lens which gave diffusion of focus was a bad lens. Depth of definition could only be obtained by contraction of aperture. He did not like fuzziness, but preferred those lenses which brought infinity rays to a sharp focus in one plane.

Dr. Johnson, in conclusion, thanked the meeting for letting him off so easily. It was needed that some one should strike out some new methods and make a bold stand.

THE ACTION ON THE NEGATIVE FILM OF METHYLATED SPIRIT AND HYPOSULPHITE OF SODA.

So far as I am aware spirit has been recommended only as a means to be used to dry the film quickly after fixing; but I believe it is a "clearer," safer, if not better, than hydrochloric acid or alum. The mode of action of the methylated spirit appears to be by mechanically contracting the pores of the film, thus forcing out with the water something more from the "depths" of the film than the hypo has removed. It will be found after the spirit has been used for some few plates, as with care it safely may, and it be allowed to settle for about twelve hours, there is a light, white substance precipitated in the bottle. It can be filtered out almost entirely by cotton-wool well pushed into the neck of the funnel, and, I think, removed entirely if about half an inch of powdered animal charcoal is superadded to the cotton-wool. (I find it better to filter the spirit after every day of using. It takes time, but as it can be done by setting it to filter during the night, there is really no loss of time.) If not filtered, the above mentioned substance, invisible when diffused through the bulk of the spirit, appears to be caught by the plate, and markings result, which are reproduced in the printing. If the spirit is kept rocking the substance is much less liable to deposit on the plate, and the advantage of getting the plate dry more quickly is but slightly diminished if it be rinsed under a tap after being in the spirit and before being set up to dry. Of course the spirit alters in specific gravity by continuous use, particularly as the best effects are produced when the plate is put into the spirit directly after it is thoroughly drained, and not later. Then a longer time must be allowed than when using fresh spirit. If put in when surface dry, *i.e.*, just as it is beginning to show dryness at the edges, the action of the

spirit is not only not so satisfactory, but may produce markings, the cause of which I will not go into now.

But what is the deposit in the spirit? It appears to be some of the unchanged chlorides, &c., that the hypo and the after washing has failed to remove. The plate will remain unchanged if no "clearer" is used.

What does the hypo do? I do not recollect to have read any definition of its course of action, beyond that of "dissolving out," but is there not some chemical action that takes away the sensitiveness? and the deposit in the spirit is probably identical with that in the hypo. I doubt if any amount of washing and soaking will remove this so well as the contractive action due to the use of spirit, which, as I have suggested, is simply mechanical, and not open to the objection that the other "clearers" are open to, of a possibly chemical action, more or less, at one time or another on the plate that may be deleterious.

HYDROKINONE.

This chemical, I have lately found, appears, as Mrs. Malaprop would say, as "Two gentlemen at once," for you may buy it with either of the two following characteristics:—(1), As a colourless, or nearly colourless substance, crystals very small and rather inclined to mass together, and inodorous; or, (2), as amber coloured crystals, long and large as compared with No. 1, and peculiarly scented. The former is rather the more powerful for photographic purposes than the other, and generally I prefer it. I saw in the *JOURNAL* of November 25, a professor in America had said the hydrokinone developer *need not* be rocked, but from my late experience, confirmed by another opinion, it *ought not* to be rocked. I had noticed the middle of some of my plates wanting in density, just where the dead point would come if not rocked very slowly and carefully, and at first I could not account for it, thinking it was some reflection from the lens, and I also noticed that when I had left the plate still directly the image had shown itself, or rather shown signs of appearing, much greater density has been the result.

W. T. F. M. INGALL.

SPOTS, STAINS, AND FADING.

[A Communication to the London and Provincial Photographic Association.]

SOME years ago, at a country Literary and Scientific Society, one of the members promised a paper on *The Spots on the Sun*. The evening came; there was a large attendance, and the subject was evidently of deep interest.

When called upon to read the paper, the gentleman who had promised rose and said:—"Mr. Chairman and Gentlemen, we are met together this evening to endeavour to elucidate something which has for ages puzzled many of our most scientific men. It is evidently a matter in which we all take a deep interest, and that is why I promised to bring forward a paper on the subject to-night." He then took a small slip of foolscap from his pocket, and read the following question:—"What do the spots on the face of the sun consist of, and are they permanent or transitory?" After expressing a hope that the discussion would be of much practical value, he bowed and sat down.

Now, gentlemen, that is exactly the course I should have liked to have taken to-night; for my sole object in saying I would give a short paper was to reopen the discussion we began on the 17th ult. In reintroducing the subject, however, I do not propose to confine my attention to spots only, although I believe spots, and spots only, has been a subject of special interest lately; but I should also like to include stain marks, fading, or, in fact, anything tending to spoil the beautiful, though much maligned, silver print, more especially after it has left our hands in a mounted condition. It is, I think, generally admitted, that mounted prints are far more likely to fade than unmounted ones; and I think we may also take it, that marks which appear in unmounted prints usually make their appearance during the course of their preparation.

Of course there are certain spots and stains familiar to us all—spots from dust between negative and paper, stains from hypo on untuned prints, and numbers of similar evils which are due solely to carelessness. We recognise these at once, grumble at the printer, and think no more about it, knowing that a few wasted prints, and possibly a few days' delay, will end the trouble. Occasionally, however, we come across spots and stains, the origin of which we are at a loss to discover. An instance of this kind occurred to me not long ago, and I much regret now having destroyed the prints. For some months, at varying intervals, a few of the prints would be marked with yellow stains, sometimes circular, sometimes comet-shaped, sometimes of no describable shape. The marks usually came after fixing and while in the washing water; they did not appear to have any centre, and were of various sizes, from a pin's-head to a sixpence. I tried to account for them in various ways, and failed; there was no alternative but to

go on as usual, and it is some time since the enemy appeared. On the last occasion it took a very mild form, and had the appearance somewhat of mildew: this I can show you.

To me, however, the most annoying of the "ills" to which photographic "flesh is heir," is when you have made your prints with all the care of which you are capable, mounted them accurately, finished them and sent them home, feeling, probably, a satisfaction in the result, there may be some demon in the mounting board, of the existence of which you are perfectly ignorant; and while you are hugging yourself in the belief that your pictures are as permanent as they can be made—for, alas! with all silver prints it is only a question of time and circumstances—there may be stealing over them spots and stains, to the great damage of your reputation and the great annoyance of your customers, to whom you thought you had done your duty in that state of life to which, as a photographer, you had been called.

It is sometimes difficult to tell who is the actual offender—the printer or the maker of the mounting boards. I am of course supposing, as I said before, that every care has been taken with the prints, that they have been well toned, thoroughly fixed and washed, and mounted with fresh starch—and here we must pause a minute: there is starch and starch. When good it is the best mountant that can be used for general work, but it is sometimes adulterated with something—and what the *something* is I am not quite sure—which causes spots, often attributed to other causes; and here I would recommend my brother photographers to buy the best white starch, and buy it in the packet as it comes from the manufacturers. Many oil and colourmen keep starch, chloride of lime, and several other equally useful articles in adjoining drawers, and they are not at all conservative in the way of scoops. A little chloride of lime, for instance, might be no disadvantage when the starch is to be used for laundry work, but would scarcely be desirable when required for photographic purposes.

To resume. I am supposing the fault *not* to be due to the mountant, but the mounts, or something which has accidentally or ignorantly been allowed to come into contact with them. I am inclined to think that, in some instances, printers do not take sufficient care when printing in bronze. Of course, if people will use mounts so printed, he must print them; but he need not necessarily allow the powder to be blown "all over the shop," and so spoil the mounts of those of his customers who do not wish their boards covered with particles of tin and copper.

I remember on one occasion being in the printing department of a large photographic warehouse, and taking a cabinet mount from a pile printed in bronze; passing my hand over the back, there came off enough powder certainly to do two or three more, and yet these were all cut and laying back to face ready to be packed up and sent home.

I have heard of people saying bronze powder will not cause fading, and that experiments have been made to bring about such a thing and failed; very likely. It is very easy sometimes to fail where you most expect to succeed, and to succeed where it would be a distinct advantage to fail. An instance of this occurred with myself only to-day. About two years ago I had a lot of large pictures to print in platinum; the weather was humid, and I was short of indiarubber cloth. It was inconvenient to get some near home, so I sent for some material such as is used for table covers. The platinum prints finished, the American cloth was left in the frames, and in due course these frames were used for silver printing. Wherever this cloth touched the silver paper, and even when a piece of blotting paper was between them, a deep brown stain was the result. Wishing to show this to-night, I attempted to bring about the same result to-day. Whether the cloth has lost that peculiar property it once possessed I cannot say, but there is the cloth, and there are the prints, and nothing whatever is the matter with them.

Now I cannot say I have had any personal experience with bronze printed mounts; I have always looked upon them as a possible source of injury, and avoided them accordingly. My greatest annoyance (for which the printer or card-maker is responsible) is in connexion with *enamelled mounts*. That all enamelled mounts cause fading or injury I am not in a position to say; in fact, I show you here some pictures so mounted which have been in a show-case for years, and whatever fading there is, is certainly not due to the mounts: they were printed in 1874.

The first case I remember of spots being caused by enamelled mounts occurred in 1874-5. I had a model to photograph, and the mounts were to be white enamelled like the pattern sent. I obtained some of the best quality cards, and having a few left after the order was completed, used them for other purposes. All the pictures mounted on these cards were covered with spots. Here is a specimen. It will be noted that the mounts have a bronze line round them. I have always, however, considered the spots due to something in the white enamel and not to superfluous bronze powder. The next batch

of enamelled cards I have to complain about caused not spots but fading. This was in 1878. They were of a buff colour, and all the prints I can find that were mounted on these have faded considerably. That you may see this is due to the mounts and not any alteration in my mode of working, I here show you some pictures on plain greenish mounts I was using at the same time; all the pictures on these are as fresh as the day they were made, or nearly so. I need scarcely say that although these pictures have been done nearly ten years, it is not a pleasant thing to reflect that, at any rate, there must be 5000 *cartes* bearing my name in this unsatisfactory condition, and through no fault of mine.

Now I am not sufficiently acquainted with the various substances used in the manufacture of cardboard to say what particular compound is most likely to have caused the result I have mentioned; but no doubt many of our better-informed members may be able to throw some light on the subject. I would also say that, in common with most of us, I have, in turning over old photographs, frequently found *faded* photographs on plain mounts. From my own experience, however, I have found those that have been enamelled the most untrustworthy, and it is my intention to avoid them in future.

One more example of marks due to enamelled mounts, and I will not further occupy your time.

Here is a *carte-de-visite* that has been printed perhaps two years. You will notice what appears to be brush marks on the face, and that it has faded in streaks. This, of course, might be due to an acid mountant. It is not so, of that I am certain, and if you will turn it over you will see similar marks on the back of the card; and not only that, but even a dark mark where it has been in contact with the little brass strut produced. What is the cause of this I am unable to say; but I hope the discussion to follow will be the means of clearing up some of these points.

In conclusion, I may say that it is now my practice to avoid (for silver prints) enamelled mounts of all kinds, and to use as far as possible only plain toned mounts of good quality; these I have found the most reliable and the least likely to cause either spots, stains, or fading.

F. A. BRIDGE.

REMOVING GELATINE FILMS FROM THEIR GLASS SUPPORT, AND CONVERSION OF AN ORDINARY NEGATIVE INTO A FILM NEGATIVE.

[A Communication to the Glasgow Photographic Association.]

I wish to bring under your notice this evening not only a very simple method of stripping a gelatine film from its glass support, which does not seem to be so well known as perhaps it should be, but also further demonstrate the possibility of converting the ordinary gelatine negative into the film form of negative. Every one knows how tenaciously the dry plate film clings to its glass support. Quite recently a manufacturer of dry plates, who had a stock of fogged plates, and who desired to recover the emulsion, mentioned to me the difficulty he had experienced in getting the film scraped off; in fact, they were about beat with it, and, as you can imagine, a scraping process, as far as the glass was concerned, was certainly not to be recommended. I suggested the use of a weak solution of hydrofluoric acid, and so effective is such a solution that I thought it might interest the members to bring it before them in a practical form this evening. Here are some old negatives varnished and unvarnished, and I will immerse them for a short time in the solution, and you will see with what result. In a very short time you have the complete film detached, longer of necessity in the case of those negatives which have been varnished, as the solution in this case, owing to the protecting layer of varnish, does not penetrate so quickly to the glass surface. The strength of the solution is a matter of no great exactitude, perhaps ten ounces of water and half an ounce of ordinary commercial hydrofluoric acid. A stronger solution might operate quicker, but as every one knows the substance we are dealing with is in the strong form employed to etch glass; a weak solution, although it may take longer, would certainly be preferable where the glass might be wanted to be used over again.

I think you will see that the glass from which the films have been removed has not been attacked in any way, and one recommendation may certainly be put forward that after being washed it may be considered as chemically clean. I perhaps should mention that as the solution even in the weak form is a highly deleterious one the fingers should not be immersed in the solution. In making the experiments for this night's communication I was somewhat careless regarding this matter myself, and for a couple of days afterwards I was reminded of the fact by a severe pain under each nail of the fingers which had been immersed in the liquid.

Now, gentlemen, having got the film off, and that in a perfect form,

it has for a long time appeared to me that here we had a veritable film negative, and that only two things were wanted to make the thing complete, namely, to prevent the expansion of the film, for you will see in the films which have been removed that a considerable extension both in breadth and length has taken place, and, further, to so increase the thickness of the film that a certain amount of stability should be imparted to it. To illustrate what I mean here is a half-plate film removed from the glass support according to the method described, and allowed to dry on a vulcanite board; you will see that it is now very much larger than the true half-plate, and that although it certainly could be used in the printing frame and give perfect results still it is rather a fragile negative. Now in the gelatine skins we have been hearing so much about to-night in connexion with Mr. Armstrong's demonstration, have we not the very thing that will enable us to turn to account the films stripped by the method now put forward? Here is such a film negative, and I beg now to show you how such has been obtained. Having immersed the skin for a minute in the soaking solution, and transferred it to the tray where the film that has been removed is floating, it will be found quite possible to bring the two out together in close contact. A vulcanite sheet being at hand they are placed upon it, and by means of water made to be perfectly flat. Air bells can be driven out by gentle application of blotting paper, and when no more of these are seen the whole can be allowed to dry, when it is a very easy matter indeed to pull off the film negative. Regarding the prevention of the film's expansion, I think this may be arrived at by means of alcohol. By means of this reagent we are not complicating matters. By the introduction of a salt into the film, as we would were we employing a solution of alum with alcohol, a subsequent washing is dispensed with.

As far as my experiments go, the proper strength to use is a solution made up half of methylated spirit and half of water. Undiluted methylated spirit has far too energetic a reaction, contracting the film most unconsciously. The soaking in the spirit may be done in the same tray in which the detaching operation has been performed, the hydrofluoric solution being gently poured off. And it is as well to leave the original plate in the tray, so that when the alcohol has reduced the dimensions of the film we may readily see when it has been brought back again to its original size when on the glass. At this stage, or perhaps shortly before, the skin should be immersed in the soaking solution recommended by the Eastman Company:—

Ammonia	$\frac{1}{4}$ ounce.
Glycerine	$\frac{1}{2}$ "
Water	64 ounces.

The skin is then, as already indicated, laid down on the top of the film and the two lifted out together. The vulcanite sheet being at hand, or, what answers as well, a ferrotype plate, the double films are placed thereon—perhaps it is the better arrangement to have the skin next the vulcanite. As the alcohol evaporates and leaves the gelatine, by means of a camel-hair brush any inequalities can be adjusted, and it will be found by a very little care that the two films will be perfectly flat and in close contact. Notwithstanding the very thin nature of the uppermost film, it can stand a good deal of pulling about. You will see that this is the case when we come to the actual demonstration.

I do not think much more remains to be said. It must be understood that I do not put forward this converting of an ordinary negative into a film negative as a perfect process, but I think you will admit that having once got the film off the glass in the very perfect manner obtainable by means of hydrofluoric acid, the possibility of still retaining that negative in the film form is not far removed. Again, take the case of a cracked negative where the film, notwithstanding the crack in the glass, still remains good, such a negative need not be thrown away, for, by following out the lines here indicated, it can be made to do duty over and over again.

For the introduction of these gelatine skins in a commercial form I think the best thanks of those interested in photography are due to the Eastman Company. I should, perhaps, just remark before closing this communication, that the skin used for a particular size of negative should be of a size larger than the actual negative we are dealing with; for example, in the case of a whole-plate negative I would recommend a skin 10 x 8, this enables one to have more latitude in adjusting the two films and saves a good deal of time. The surplus margin of the skin can very easily be cut off when dry.

WILLIAM LANG, JUN., F.C.S.

PHOTOGRAPHING BY THE FLASHING MAGNESIUM LIGHT.

[A Communication to the Glasgow Photographic Association.]

It was originally intended that my paper and demonstration to-night should treat merely of Eastman's stripping films, but at the end of

last week my kind friend, Mr. Reid, threw out a suggestion which at once impressed me as a good one, viz., that, conjointly, we might on this occasion, with the aid of artificial light, expose a few Eastman strippers, and then develop, strip, and skin them in your presence. To enable us to do this, we have received at the hands of Mr. Mason much kind assistance in providing the necessary accessories to enable us to carry this into effect. I should have much preferred, had I been able, to expose a few films outside and show the development and after treatment of such, but you are aware the weather has been so bad lately that such was not possible.

Quite recently the taking of pictures by artificial light without the aid of elaborate and costly accessories has received fresh impetus, chiefly through the revival of what is really not a new method of making exposures, for so far back as November, 1865, I find that almost identically the same ingredients were then in use and recommended by Mr. Traill Taylor as we find now trotted out as quite new, and which, I understand, has been attempted to form into patents.

In November, 1865, Mr. Traill Taylor recommended a mixture of sulphide of antimony, chlorate of potash, sulphur, and magnesium filings, and, if I am not mistaken, this is practically the same compound as we hear so much made of by Dr. W. H. Vogel, who designates it "the latest novelty in Germany," attributing its discovery to Messrs. Gädicke and Miethe. This compound, after all, is not so desirable as it would at first appear, for it is undoubtedly of most explosive character, being easily exploded by friction or a blow; then, again, another objection arises, and that is the character of the fumes given off from the mixture—the sulphide of antimony when burnt gives off sulphurous gases, and also fumes of antimony oxide, the latter being poisonous. More recently it has been suggested to use, instead of sulphide of antimony, a substitute in the shape of powdered sugar; but when such is employed a very black smoke is given off, which is undesirable.

Very recently there was exhibited before the Society of Amateur Photographers of New York, by Dr. H. G. Piffard, a mixture of guncotton and magnesium powder, and much success has attended its use. I show you a picture which forms the frontispiece of *Anthony's Bulletin*, under date November 12, 1887. This is an instantaneous photograph at night by Geo. G. Roelwood, and was taken by means of Dr. Piffard's magnesium flash light. You can form your opinion, gentlemen, as to the excellence of this production.

Within the last few days my friend, Mr. Reid, and myself have been experimenting somewhat with this flash light. At first we met with some little difficulties, but to-night we hope to show you that a fairly good negative is obtainable by the use of magnesium powder being burnt in conjunction with a few inches of magnesium ribbon.

Our first experiment was with cotton and powder alone, in the proportion of eight grains of cotton to fifteen grains magnesium powder. This yielded a somewhat under-exposed plate; but it is only fair to state it was our first attempt, and it is just possible the light was placed at too great a distance from our sitter. Approaching nearer to the sitter and using a somewhat more powerful light we obtained a fully exposed negative, but with this drawback, that there was a much too even illumination of the face—there being a lack of contrast in high lights and shadows; this might easily be the result of not throwing the light on our sitter from a proper angle or height, but we found this not so easy to overcome, through having to burn the light on an iron receiver, which tends to throw a cast shadow downwards. To enable us to overcome this difficulty, we thought upon the plan of burning a few inches of magnesium ribbon for just a few seconds before igniting the cotton, and in this we partly overcame the difficulty. The ribbon can be so held as to throw a powerful light on the prominent features of the face, and so bring up contrast between high lights and shadows. To do this we had the use of a very neat little magnesium lamp, which I now show you. You will observe the old-fashioned bright metal reflector has been removed, and in its place is substituted an opal glass reflector, which gives a much softer and more diffused light, just the very thing wanted. This lamp goes by clock-work, and once lighted runs on, as a rule, right merrily, giving a very certain and steady supply of ribbon. I hope it will behave itself later on, gentlemen, when we come to operate. Should it not, it will be the fault of the ribbon not the lamp.

Notwithstanding the success which attended our experiments with guncotton and magnesium powder, we were forcibly struck when using such with the yellow nature of the light emitted from the cotton, which in part measure neutralised the very actinic light of the magnesium powder, and we were therefore convinced that guncotton was not the best agent to employ. Our experiments clearly demonstrated to us that in the powder alone lay all that was required, so far as the light was concerned, and it resolved itself into a question of how best to use the powder. At first I tried several other means,

among which was dusting the powder through a homely pepper-box on to a sheet of gauze made red-hot over a Fletcher burner, and here I found I was on the right track in so far as the brilliant light obtained was concerned. But then we had to overcome the difficulty of the cast shadow downwards, and the trouble of placing the light sufficiently high to throw the rays about an angle of forty-five degrees. We then, luckily, tried what a bottle of this description would do, and on using same were overjoyed to find the problem settled. With this cooling bottle containing a quantity of magnesium powder and an elastic tube attached to the ingress pipe, the least puff sent out a spray of the powder, which immediately ignites on any suitable medium for combustion. On blowing a spray of the powder through an ordinary gas flame from any common burner a most brilliant flash is obtained, far and away beyond the gun-cotton light, and this also enables us to direct our light from a suitable angle. When experimenting with this flash light last night I found that when flashed about six feet from the sitter the light was so penetrating as to considerably over expose the film, and so I had to place a gauze screen between the light and the sitter. This done, I obtained a nice negative, and it will be on these lines that I shall proceed to-night. Just a word about this wash bottle. It may appear to some that a considerable quantity of the magnesium powder is forced through the gas flame without ignition, and therefore a considerable loss in material; at first I was of the same opinion, but on closely observing the matter I found such was not the case, and that one short, quick puff did really not eject more than about twelve grains of the powder. I consider the blowing through a gas flame of this powder a great stride in the right direction in the class of work we are considering to-night, especially as it solves the difficulty of being able to throw the light from any desired angle, which is easily done by a common movable gas bracket with universal joints. I am sorry we have not one of such fitted in the room to-night, but I hope to succeed without its aid.

And now, gentlemen, having given you an outline of what we consider the best flash light to use, I will be as brief as possible in referring to the strippers. Any one reading the printed instructions for the working of Eastman films very likely will at once conclude that there is a deal more bother in the working of them than with a glass plate. At first, I must say, such was the impression I formed; but, somehow or other, when you come to work them this does not appear to be the case, and now I am so fond of these films that I shall discontinue plates for outside work in future. In my roll holder I carry sufficient films for forty-eight exposures, and this will at once strike you as a great advantage; the weight of this roll holder, when fully charged with a fresh spool, does not weigh so much as one of my double backs with two plates—fancy the benefit here also. Then, again, no breakage, no space occupied in storing away glass plates, with the accumulation of dust and dirt. The films go into any ordinary book, between the pages, and can be indexed up like an invoice; the development is just as easy, the washing not so tedious—half an hour being amply sufficient in running water—no varnishing. Against all these advantages what have we to set off as extra work?—the collodionising of a plate, a very simple and easy matter, the laying of the film down on same, and, after drying, placing same under the hot-water tap till the paper support peels off, then squeegee a skin on the negative, and the thing is done. The result being a negative capable of being printed upon from either side, a matter in itself of so much importance to carbon workers as to make them almost bless the day they were invented. I have found these films very uniform in quality, of a great rapidity, much the same in this respect as Paget's sixty, and for outside work can recommend them. And now, gentlemen, as we go along I shall be glad to offer any explanation that may be desired.

T. N. ARMSTRONG.

THE LONDON STEREOSCOPIC COMPANY'S EXHIBITION.

THE Third Annual Amateur Exhibition of this Company is now open in one of the rooms of their premises at 108 and 110, Regent-street, London, and contains much work of a high type of excellence.

A first glance round among the frames, of which there are eighty-one, is suggestive of Artemus Ward's army, in which every man was an officer; for we fail to discover one that does not bear the insignia of "Gold Medal," "Silver Medal," "Bronze Medal," "Highly Commended," or, more tangible still, "£10" and "£5." This system of giving one or more awards to every exhibitor—for several exhibit in more than one of the fourteen classes—cannot fail to tell favourably on the future exhibitions of this Company.

Some of the pictures have a familiar appearance, as if we had made their acquaintance at other exhibitions; but as a good story is not the worse for being twice told, so neither is a good photograph the worse for being shown at every exhibition in the world, but, on the contrary,

all the better; and if it be the gainer of a medal, wherever exhibited, why not?

Mrs. Edward Penton leads the list with a frame of three views, two being of windows of Tintern Abbey. Harry Tolley exhibits several of his undoubtedly excellent works, some, if not all, of which are already familiar to many of our readers. A series of fishing boats and other subjects taken in the Shetland Isles by John Leisk, afford a glimpse of life in regions considered almost hyperborean. A frame of yachts and other ships by Captain C. M. Harrison, each picture excellent in itself, suggest how desirable it would be if photographers, when mounting subjects of this class, with well defined horizon lines alongside of each other, would try and have the horizon of all in one row as nearly as possible in a straight line. Captain Harrison is not alone in this, for in his immediate vicinity the same anomaly prevails in Surgeon F. M. Puddicombe's views of torpedo boats and others.

In a frame of four views, *Yachting on Windermere* by W. Gaddum, one is rather spoilt by being too abruptly vignettied. So many other-wise good pictures are injured by sudden vignetting, that it is a wonder photographers do not exercise more taste in this direction. If a negative will not print out to the margin there is no reason why a clean cut oval mask cannot be employed, failing the far more beautiful easy gradation of the subject into nothingness. Surgeon-Major Mantell's photographs of *Clifton Suspension Bridge* and *Rime on Trees*, and J. E. Dumont's *His Own Barber*, are a good deal above the average. H. J. Kennard has a frame of views of glaciers and other mountainous subjects possessing much merit, and *Seven Animal Studies* by Lieutenant Croft deserve special attention. Two of Dr. Alabone's views of jumpers "Going" and "Gone" are slightly marred by the evident knowledge of all the party that they are being photographed, and the consequent staring at the camera. Edward Pritchard shows a series of charming little landscapes, all the more commendable from his exhibiting in a class which shows that he is not yet one year old in photography.

It is an axiom with artists that no straight vertical line, or anything else, should be allowed to interfere with the head of a portrait. This has been overlooked by Miss Joyce Croft in her picture, *The Skipper*, whose figure is perpetuated, as it were, by his being posed against a strongly pronounced central bar of a window. Miss Miles, too, has allowed a flower or shrub to appear as if growing out of the head of her *Duchess of Richelieu*. With more experience and a knowledge of art canons these exhibitors will do better another time. D. R. Clark's *Filling the Water Cart*, and others, have a pleasing engraving-like appearance. The *Fabiola* of J. E. Dumont, in which there is a face visible with a body or figure so shrouded in darkness as not to be seen unless by close scrutiny, is suggestive of some of the faces to be occasionally seen at spirit *séances*, produced one can only guess how. If *Four Figure Studies* by A. Clark could have been in some measure isolated from their backgrounds a great improvement would have been effected. As it is, the backgrounds are so very sharp and pronounced as to distract attention from the figures.

We shall resume this subject next week, and meanwhile recommend such of our readers as can make it convenient to look in and see this exhibition, which is now open, free, to the public.

PHOTOGRAPHY IN COURT.

BULL, BEVAN, & CO., LIMITED, v. THE PHOTOGRAPHIC AND CHEMICAL APPARATUS COMPANY, LIMITED.

In the Court of Queen's Bench, on Tuesday, before Mr. Justice Denman, the above case was tried, Mr. C. Plumptre being counsel for the plaintiffs and Mr. Crump, Q.C., for the defendants.

Mr. Plumptre explained that the action was brought for the enforcement of an agreement to give a bill of exchange for 150*l.*, for damages in the alternative. In October, 1886, a Mr. J. M. Copeland, for whom the plaintiffs had acted as agents, was indebted to them in the sum of 145*l.* 10*s.* 9*d.* Not being able to get payment of the amount, an action was commenced, whereupon J. M. Copeland swore by affidavit that the signatures to certain bills of exchange held by the plaintiffs were neither his nor his partners'. The plaintiffs then laid an information before the magistrate at Bow-street for perjury and a summons was granted. On the return of the summons, counsel appeared for Copeland, and after a formal hearing the proceedings were adjourned. Shortly after the parties met, when Copeland assured the plaintiff of his innocence and ascribed the denial of his signature to a pure mistake, stating at the same time that he was quite prepared to pay them. They in their turn said they had no vindictive feeling against him, and that if he could satisfy the magistrate that he was innocent they would be satisfied if they got their money. At that time a further bill of 42*l.* had become due, and altogether the sum of 250*l.* was admitted to be due by Copeland, who expressed his readiness to pay them 50*l.* for costs incurred in the matter and to give acceptance for 250*l.*, mentioning that his business was being converted into a company,

who would take up his acceptances and make them debtors, and that he would further secure them by depositing certain photographic lenses of the value as he represented of 237*l.* by way of collateral security. In December, Copeland's business was changed to that of a company, called Copeland & Co., Limited, and now the defendant Company, the change having taken place since the action was brought. On December 15th an acceptance was signed by Copeland himself for 100*l.*, and on the 20th another one for 150*l.*, which he promised would be exchanged for one of the present Company's when it was formed. On the 6th January, 1887, the bill for 100*l.* became due, and then one Phillip Mordaunt appeared on the scene, he being one of the directors of the Company. He paid the plaintiffs the 100*l.* due; and a day or two afterwards Mordaunt said that if they would stay proceedings in both the action and the prosecution, and hand over to him the lenses and the dishonoured acceptances, they—the defendant Company—would give them a bill for 150*l.* and a cheque for 50*l.* for costs. On the 10th January the agreement was carried out so far as was possible then, viz., by Copeland & Co. backing J. M. Copeland's bill for 150*l.* and altering it into their acceptance by adding the word "fifty" and by Mordaunt and one of the directors signing it, when plaintiffs gave up the lenses and the dishonoured acceptance. Then on the 15th January, after the matter had been before Mr. Vaughan, the magistrate, on a good many occasions, and on the plaintiffs' manager telling the magistrate he had inquired into the whole matter, and it appeared that Copeland had not seen the acceptances when he swore that the signatures were not his and that it was clearly a mistake of memory as regards books and accounts, the magistrate allowed the proceedings to be withdrawn.

Mr. Crump, in reply to his lordship, said that he would admit all the facts with regard to the acceptances, but not as to the conversation which took place before the magistrate. The plea in the present action was one of illegal contract.

Mr. Plumptre, resuming, said that on the 16th February they were told by Mordaunt for the first time that the lenses were not of the value they represented, but they did not represent their value at all, simply mentioning the value that was put upon them by Mr. Copeland. Upon that ground the defendants said they would not pay the bills when they became due, also objecting that the proceedings in the police court were not stopped earlier. The action was then commenced, when the defendants set up the defence already mentioned, and also a further defence which he ventured to describe as a very shabby one, viz., that the bill having been altered in the way he had mentioned it was invalid under the statute.

Mr. Justice Denman: What was set up in defence before?

Mr. Plumptre: Want of consideration. Then in this action for the first time they set up the defence of illegality, having got the plaintiffs' lenses and their dishonoured acceptances. The whole question for the court to decide was whether there had been a compounding of a misdemeanour so as to preclude the plaintiffs from recovering.

Mr. Alfred Bull, managing director of the plaintiff Company, was then called, and gave evidence in confirmation of the facts stated by the learned counsel, adding, in the course of examination, that Copeland went to him while the criminal proceedings were pending and said that the reason he swore the bills were not in his handwriting was that he was under the impression, not having seen the bills, they were signed by a man of the name of Lofthouse. Lofthouse was assumed to be his partner, but in one of his affidavits he said that Lofthouse was not his partner, but Mrs. Lofthouse was, and witness had never yet found out whether Lofthouse was his partner or not. Copeland also told him that he thought he was quite justified, believing no such bills to be in existence, in swearing that he never accepted them. Witness told him that he had no vindictive feelings towards him, and if he could satisfy his solicitors as to his *bona-fides* he would take him on to them there and then. He did so; and Copeland, on the bills being shown to him, said, "I can assure you I had no knowledge that my name was on these bills in my own handwriting;" and he then said, "I will undertake to assure the magistrate, owing to the bad state in which the books were kept, that I am perfectly innocent of such a charge." Witness got his assurance to that effect, and the necessary arrangement was made.

Mr. Justice Denman.—You got his assurance to that effect of what?

The Witness.—That he would pay us the money that he owed us and clear himself at the police court. That really was the end of the arrangement. He mentioned that his present firm were starting a company and they would espouse the debt. The bills were to be 100*l.* at one month, 150*l.* at three months, and 50*l.* was the agreed amount of the costs, and he gave as collateral security eight or nine lenses which he valued at about 230*l.* The 100*l.* was met by Mordaunt (as described).

In cross-examination by Mr. Crump, the witness said his firm had done business with Mr. Copeland for about twelve months before they knew anything of defendant Company. Copeland had supplied plaintiffs with goods, so that they were his debtors. But it happened also that he became their debtor because they supplied him with money to start a shop in the City for the sale of photographic goods. They agreed to lend him between 150*l.* and 200*l.*, for which he gave bills, and it was these bills which he said the Company would take up when it was formed. There were four or five bills altogether, some of which were renewals. He admitted having told Mr. Mordaunt that the liability on one or two bills was for stock in the business the Company were taking over, and did not think it likely they would have undertaken the liability if it had been an accommodation bill simply for Mr. Copeland; and he told Mr.

Mordaunt that Copeland valued the lenses at 250*l.*, and that Mr. Hunt also corroborated that value. Witness could not say how any mistakes in bookkeeping, or any defect in bookkeeping, could induce a man to repudiate his signature to a bill of exchange, but the mistake arose from the fact that no proper record was kept.

Mr. Ernest L. Bennett, a director of the plaintiff Company, was also examined, and gave as an explanation of the forgetfulness of Copeland in regard to his signature that he heard and believed that Copeland was frequently under the influence of drugs or liquor, and scarcely knew what he was about.

Mr. Crump for the defence said he had a few remarks to make before he called his witnesses, whereupon a long argument took place between his lordship and the two learned counsel on the legal aspect of the case, after which Mr. Justice Denman delivered judgment, remarking that the court would not grant specific performance of a contract unless it saw very clearly indeed that it was a straightforward thing to enforce. It was stronger than if there was a bill of exchange given or anything of that sort. Even if it were an action on a bill given for that consideration it would be a bad consideration, and an illegal transaction. The defendants in the month of January, in consideration of the plaintiffs agreeing to withdraw with the consent of the magistrate from certain criminal proceedings against Copeland, and also on their delivering up certain dishonoured acceptances with certain other goods, agreed to give them a valid acceptance for 150*l.* The plaintiffs now asked for the specific enforcement of that agreement and the payment of that bill, which they said ought to have been given with interest. Now the only words in the statement of claim giving a colour to the argument were the words "with the consent of the magistrate." He thought the case which had been cited showed, upon the authority of Mr. Justice Stephen and Mr. Justice Cave, sitting in bankruptcy, that it would be a bad consideration, notwithstanding the consent of the magistrate, and he could not find that in any of the cases there was any distinction drawn between cases where the thing was launched before the magistrate, and cases where a magistrate had actually committed. The present case was one in which that very distinction existed, and the magistrate would be much more in the dark. After he had committed he knew generally the worst of the matter, but before he had committed, when the thing was before him, so that he might adjourn the case from time to time, there was a greater opportunity of the parties hoodwinking him, keeping him in the dark, so that he might find it impossible on his own authority to get at the real truth of the case. The case, therefore, was one in which the mischief would be greater than in the other case. It was enough to say that there was no such distinction in the law as was sought to be made out, and he must, therefore, entirely refuse to grant any specific preference; so the action must be dismissed with costs.

Our Editorial Table.

THE "PERFECT" PHOTOMETER.

THE London Stereoscopic and Photographic Company have just brought out a very pretty little instrument bearing the above name. It consists of a metal disc perforated with holes, which are covered by a translucent substance which exercises a power of stopping out the light more and more in succession, there being in all sixteen grades. The disc is rotated in a case which permits only one to be seen at a time. Its use will be perceived from the following extract from the instructions which accompany the instrument:—

"Having carefully focussed the picture, place the photometer against the ground-glass with the most transparent apertures over the half tones of the picture, viz., over such parts as are neither very strong in high lights nor in dense shadow; now carefully turn the centre button from left to right, keeping the eye about eighteen inches away from the aperture, when it will be found that the light admitted through the three small holes at the side of the larger one will become gradually less until they become *almost* undiscernible, but leaving the aperture still visible.

"When this is attained remove the instrument and ascertain the letter visible in the circular aperture at the back; the necessary exposure will at once be found opposite the corresponding letter on the table. For example, if the light transmitted be indicated by the letter O, the required exposure will be three minutes; if I be visible, six seconds. On the table given, the left-hand column represents seconds and tenths of a second; the right-hand column is given for minutes and parts of a minute."

GELATINO-CHLORIDE PLATES FOR CONTACT PRINTING.

By W. H. PRESTWICH, Warmington House, Tottenham.

MR. PRESTWICH having for some time been directing his attention to the preparation of opal plates capable of being printed out under a negative, has now brought his labours to a successful issue.

Some specimen plates received from him have printed very quickly

and given admirable gradation. The treatment throughout is the same as if albumenised paper were employed.

This will prove very useful to those photographers who would willingly produce opals were it not for the trouble and uncertainty encountered in their development, and the necessity of accurate timing of the exposure—drawbacks which are quite abrogated in these plates, in which the progress of the printing can be watched. The same system has been applied by Mr. Prestwich for producing clear glass plates for lantern or window transparencies.

Meetings of Societies.

" 15.....	London and Provincial	Mason's Hall, Basinghall-street.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday night, December 1, at a meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. William Bedford presided.

Mr. F. A. BRIDGE read a paper upon *Spots, Stains, and Fading* [see page 775].

Mr. J. HUBERT said that he used bronzed enamelled mounts exclusively and never had spots upon his prints except from his own carelessness. He bought these mounts from a German firm; he had bought some of English make which he could not use.

Mr. H. M. SMITH exhibited a spotted photograph on a mount which had such excess of bronze that some of the latter could be rubbed off by the hand.

Mr. J. J. BRIGHAM said that the spots spoken of by Mr. Smith looked like measles in the paper.

Mr. A. HADDON remarked that the most injurious element in bronze was sulphide of tin.

Mr. A. COWAN stated that there were varieties of bronze; one variety was said to be exclusively brass powder. He had mounted photographs on the printed side of some bronze mounts and no signs of fading had appeared in nine months. Recently some photographs so mounted which had not been dried quickly showed faintly the lettering of the bronze printing.

Mr. W. H. PRESTWICH always used bronze mounts bought at different places and had never known them to cause spots, perhaps because he dried his prints quickly in a drying box.

Mr. BRIDGE stated that spots on some of the prints he had sent round seemed to be due to something in the white enamel; he should like to know what that something was.

Mr. HADDON thought that some bronze powder was "Dutch metal," which consists of copper and tin and contains no sulphur.

The CHAIRMAN had been troubled by spots which appeared only in the winter months; they were caused by the making up of a coke fire while the prints were washing. He supposed sulphur in the coke dust to be the injurious agent. He had seen mounted prints which had been done up in packets and the bronze designs on the backs of some appeared on the faces of others.

Mr. J. TRAIL TAYLOR had put damp prints upon a table and given some taps to a gas burner above them; this brought down dust, which caused spots. Impurities in the washing waters sometimes caused spots and occasionally found their way there by being washed out of cheap white indiarubber tubing used to convey the water. Sometimes shaking a daily newspaper over prints would cause spots, perhaps from the "chlor" or "antichlor" present. He bought some bronze powder once, and on the mount, where the face of the sitter would afterwards come, he painted therewith a skull and crossbones; it was long before any development of the design took place upon the print, indeed he had to place the print in a damp place for some time to force it to come out. In this case he had applied the bronze powder suspended in gum containing acetic acid. Perhaps the acid had as much to do with the appearance of the design as the bronze, but anyhow bronze was a nasty thing in the establishment of any photographer. Mr. Mason, of Glasgow, had told him that all photographers who bought bronze mounts of his firm were apprised that they did so at their own risk. Spots innumerable made their appearance from various causes before mounting.

Mr. W. M. ASHMAN said that in course of time out of thirty thousand prints on bronze mounts twenty thousand had been brought back to him with the demand for fresh photographs. The spots were just like those exhibited by Mr. Bridge. Bronze should neither be used upon mounts nor for the ornamentation of albums. Some peculiar marks upon a panel print exhibited by Mr. Bridge he thought to be due to dust from indiarubber tubing.

Mr. BRIDGE never used the white tubing; he used the red.

Mr. HUBERT stated that one cause of spots was the keeping of prints together too long while they were in a damp state.

Mr. P. EVERITT remarked that blotting and other papers sometimes contained chloride of lime. Once he had placed damp prints in a photographic *Year-Book*, and a few days later, on opening it, he found them covered with white spots the size of a pea.

Mr. ASHMAN said that Saxe and five papers could be trusted to be free from such impurities. The paper of almanacs was not supposed to be chemically pure.

The CHAIRMAN pointed out that after prints were fixed in hypo there could not possibly be any chloride of lime in the paper.

The HON. SECRETARY had recently seen a batch of paper pulp which had been bleached by ozone only.

Mr. EVERITT considered red blotting paper to be better for the surface-drying of prints than white; the former was coloured by Turkey red, obtained as waste from the cotton mills.

Mr. BRIDGE pointed out that where a piece of brass had been kept in contact with part of the face of a print, the print had become discoloured.

Mr. HADDON was not sure that the print had not been protected by the brass, while the surrounding portions had somewhat faded.

Mr. J. H. ZAEHNDORFF said that both starch and paste soon went sour. Was fresh starch always used for mounting?

Mr. BRIDGE replied that it was the custom always to use fresh starch. Some mounts had a bad smell when they were received from the makers.

Mr. ZAEHNDORFF remarked that the mounts themselves might be made by means of sour paste.

Mr. HUBERT stated that when unmounted prints were kept long in a damp state on the top of each other they acquired a bad smell.

Mr. ZAEHNDORFF was aware that alum was always put into paste to make it keep, so that it was actually boiled sour before being used in the manufacture of mounts.

Mr. HADDON thought that the chemical composition of the silver salt in faded prints should be ascertained. Sulphur seemed to be the chief delinquent in causing the fading. The dust falling from gas burners contained sulphur, so also did the dust found everywhere in the atmospheres of towns. The coal fires of London discharged tons of sulphuric acid into the air every day.

Mr. W. COBB knew insufficient fixing to be a fertile source of fading.

Mr. A. MACKIE said that it was remarkable that the gold of prints seemed to bleach as much as did the silver.

Mr. W. M. AYRES thought that albumen should never be more than two days old before it was used for preparing the paper; he was convinced of this from experiments which he had tried. Paper prepared with albumen fourteen days old gave innumerable spots, and speedily turned yellow.

Mr. COBB remarked that Mr. Valentine Blanchard had once astonished a photographic society by bringing forward his experience that stinking albumen yielded best prints.

Mr. TAYLOR said that salters of paper preferred for use albumen which had been kept a few days.

Mr. COBB stated that perhaps hypo was not such an enemy to the permanency of prints as commonly supposed. The late Mr. Pearsall tried to make a print fade by putting it into hypo, and afterwards keeping it without washing; two years later that print was in as good condition as any of the others in the album.

Mr. COWAN remarked that Mr. Pearsall took the print direct from the hypo bath, and mounted it straight away.

Mr. MACKIE believed that Mr. Bolton had tried the same experiment.

Mr. BRIDGE said that others had had the same experience.

The HON. SECRETARY stated that his first negatives were simply rinsed under a tap, because he then knew no better, and some of them were at present better than any he had taken since.

Mr. EDGAR CLIFTON had known similar cases.

Mr. BRIDGE had known bromide enlargements to keep well for years after being simply rinsed when taken out of the hypo.

Mr. COBB, from what had just been stated, began to suppose that hypo in the film was really a preservative.

Mr. CLIFTON thought that if the prints were only left long enough in a sufficiently strong fixing solution, there was not much to fear if hypo were left in them afterwards.

Mr. ASHMAN said that Mr. Dunmore had long publicly argued that hypo was harmless when left in prints.

Mr. MACKIE thought it likely that hyposulphite of silver, rather than hyposulphite of soda, in the film, was the cause of fading. As he understood the matter, when the prints were put in the hypo, hyposulphite of silver, a salt insoluble in water, was first formed; this then began to dissolve in the excess of hypo present, forming therewith a double salt, soluble in water; consequently, if the fixing bath were not strong enough, or the prints not kept in it long enough, hyposulphite of silver might be left in them, instead of being wholly transformed into double salt removable by the washing waters.

Mr. COBB thought, after the revelations of that evening, that the Association ought to boycott every photographer who used bronze powder.

Mr. CLIFTON possessed one of the cheapest, commonest, German bronze printed albums, but it had not injured the prints contained therein.

Mr. HUBERT stated that the makers could not get rid of those albums in Germany, so sent them over here.

A question in the box asked what were the qualities of dry plates prepared with a maximum of bromide of silver and a minimum of gelatine.

Mr. ASHMAN replied that they would have a matt surface.

Mr. COWAN said that they would give clean shadows.

Mr. HUBERT thought that they would be deficient in half tone.

Mr. ASHMAN added that they developed more quickly and gave a nice negative quicker than if they contained a larger proportion of gelatine. Mr. Starnes had tried the opposite extremes of the minimum of bromide of silver and the maximum of gelatine; in fact, he sometimes used only a quarter of a grain of bromide of silver to each quarter-plate, but then he required from twenty to thirty minutes to develop a picture, so the plates would not do for professional photographers.

Mr. J. B. B. WELLINGTON stated that the less the proportion of gelatine in the emulsion the more opaque was the image. He had sometimes found plates rich in gelatine to develop and fix quicker than those with less gelatine.

Mr. ALLEN exhibited and called attention to Wolff's patent adhesive mounts.

Mr. TAYLOR stated that in about the year 1876 he was called upon by Mr. Edwards, a patent agent living in Southampton-buildings, Chancery-lane, who showed him a specification for making mounts of exactly the same description as Wolff's, and at the request of the agent he went to a "swearist" and swore

[Oh!] that the thing was likely to be useful. However, the wise people at the Patent Office would not grant provisional protection to the invention, which they looked upon as one quite beneath their dignity to notice. Quite recently, nevertheless, they had granted a patent for this very identical thing which they had previously rejected.

Mr. MACKIE said that somebody had written to a journal to prove that the mounts before them were cheaper than those of ordinary make, but the letter itself conclusively proved that they were dearer.

Mr. H. M. HASTINGS exhibited negatives and prints of gas and candle flames, photographed instantaneously by means of the flash produced by igniting magnesium powder and gun cotton. The gas fittings, candlesticks, and candle smoke, also appeared in the pictures. The exposures, he said, were too short to give good images of the flames without the magnesium flash, some of the light from which was therefore evidently reflected by the flames.

Mr. TAYLOR, replying to a question, said that a little lump of camphor in gum would make the latter keep at least fourteen months without getting mouldy.

Mr. BRIDGE said that it was a curious thing that camphor in the silver sensitising solution in some cases prevented the blistering of prints.

Mr. SMITH asked the value as a mount of the "gloy" used by box-makers. Mr. CLIFTON had known prints to change when mounted with gloy.

Mr. ZAEHNDORFF remarked that gloy was made from Irish seaweed; there were two varieties of it—the one neutral and the other acid. He did not think that they would be good for mounting purposes.

Mr. ASHMAN stated that camphor would make a weak solution of albumen, containing a trace of ammonia, keep well for more than a year. He thought that camphor could be more utilised by photographers than it is at present.

Mr. L. MEDLAND said that Mr. Ingall dissolved some commercial stuff in the oil of the optical lantern, and it was a great preventative of smell and smoke. The stuff smelt as if it contained camphor.

Mr. BRIDGE remarked that in the days of sperm oil lamps in optical lanterns, camphor was usually dissolved in the oil to increase the light.

Mr. Hubert exhibited a photograph taken by a flash of light produced by gun cotton and powdered magnesium.

Mr. TAYLOR said that in 1865 he exhibited to the South London Photographic Society pictures taken by a flashing magnesium light; the mixture contained sulphide of antimony, chlorate of potash, and powdered magnesium. The flash was so quick that the sitter was taken before he had time to blink or start. He had a portrait of himself, taken at that time and in that way, so the plan was not quite so new as some of their German friends seemed to think.

Mr. Cowan exhibited a strongly marked example of a positive image left upon a plate, after dissolving off a negative image with hot water.

Mr. F. B. Cembrano exhibited some platinotype prints of landscapes.

Mr. ASHMAN called attention to Mr. H. J. Burton's actinometer, as used by the Autotype Company, consisting of a row of small portrait negatives of the same density, covered with an increasingly dense screen, both placed upon a piece of standardised sensitive silver paper, which printed at the same rate as the carbon tissue in use. The large negative to be printed was compared with that of one of the little ones which seemed to be of the same density as itself; consequently when the little one gave a good silver print of itself, the large one had been exposed the proper time over the tissue. On the tissue there was, of course, no visible image, hence the utility of the little silver print.

The HON. SECRETARY announced that next Thursday evening, December 15, Mr. W. H. Harrison will read a paper before the Association on *Lanterns and Lantern Slides in the Nineteenth Century*, and that on the following Thursday Mr. Norman Macbeth will read a memoir upon *Art as Applied to Portraiture*.

CAMERA CLUB.

On Thursday, December 1, Mr. T. C. HEPPWORTH delivered a popular address to the members on *The Application of Photography to the Arts and Sciences*. Mr. H. Trueman Wood occupied the chair.

The lecture was fully illustrated by means of the optical lantern. Mr. Heppworth described several of the processes used in photography, and showed transparencies to illustrate the characteristics of different methods. Slides showing the uses of photography in microscopic and telescopic work and illustrating spectrum analysis were also put through the lantern in connexion with the course of the lecturer's remarks.

A discussion and conversation followed, in which the Chairman, and Messrs. Lyonel Clark, Rodgers, Davison, Ferrero, and Spiers, took part, and the proceedings were brought to a close by a reply from Mr. Heppworth.

On Thursday, December 15, the two hundred English lantern slides intended for the American exchange of this year will be exhibited. Meeting at eight p.m.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

The Committee of this Association met on the 1st instant.

After the minutes of the previous meeting had been confirmed, the Committee proceeded to discuss the best means of attaining the fulfilment of the stipulated conditions of the Special Orphanage Fund, viz., to raise the sum of 500*l.* within one year, the originator having given twenty guineas to start the fund. It was thought that this sum could be raised amongst photographers, and a sub-committee was appointed to draft a prospectus for issue to all connected with the profession.

The following sums were also promised:—The Chairman (Mr. W. M. Ashman), 10*l.* 10*s.*; Mr. W. Bedford, 5*l.*; Mr. J. Zaehnsdorf, 2*l.* 2*s.*; and through a member of the Committee, 12*l.* Mr. BEDFORD also stated he believed he could bring another donation of 10*l.*

Mr. C. Darker, of Forest Hill, was elected a member of the Association.

Mr. T. S. Hicks was appointed Local Secretary for the Sheffield district.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The annual meeting was held on Thursday, the 24th ultimo, at the Royal Institution, Colquitt-street.—The President, Mr. George H. Rutter, in the chair.

The minutes of the last meeting were read and confirmed.

Messrs. W. C. Bustard and T. O. Forshaw were unanimously elected members of the Association.

Mr. T. S. MAYNE, Hon. Secretary of the Exhibition Sub-Committee, gave some particulars of the arrangements, and distributed prospectuses which had been prepared for circulation.

The HON. SECRETARY called attention to the competitions instituted by Messrs. Fry & Co. for lantern slides and argentic bromide paper, and distributed some entry forms that had been forwarded to him. He also exhibited negatives and prints therefrom of a coloured diagram, taken on an Edwards's orthochromatic plate, with an exposure of ten minutes to gaslight in a room lighted with three ordinary burners.

The President exhibited Marion's developing box, filled with "ten per cent." solutions.

The HON. SECRETARY had to apologise for the non-exhibition of the competition prints which had been announced, as a good deal of disappointment was felt at the failure of this part of the programme. Mr. B. J. Sayce kindly agreed to allow them to remain on exhibition at his office, 11, Redcross-street, for a week from November 28.

The HON. SECRETARY read his annual report, from which we make the following abstract:—

During the year nineteen new members have been added and thirteen have retired or lapsed, bringing the total number to one hundred and forty-six, a growth which is satisfactory, though not apparently so large as in some previous years, when it is remembered that it represents an actual addition of the working strength of the Association of more than a dozen members. The numbers on the books for the five years are:—1883, one hundred and fifteen; 1884, one hundred and thirty-eight; 1885, one hundred and thirty-four; 1886, one hundred and forty; 1887, one hundred and forty-six.

As regards the work of the Association, the meetings have kept up their interest, though without any special novelties or striking discoveries to record. Papers have been read on *A Holiday in the North Riding*, by Mr. A. W. Beer; *Odds-and-Ends*, by Mr. George H. Rutter; *Orthochromatic Photography*, by Mr. W. A. Watts; *The Objects of Antiquarian and Photographic Interest in the Hundred of Wirral*, by Mr. John Hargreaves, F.R.H.S.; *Five Dry-plate Processes from 1861 to 1885*, by Mr. B. J. Sayce; *Notes of a Visit to the Autotype Works*, by Mr. W. A. Watts; *Slow Development*, by Mr. A. W. Beer; *A Holiday among the Turks*, by Mr. W. B. Irvine; and *Picturesque Italy*, by Mr. G. E. Thompson. Also a demonstration of the Eastman stripping films has been given by Dr. Kenyon, and discussions have been held on *Defective Cameras*, *Paper Films versus Glass*, and *Slow Development*.

In addition to the papers and discussions, interesting exhibits of work and apparatus have been made by many members.

It is much to be desired that members having anything to exhibit would hand it to either the Exhibits Sub-Committee or the Hon. Secretary, with particulars they may wish mentioning, as thereby a wider circle of interest is secured and the Hon. Secretary is enabled to keep a more accurate record of the proceedings.

At the March meeting the Annual Lantern Slide Competition was held, at which there were five competitors, who had sent in three slides each. It had been decided by the Committee that the prizes at this and, if possible, all future competitions should consist of medals, and accordingly the silver medal was awarded by the Judges, Messrs. Atkins, Boothroyd, and Sayce, to Mr. A. W. Cornish.

The Annual Competition was held as usual, the Judges being Messrs. Boadle, Boothroyd, and Thompson. The prints were sent in at the October meeting, and the Judges gave their decision in writing during the ensuing week. Eleven competitions were sent in, and the result of the competition was that the prizes for "Street view" and "Architectural" were awarded to Mr. A. W. Beer; those for "Bridge" and the "Best picture taken at an excursion" to Mr. J. H. Day; that for "Marine" to Mr. T. B. Sutton; and for "Instantaneous" to Mr. David Lewis.

As it had been felt for some time past that the nature of the prizes given required revision, neither money prizes nor prints appearing quite satisfactory, the Council have had under their consideration for nearly the whole year the advisability of substituting medals for any other form of prize, thus assimilating the practice of this Association to that of the more important Photographic Societies elsewhere; accordingly the nature of the prizes was not announced at the beginning of the year, but the question was left open for future decision. At the Lantern Slide Competition in March, a silver medal was awarded, but this was not the Association's own medal, hence this form was unsuitable for permanent adoption, and it was found impracticable to adopt any permanent form of prize until the Association had its own medal.

After much discussion a design has been selected, and the die is in progress of execution, and as this decision was come to before the prints in the Annual Competition were actually received, the Council decided to give the medal to those prize-winners who preferred to receive it. The gentlemen named above are therefore entitled each to a bronze medal. The Council believe that the substitution of medals for prizes of a more ephemeral nature will prove highly satisfactory to the competitors themselves, and that it will lead to a more general interest being taken in the Prize Competition, and to a larger number of members striving to secure so honourable a reward for their work.

For the competition of 1883 the Council recommend certain alterations in the by-laws: first, to revert to the old method of sending in, viz., on the evening of the annual meeting, the award to be made same evening; second, to require competitors, except for the enlargement, to send in a series of six pictures, no special subjects being announced for each class; third, to award a silver and bronze medal for the best and second best series of size "half-plate and under," and over half-plate respectively; also a medal for best enlargement, and silver and bronze medal for the best and second best set of six lantern slides; fourth, only winning exhibits to become the property of the Association, but competitors to give an unmounted print of each subject in exchange for their mounted exhibits.

The Council selected two negatives, viz., *A Cheshire Lane* (by Mr. Boor) and *Doorway at Tabley Hall* (by Mr. Day), for reproduction as presentation prints for last year. They were accordingly executed in carbon as 15×12 enlargements, and copies have been presented to all members who have paid their subscriptions for 1886.

For this year a suitable presentation print or prints will be selected and distributed among the members elected prior to October, 1887.

It was not thought desirable this year to take the usual part in the associated *soirée*, mainly on the ground that with the large variety of interesting objects there exhibited photographic objects scarcely seemed to secure their due share of attention; and it has been decided that the Association shall have its own *soirée* and exhibition of photographs, in hopes that thereby the general public may be enabled to have a better idea of the progress photography is making.

The HON. TREASURER next read his report and balance sheet, which were highly favourable.

Both reports were unanimously adopted.

The election of officers was then proceeded with, the following being duly elected:—*President*: Mr. B. J. Sayce.—*Vice-Presidents*: Messrs. F. T. Paul, F.R.C.S., and H. N. Atkins.—*Treasurer*: Mr. Joseph Earp.—*Librarian*: Mr. Walter Hughes.—*Auditor*: Mr. W. H. Kirkby.—*Hon. Secretary*: Mr. W. A. Watts, Farnworth, Widnes.—*Council*: Messrs. P. Lange, H. Lupton, W. P. Riley, and G. H. Rutter to replace the four retiring members.

The PRESIDENT then stated that the Council recommended certain alterations in the rules for the annual competition, as stated in the report. These were carried unanimously, with the alteration that in the class for enlargements there should be a silver and a bronze medal for best and second best series of two.

Mr. E. TWIGGE exhibited a series of lantern slides mounted as transparencies, developed by various processes, as an illustration of the nature of the slides desired by the Recreative Evening Schools Association, of which Miss F. Calder is Hon. Secretary. He recommended their undertaking to the attention of the members, and pointed out how they could assist them by undertaking to make some lantern slides illustrating the fifty years of the reign of Queen Victoria.

BOLTON PHOTOGRAPHIC SOCIETY.

ORDINARY monthly meeting held at the Baths, Bridgman-street, December 1, 1887.—Mr. E. N. Ashworth in the chair.

After the minutes of last meeting had been read and confirmed, the Secretary laid before each member circulars from the Liverpool and Hyde Societies referring to their various exhibitions.

Mr. JANIZ BOOTHROYD then gave a lecture on *Photographing in Colours: is it Possible?* in which he took the negative.

After the lecture there was a discussion, to which Mr. Boothroyd replied.

Mr. C. K. DALTON proposed a vote of thanks to Mr. Boothroyd, and hoped that other members would volunteer to give papers or demonstrations. Mr. ASHWORTH seconded the vote, which was accorded unanimously, and Mr. Boothroyd replied.

Mr. Johnston, M.D., exhibited a series of views from various countries, which were examined with interest and much admired.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE first popular meeting of members and friends was held in the Large Hall of the Philosophical Society's Rooms on November 10.

Mr. LANG, JUN., F.C.S., occupied the chair, and introduced Mr. T. N. ARMSTRONG, who delivered a lecture entitled *A Trip to Brighton*, which was illustrated by a series of limelight views, and proved very interesting, the audience showing their appreciation by frequent and hearty applause.

A short poem, illustrated with slides, was read, with much acceptance, by Mr. ARMSTRONG, the meeting all through being of a very agreeable nature. The audience, too, was one of the largest that has yet assembled at any of these popular meetings, which are proving very popular indeed among our members and their friends.

At the close of the lecture a vote of thanks, proposed by the CHAIRMAN, was heartily given to Mr. Armstrong for his pleasant and agreeable lecture.

THE usual monthly meeting of the Association was held in the Philosophical Society's Rooms, 207, Bath-street, on Thursday, December 1. Mr. William Lang, jun., F.C.S. (President), occupied the chair.

The business of the evening being of great interest, a very large audience was present.

After the routine business had been disposed of, Messrs. R. Rae (67, Bothwell-street), W. H. Turner (Gourock), and Ex-Bailie Crawford (Mitter-street), were unanimously admitted members of the Association.

The CHAIRMAN then called upon Mr. T. N. ARMSTRONG to read his paper on *Photographing by the Flashing Magnesium Light* [see page 777].

The above paper proved exceedingly interesting, and showed that Mr. Armstrong had been at great pains in perfecting this latest mode of artificial lighting.

An extemporised studio having been fitted up in the rooms, a demonstration followed, when Mr. Mason and Mr. Sloan sat for their portraits, and when the negatives obtained were developed they showed clearly that the light thus arranged and adapted was all that could be desired for the purpose.

After the demonstration of the light, the negatives, which were taken on Eastman's films, were developed, as has been said, and the method of stripping, fixing on extra support, &c., was shown by Mr. Armstrong; and thereafter the Chairman called upon the members to ask any questions or to make any remarks they wished on the paper and processes brought before them.

Mr. URE said that he was sure that he spoke the feeling of the Association when he said that Mr. Armstrong had conferred a benefit upon the Association in bringing the results of his experiments before them. Of the many lights he had tried he had not in all his experience seen one which was likely to prove so successful or so easy of adaptation as the one shown to-night. He was sure that it would entirely supersede all others now in use. The films also, he thought, were likely to come more and more to the front, removing as they did the unwieldy glass plate, and doing away with the weight of the glass, which was a thing greatly to be desired, as the weight of a photographer's negative caused great inconvenience. Altogether both demonstrations had proved very successful, and he was sure many would be induced to make a trial of the light after the splendid results which had just been obtained.

Mr. STEWART said that Mr. Armstrong's demonstration had proved the great advantage such a light must be to those engaged during the day, and who had no time except at night to devote to photography with the simple expedients seen to-night, which were easily procurable in every house. Amateurs were placed in a position to take advantage of the only time at their disposal. He however, disagreed with Mr. Armstrong regarding the loss of the powder in blowing it through an ordinary gas jet; from the experiments he had made himself he found a considerable quantity was blown through without igniting, and was thus wasted. He would recommend instead that a large Bunsen burner be employed, and that a long thin tube be used (in which fifteen grains of the powder had been placed—that being about the quantity necessary) to blow it into the flame, thus securing an equal light every time along with more perfect combustion.

Mr. ARMSTRONG, in reply to Mr. Stewart, said that while experimenting he had tried the Bunsen burner, but dispensed with it, as he thought a greater amount was blown through without ignition than in the ordinary gas jet. He found also that the Bunsen burner was exceedingly difficult to fix without

casting a shadow, while a light gas jet could be readily placed in any position and no shadow was cast from it. Regarding the tube, with a measured quantity of powder, he thought it a very good idea, but thought the wash bottle could be adapted with a bulb to blow just a certain quantity every time and thus save the difficulty of measuring for every discharge.

Mr. G. BELL suggested that the magnesium might be burned in a lamp with a chimney to carry away the fumes, as they were anything but pleasant, and he was sure would—if a number of photographs were done at the same time—soon fill the room or studio with smoke, and put a stop to any further photographing.

A number of other members spoke corroborating what had already been said, and thereafter a hearty vote of thanks was accorded Mr. Armstrong for the trouble he had been at, and for the exceptionally interesting nature of the subject which he had treated so admirably.

The CHAIRMAN (Mr. Robertson) then called upon the PRESIDENT to read his paper on *Removing Gelatine Films from their Glass Support, and Conversion of an Ordinary Negative into a Film Negative* [see page 776].

The paper, which is intended to stimulate experimenters to try, if possible, to remove the film in such a manner as the glass may be itself uninjured, while the film is removed without injury, so that it may be preserved and printed from. Mr. Lang passed round some he had stripped in the manner described in his paper. These showed that there was something in his suggestions which might easily be developed were someone to experiment in this direction.

After the reading of the paper, Mr. Lang showed the removal of the film from its glass support; but, as the hour was now late, he did not succeed in time in adjusting it to the Eastman film (which he uses as a support instead of the glass) to show the final result to the meeting.

After a few members had spoken regarding the great advantage of an easy and simple process such as Mr. Lang aimed at in his paper, a vote of thanks was accorded Mr. Lang, and thereafter the meeting separated.

Correspondence.

DECEMBER MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.—INSTANTANEOUS PROOFS.—A DODGE TO REPLACE LARGE PRINTING FRAMES.—AN INSTANTANEOUS SHUTTER.—A COLOURED GELATINE FOR LANTERNS, &c.

THE Photographic Society of France held their monthly meeting on Friday evening last, the 2nd instant, M. Davanne in the chair.

Some very fine instantaneous proofs were exhibited by M. Roger. Views of a farmyard, with ducks, geese, cocks, hens, and other poultry, were shown. These gave great satisfaction, and the author was complimented by the members, who knew the difficulties to be overcome in photographing a number of hens while picking up their food, especially when their images are photographed to a certain size. In those sent round the image of a hen covered the space of about an inch square.

An idea was suggested that in order to economise the expense of purchasing printing frames for very large operations, such as maps, plans, and very large photographic proofs, the printing frame and its heavy glass could be replaced by a light wooden cylinder; the paper, whether albumenised, platinised, or ferro-prussiate, is stretched on the cylinder by means of drawing-pins, and the paper or film negative is laid upon it. The apparatus is then set out in open day and kept turning, so that every part shall be equally exposed to light. "This rotary motion I obtain," said the proposer of the system, "by means of a clockwork apparatus, as used for roasting joints of meat."

M. Conti exhibited an instantaneous shutter, which opened and closed in the centre, slit fashion. Long and short exposures can be obtained. So many shutters are now in the market that it is impossible to describe every new one. It was said before the Society that a gentleman (I think Eder) had taken the trouble to count, and he had found that three thousand had been presented to different societies. I imagine myself that he is below the mark.

M. Nadar exhibited McKellen's camera, a new detective camera made after his own designs, and some proofs on Eastman's paper, which were toned in different shades, from the photographic colour to the sepia tint.

M. Marguerie exhibited a metallic tissue covered with gelatine-tinted red for dark-room illumination. This system is to be preferred to the simple gelatine sheet, as it cannot be cracked or broken. It will bear bending to any shape, and is useful to make cylinders for lanterns. (I send a piece, which can be seen at the editorial office of this JOURNAL.)

59, Rue des Batignolles, Paris.

PROF. E. STEBBING.

FOREIGN CORRESPONDENCE.

To the Editors.

GENTLEMEN,—Thinking the enclosed extract might be of interest to some of your readers, I have ventured to send it to you:—

"RELIGION AND PHOTOGRAPHY.—A writer in the Melbourne *Weekly Times* gives the following:—One would scarcely expect to find much religion in connexion with photography. The other day, however, I was talking to a man whom I once knew to be a very pronounced Atheist. To my surprise I now found him a sincere and reverent believer in the existence of an omnipotent God. His conversion had not been the result of argument, but was due solely to photography.

"Some couple of years ago," he told me, "I took to the pursuit of photography for amusement. The fascination which it appears to have for all who dabble in it took a strong hold upon me. Whenever I could get a spare hour I was out in the fields or along the river banks pointing my lens at the various

pictures which nature scatters all round us, if we have but the eyes to see them. I used to take my pictures home, and night after night in my lonely lodgings I would spend hours gazing at them. It was at first merely the pleasure of a gratified sense, but after the pleasure came thought. As I gazed at the miniatures, in which every leaf of the tree, every shell upon the shore, had struck its faithful image on the tiny plate, I became lost in wonder at the powers of science and at the skill of man to put those powers in motion. This led me on. Man put the power of light and chemistry in motion; who put the man in motion? This could only admit of one answer—a Higher Power. The rays that were striking the pictures upon my sensitive plates had brought the light to me. I was an Atheist no longer; and I believe that any man who reads the Book of Nature as illustrated by that most faithful of all artists, Photography, must believe thoroughly in the existence of a Supreme Being. Man can make the light act as his artist, but there must be some First Source who has said "Let there be light" for him."

The phase of our art-science here referred to is one which I have not seen noticed before; but if it should, in any instance, lead to the happy result described, then I think its followers have another reason for feeling interested in its pursuit, as well as for being proud and grateful to think that so fascinating an art may have so elevating and refining an effect upon its students: but such a result could only have occurred to a thoughtful, reasoning mind, of which there are, undoubtedly, many in the brotherhood.

While writing, I cannot refrain from referring to a subject which has always been of deep interest to me, and, I am sure, to others also. I mean the mode of working adopted by the late Mr. Breeze in producing the wonderful transparencies which were so frequently referred to a few years since.

A neighbour of mine here states that in the summer of 1873 or 1874 he was staying at Matlock. Mr. Breeze being there at the time; he showed my friend (who was about nineteen or twenty years of age at the time) a very large collection of transparencies, some of them being of most exquisite beauty, and many being instantaneous, as, for instance, seascapes, with the waves standing up, the crests sparkling and in the very act of breaking, looking as if arrested and suddenly transformed into ice or glass! Scenes having the moon showing its reflection upon the ripples of water! One very wonderful picture—which Mr. Breeze said had been exhibited in Paris, and puzzled all the artists (photographers) there—was a landscape showing a beautiful valley, over which hovered the form of an angel, producing a very startling effect. Mr. Breeze used to wait ready at the window of a cottage there and take instantaneous shots at a passing train; he used also to go out with the camera on bright moonlight nights to take views about the vicinity of Matlock. My friend says he has seen these pictures, but, not being a photographer, he had no idea how they were done. He knows that the train was taken sharply by an instantaneous exposure, for he has seen him flashing a black velvet screen from before the camera at the window. While Mr. Breeze persisted in affirming that he had discovered a means of taking these moonlight pictures, at the same time he said he never would divulge the secret, which he had worked out himself, and which others would have to do if they desired the knowledge. Upon one occasion he read a letter from some lady of eminence (an authoress, or a lady of title, he thinks) in which a very urgent appeal was made to Mr. Breeze not to let the secret die with him; but the arguments and entreaties were used in vain—Mr. Breeze was obdurate and would divulge nothing. He seemed to have been annoyed and made stubborn, to some extent, by persons who never succeeded in doing it saying they knew how these pictures were made; and by others affirming that they were not what they professed to be. Anyway, he seems to have worked much in the spirit of the ancient alchemists when seeking the means of transmuting metals.

Of course, never having had the luck to be able to see the dear old country (although a dream of my life), I have never seen one of these wonderful productions of Mr. Breeze, and all I know of them is from what I have read in your pages; but, from what my friend tells me, he had a very large number of them—some boxes full—and possibly these are in existence yet, or some of them; if they are, might it not be possible, in the light of the discoveries of the last eight or ten years, to find out something of the way in which these very beautiful pictures were made, by a critical examination of some of them, if they could be got at (and authenticated)? I don't know anything more beautiful in photography than these same transparencies.

I recently had a very peculiar experience, which is, perhaps, worth relating. I had used an enamelled baking (or pie) dish for fixing a few plates in, and had left the old hyposulphate of soda solution standing in it for some weeks; finally, I threw it out, and filling the dish with clean water I threw some old plates in it to soak, leaving it standing in this condition for some considerable time longer. The hyposulphite had stained the bottom of the dish almost black, but I thought this would give way to rubbing, perhaps, with soda, or whiting, or wood ashes; but I was much surprised to find my efforts almost without any effect, the enamel seemed to be permanently blackened as far up as the hypo had reached; finally, I poured in a few drops of hydrochloric acid, running it over the stained parts for a few minutes; this quickly removed most of the stain, but not all, and it left the bottom of the dish of a faint yellow tinge instead of white. However, I washed it out with clean water copiously, and, filling it, put two or three small prints in it to wash; after running the water off a few times, I left it full, with the

prints in it, standing out in the light. In the morning I was surprised to find the dish again almost as black as ever, with distinct marks of where the prints had laid upon the bottom, lighter in the colour than the rest. I emptied it and refilled it several times; finally, I left it full of water, thinking the stain permanent, but after the lapse of a few weeks I find almost all the black colour gone, but with it the glassy surface of the enamel, which now presents the appearance and feel of a piece of sandstone, while from the line of the stain up to the margin of the dish it is smooth and white, having a perfectly vitreous surface.

The question I should like to solve is, What dissolved or disintegrated the surface of the enamel? Evidently some enamels are not safe for photographic use.—I am, yours, &c.,

ALEX. J. SIMPSON.

Lismore, N. S. Wales, Australia, Oct. 22, 1887.

PHOSPHORESCENCE IN THE DARK ROOM.

To the Editors.

GENTLEMEN,—I have read with interest your article on *Phosphorescence in the Dark Room* in your impression of the 18th ult., and should be glad if you would explain the following case of phosphorescence which your article does not appear to include. I almost invariably observe a vivid flash of phosphorescence when putting the developed and rinsed plate into the alum bath (saturated solution, no acid or other chemical) before fixing. This flash never takes place when ammonia is used in the developer. The developer used is that of Eastman (for paper negatives) with a small quantity of bromide, and the Platinotype Company's sulphopyrogallol.

I have tried to produce the phosphorescence with the above developer in the way you described (without the dry plate), but have not met with success.—Awaiting your elucidation, I am, yours, &c.,

C. E. HODGKIN.

[The natural acidity of the alum solution in our correspondent's case no doubt affords the necessary stimulus, the remaining and really active agents being the same as in the experiments quoted by us. Soda appears to have a stronger effect than ammonia, which possibly requires the presence of a larger proportion of bromide to produce the result. With regard to the want of success in repeating our experiment, perhaps here, also, our correspondent fails from want of sufficient bromide, which, as we pointed out, is the chief essential.—Eds.]

THE PHOTOGRAPHIC SOCIETY.

To the Editors.

GENTLEMEN,—I observe Tuesday, the 13th, is fixed for the meeting to finally approve the new laws of the Photographic Society of Great Britain. In the copy of the proposed laws which has reached me I note specially No 13, on "Photographic Exhibitions." I find the words, "That if the necessity arises for awards, the election of judges be in the hands of the body of members." This is well as far as it reaches, but unless I have entirely misunderstood the wishes of those members with whom I have come in contact, something far beyond this is wished by most. This is the moment, in my opinion, to carry out the long-desired plan of putting an end, once and for all, to the great complaints of unfair awards, by allowing the body of members of the Society to themselves adjudge the medals, which I propose to effect in this simple manner:—

Let due notice be given of the day and hour when the hanging is to be completed, and at that time let all members who are inclined, and whose subscriptions are paid, attend, and being furnished with a paper by the Assistant Secretary, and all other persons being excluded, let them then and there examine the pictures, and write on the paper the numbers and names which in their opinion are entitled to medals. These papers being signed, shall then be handed in to the Assistant Secretary, and a committee of five of those members then present being appointed then and there shall at once examine these papers, and from them award the medals to those having the highest number of votes.

I propose, if the state of my health permit, to attend the meeting, and to offer a resolution embodying the above proposal, which I fully believe would put an end to complaints of unfairness in distribution of medals. I respectfully invite members to attend in full force, and, if agreeable to them, to support me on the occasion.—I am, yours, &c.,

SAMUEL FRY.

Sherington House, Grove-crescent, Kingston-on-Thames, Dec. 5, 1887.

THE LIVERPOOL EXHIBITION.

To the Editors.

GENTLEMEN,—Is not your correspondent, "A Medallist," a trifle severe on the Liverpool authorities, who ought rather to receive a word of praise for their courage in venturing a departure from the well-worn rut in which the chariot of fame has for photographers jolted hitherto so painfully along.

It is not the medallist in person who has been boycotted, and your correspondent usually speaks in such pleasant fashion, and with such grace of diction, that it is a positive joke to catch him tripping. Liverpool desires to see some new work, not the same old clothes and the same old hats which have done good service in the south furnished up afresh for the northern metropolis. Granted some of its old ideas have been exceedingly fine, large as well, if the concession will salve a

wounded spirit, but surely it is not an impossibility to endeavour to excel past merit, late though the hour may be. There is plenty of weather before us, and plenty of subject, to warrant an attempt if not at beating the record at least of running it closely.

Instead of sitting down in doleful dumps let medallists and non-medallists do their level best to make the Liverpool show not a home for the destitute or mediocrity's millennium, but a survival of the fittest photographers.—I am, yours, &c.,
SCRIMDLER.

Harrogate, December 5, 1887.

To the Editors.

GENTLEMEN,—It has always been my idea that the first consideration in a provincial exhibition was to attract the best work that had been done during the preceding year, the second to get together sufficient padding to make up an exhibition. The committee of the Liverpool Association seem to be reversing this order, and offer prizes to the padding, and the cold shoulder to the best work. It has not perhaps occurred to them, as pointed out by "A Medallist" in your last, that they have done their level best to deprive themselves of the best work of the masters of the art in their coming exhibition. Is it too late to correct this stultifying error?—I am, yours, &c.,
E. R.

Aigburth, December 6, 1887.

Answers to Correspondents.

J. C. BROWNE and numerous correspondents next week.

R. H. BLYTH.—The front may be employed as a landscape lens.

B. C.—The difficulty arises from the tissue being insoluble, probably from long keeping.

R. W. S.—Follow the instructions given in the article implicitly, then, if you require any further information, write again.

F. A. C.—Transparencies are frequently made by immersing the paper in silver and printing with either side next to the negative.

A. R. CORDON inquires the difference between the orthographic and the orthoscopic lenses.—They are the same lenses under different names, with perhaps a trifling modification by the different makers.

W. W.—The cameras and lenses named are quite as good as can reasonably be expected for the money charged for them; but, of course, they will not compare with instruments of the more expensive class.

PROVINCIAL.—If you can prove that the enlargement was injured by a projecting nail in the packing case, the firm who sent it thus carelessly packed should certainly replace it. We do not at all see how the railway company can be made responsible.

SCOT.—We cannot tell where you can procure sheet gelatine from the sixteenth to the eighth of an inch in thickness. We surmise you will have to make it for yourself. Perhaps, however, those who manufacture the thin sheets will make the thick to your order. Try.

E. J. A. inquires: "1. Does registering a photograph make it copyright?—2. Must I have copyright printed on every copy that is sold?—3. If not, can any one copy it?"—1. No, unless you possess the right to do so.—2. No.—3. If copyright it can only be copied at one's peril.

A. Z. (Worcester).—The reason you cannot get the image in focus when copying the portrait the same size is that the camera does not extend to a sufficient length. Bear in mind, in copying an object the same size, that the camera must extend to double the equivalent focus of the lens.

Y. Z. X.—Why trouble yourself to prepare the iodised paper, even if you could obtain a suitable kind of paper, when you can purchase gelatino-bromide papers of different grades ready for use? They will yield results far superior to any you enclose, or perhaps any you will succeed in getting by your method of working.

PINHOLE PHOTOGRAPHY.—No fewer than six correspondents inquire what Mr. Forgan, of Edinburgh, means by a "pinhole" which is forty-eight hundredths of an inch in diameter. The paper was printed as received. One says, "Surely a trifle under half an inch is not a very small aperture, and Mr. Forgan must get his pins made to order. I never met with one of that size."

J. S. RAYNER.—The fault in the prints is not due to the tanning but to the unevenness in the albumen on the paper, some portions having a thicker coating than others. Furthermore, there are a number of air-bubbles in the albumen which produce what you term the "blotches." It is the most unsatisfactory sample of albumenised paper we have seen for a long time. Is it of your own albumenising?

C. W. WARD complains that he cannot succeed in making a solution of india-rubber, as the rubber will not dissolve.—The difficulty may arise either from an unsuitable rubber being used or a wrong medium being tried. Vulcanised rubber cannot be dissolved in the usual solvents, nor can the proper kind of rubber be dissolved in the benzoline of the oilshops, which is often tried for the purpose. If our correspondent will procure a sample of what is known as "masticated rubber" and use good benzol—not benzoline—his difficulty will disappear.

W. J. HARDING (Wanganin).—As the gold residues are in the condition you state the best plan will be to add sufficient solution of protosulphate of iron to ensure the precipitation of all the gold in the metallic form, then wash well with water, and afterwards treat the residue with dilute hydrochloric acid; this will dissolve out the lime and any iron that may be present, leaving the gold behind; this may then be dissolved in the aqua regia in the same manner as you have done before. Your plan of making chloride of gold is an excellent one; indeed, you could not have a better.

Tony.—1. Any dark backing will prevent halation. Make a mixture of Spanish brown, water, a little glycerine, and just enough gum water to give it coherence.—2. The distance between the slot and the ground-glass will be just a trifle over the true focus when used under the circumstances mentioned.

COL. GUBBINS writes: "Will you kindly tell me the cause of diluted ammonia becoming milky? I diluted a bottle of liq. amm. fortiss. with three times its bulk of water from the rain water pump; in a short time it got quite milky, and in a day or two was quite clear, with a white deposit at the bottom of the bottle."—The turbidity and precipitate is caused by some impurity in the water, the nature of which it is impossible to say accurately without an analysis. Probably alumina was present. It will do no harm practically. Few persons use distilled water for diluting the ammonia for photographic purposes.

H. N. BATES writes as follows: "Could you tell me in your 'Answers to Correspondents' if, in the United Kingdom, there are any artists, true artists I mean, who have a photographic studio as well as their own art. By artists I do not mean ordinary photographers, but men who have studied under good masters and in the best Continental or London schools of art. I ask this question as art in portrait as well as landscape photography in the United Kingdom is especially and unfortunately grossly neglected. One sees nothing but the common photographs everywhere, in the largest to the smallest city, exceptions to the rule being extremely rare. Trusting you can give a little information on the matter."—Many photographers have studied art, though many have not. The best reply we can give our correspondent is to visit some of the photographic exhibitions and judge for himself.

S. STEPHENS asks: "1. Is acetate of soda put in the toning bath to neutralise the gold; or what is its use in the bath?—2. Which is the best way to vignette in the camera? I have tried cutting a cardboard vignette but get hard margin, or not the proper size for the head or shoulders. Are there any vignettes made for the purpose?—3. What is the cause of the discolouring of the sulphite of soda for developing. Formula I use: Bromide of ammonia, six hundred grains; pyro, one ounce; saturated solution of sulphite of soda, six ounces; nitric acid, one drachm. The above developer, after a few days' standing, turns a light ruby colour."—In reply: 1. Yes.—2. The mask must be placed sufficiently far from the plate to produce the necessary softness. It is a good plan to keep the mask moving backwards and forwards during exposure. A very simple mechanical contrivance will enable this to be done. Or the mask may be placed between the object to be photographed and the lens. No special masks are made for this purpose.—3. A slight oxidation, but it will do no harm.

P. P., writing from a certain provincial town, says: "Some time ago I engaged an agent in London to forward to me goods, mostly photographic lenses, cameras, &c., insured for 100*l*. They arrived here, at a branch office of the agent, but were grossly damaged, and, consequently, I declined to take them in this state, and claimed as a compensation a sum of 45*l*. At the County Court it was alleged that the railway company was responsible, and not the agent; and I was ordered to pay to the latter his claim for transit and costs, together 15*l*. 15*s*. 6*d*., by monthly instalments. After this decision by the Court I demanded of the agent to deliver the goods, but this he declined, keeping them as security, and telling me at the same time that I should have to pay for warehousing till the amount be paid. Now I wish to know is the agent entitled to keep the goods as security after decision of the Court, and is he also entitled to a claim for warehousing?"—In reply: Make application to the judge, and state that you have not received the goods, and ask him to rescind the order for payment until the goods have been delivered to you.

PHOTOGRAPHIC CLUB.—The annual dinner will take place on Wednesday, December 14, 1887.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—On Thursday, December 15, a paper will be read by Mr. W. H. Harrison, subject, *The Lanterns and Lantern Slides of the Nineteenth Century*.

RECEIVED.—Dallmeyer's *Choice and Use of Photographic Lenses*, New Edition; *Photography Simplified*, by Mawson & Swan; *Developing Trays, &c.*, by W. Tylar; and Woodbury's *Hypo Eliminator*. These in our next.

THE JENNINGS'S FUND.—The following additional contributions have been received by Dr. Maddox, Greenbank, Park-road, Portsmouth, Southampton, and Mr. Andrew Pringle, Cromwell House, Bexley Heath, Kent:—Adolphe Schulze, 1*l*. 1*s*.; John Williams Clinch, 10*s*.; A. J. J., 5*s*.

IPSWICH SCIENTIFIC SOCIETY.—At the annual *conversazione* of this Society a large collection of photographs by Mr. W. Vick and other local artists formed prominent objects of interest. Mr. Vick added greatly to the attractions of the evening by practical demonstrations of the platinotype process. All through the evening he was surrounded by a crowd watching with eager attention as he developed photographs upon stuff. He showed how, by this process, photographic views could be transferred to d'oyeys and pincushions, and pointed out a novel method of marking stuff napkin rings by imprinting upon each the portrait of the person to whom it belongs.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1441. Vol. XXXIV.—DECEMBER 16, 1887.

THE PHOTOGRAPHIC CONVENTION OF 1888.

ALL things are progressing favourably for the meeting of British photographers which is to be held in Birmingham in the summer of 1888, and we anticipate a large and enthusiastic gathering.

A powerful local committee has been formed, with Mr. Jerome Harrison as Chairman; while the Secretaries of the Birmingham Photographic Society, Messrs. J. H. Pickard and W. Rooke, have been unceasing in their endeavours to complete in good time all the necessary arrangements. Sub-committees have been placed in charge of the Entertainment, Exhibition, and Excursion arrangements respectively.

Subject to the approval of the Council of the Convention, the meeting will commence on Monday, July 23, and terminate on Saturday, July 28.

The Masonic Hall, New-street, an admirable building in the very centre of the town, has been engaged for the purposes of the meeting, and the principal room is admirably suited for the exhibition of pictures and apparatus. It will also seat some 700 people for the evening meetings, when papers will be read and discussed, and lantern exhibitions given. It is proposed, we believe, to have a dinner on one evening during the week, and a smoking concert on another.

Numerous excursions will be arranged, which will probably include visits to Stratford-on-Avon, Warwick, Leamington, Coventry, Lichfield, Maxtoke Priory, Worcester (with a trip down the Severn on a steamer), Dudley (including the descent of a coal-pit, when the magnesium light will be set to work), the famous string of Shakespearian villages along the Avon—Bridgenorth, Evesham, &c. Several excursions will probably be arranged for each day so as to avoid crowded parties, and the difficulty will be to decide among the good things provided.

A full and descriptive programme, containing maps of the town and district, and all necessary information, will be issued in good time.

Already we hear from many parts, not only of England but also of Scotland and Ireland, of photographers who intend to make the journey to Birmingham; and, indeed, no better place, so far as centrality and convenience of access are considered, could have been chosen. The Convention will thus celebrate its third anniversary under the most favourable circumstances, and we believe that it will mark an important step in the history of photographic progress.

DRYING NEGATIVES.

JUST now, when the professional photographer wishes to utilise every moment of daylight for printing purposes, in the endeavour, as best he can, to satisfy the clamour for photographs for Christmas, one of the most harassing accompaniments of the season is the stock of negatives on the drying racks which will not dry in any reasonable time, and which, during the continuation of weather such as we often have in the winter months, will retain a considerable amount of moisture after even twenty-four hours exposure to the air. This loss of time is serious, for we gather from our professional friends that near Christmas orders are given which become cancelled if not finished by that day. We do not now refer to the usual photographic Christmas cards of the stationers' shops, the orders for these being, as is well known, given in spring or summer for the ensuing season; we more particularly allude to the *cartes*, the cabinets, the panels, &c., that so often do duty as Christmas cards, and which, with a little effort, might, and with great advantage to the photographer, still further be made to take the place of the meaningless prettinesses of cards whose day is already almost past.

The professional photographer in a large way of business can afford to have warm drying rooms and plenty of airy space, though during strongly marked hygrometric conditions of the atmosphere the drying will even then still be slow; but those in a smaller way cannot afford the convenience and have not often the space. Where great speed in an important object, the plan often described by us of soaking the negative in methylated spirit and then placing to dry is the most effective of all, but it entails a considerable expenditure of spirit, as the same liquid cannot be often utilised for the purpose, on account of the water it absorbs from the film. It must be remembered that some brands of plates when submitted to this treatment give a peculiar opalescence after drying, which renders the negative quite unfit for printing from; if such an appearance be met with it may be removed by soaking in water afresh, but the time is lost.

We may, perhaps, point out that the cause of slow drying is not alone low temperature, it is the presence of a larger proportion of watery vapour in the atmosphere in winter, so that evaporation, in consequence, scarcely takes place at all; indeed, there are days when actual precipitation of water happens. It naturally follows that, if the moisture can be removed from the air, evaporation from the negative would take place much more freely, more, indeed, than would often happen with the normal

atmosphere raised in temperature. To attain this end, many photographers have adopted the method of placing their negatives in drying boxes or cupboards containing a desiccating agent, and the plan is thoroughly effectual, and has much in its favour. The three agents oftenest recommended for the purpose are sulphuric acid, caustic potash, and chloride of calcium. The first named is only fit for use in the hands of the practised chemist—it is too dangerous a substance to lie about a photographic dark room; otherwise, it is cheap and effectual. Fused potash is useful, but needlessly expensive while there is available chloride of calcium, which is a most excellent moisture absorber, cheap, and above all can, when “spent,” be readily made equal to a fresh sample by simply heating on a shovel over a fire. The moisture is driven off, and again the fused salt is rendered greedily absorbent of moisture.

We have lately had the whole subject brought before us by several of our correspondents, the majority of the plans submitted to us by whom consisted in stacking the negatives with free air space between them, and then, by one means or another, causing a circulation of air. If the plates are placed in racks side by side, as in the old draining racks, an artificially produced current of air becomes a necessity unless the atmosphere is unusually dry and warm.

Mr. Werge in his contribution to our ALMANAC gives a remarkable example of a danger that may attend the slow drying of negatives so placed. An instance was brought under his notice in which he was able to trace the production of certain peculiar transparent patches in the centres of some negatives to their having been placed to dry in this manner. They had not, as we are afraid is too often the case, been sufficiently washed, and the centres of the plates, naturally, when so stacked remaining longest moist, the hypo solution had full opportunity to act as it is known to do when allowed to remain on a plate exposed to the air, that is to say, it reduces it. In a contrary direction the use of methylated spirit is by some said to impart density.

Most of our correspondents' plans consisting, as we say, in the production of an air current round or through stacked plates, we may give our readers the benefit of some of their suggestions in their incomplete and untried state.

One gentleman proposed to attach an indiarubber hose to the exit end of the siphon of his washing tank after the negatives had been subjected to the action of the water for a sufficient length of time, and to attach this hose to some apparatus for producing a current. Given this current apparatus, the method seems to us the most feasible of any, and one entailing little expense.

Another would make use of the falling power of the waste washing waters to actuate a small vane or water wheel, which should produce a current to be directed upon the plates in a manner somewhat after the idea of one gentleman who believed that sufficient head of water would be found in most studios to work a small turbine, which could, by exhaust or direct action, produce any current likely to be needed, and, at the same time, provide power for sundry other minor purposes. The merit of this plan would be that the machine could be worked efficiently by the same water that was needed for ordinary photographic use, the quantity so used being quite sufficient for the purpose, and it might be run into a tank ready for producing power instead of direct to the sink.

Probably the method of easiest general adoption would be the usual one of the chemical laboratories, the production of a

current by a gas flame enclosed in a chimney, which might in this case be connected with the cupboard or drying box in which the negatives were placed. These are somewhat costly to make, hence the idea of the washing trough with the indiarubber hose attached to such a chimney seemed to us to possess the germs of real utility. We trust some one of our readers may put it to the test. It is obvious that arrangements for emptying out the last drop of water from the trough should be made or there would be great waste of power.

We have not touched upon the use of heated air in this connexion, though there is no doubt it is far more easy of successful adoption than in the drying cupboard of the plate maker, frilling plates being so liable to be produced if this method of drying be adopted by him. It is evident that the temperature which a plate will withstand without injury will vary according to the brand employed. We have some experiments in hand upon this branch of the subject, and when they are completed our readers shall have the benefit of the conclusions obtained.

HOME-MADE STRIPPING FILMS.

HAVING shortly described the preparation of the gelatine transfer paper, we now proceed to speak of its various applications and uses. We have already mentioned the very practical use the late Mr. W. B. Woodbury put gelatinised paper to on the occasion of a lengthened tour in Italy for the benefit of his health when necessarily he could not burden himself with a vast amount of luggage. Nevertheless, he brought home with him a series of upwards of 200 negatives, $7\frac{1}{4} \times 4\frac{1}{2}$, which formed, perhaps, the most perfect collection of collodion emulsion pictures taken up to the present time.

Mr. Woodbury's method was as follows. Provided with a stock of emulsion, a couple of dozen plates, and all necessary developing materials, he cleaned and coated in the bedroom of his hotel or lodging one dozen of the glasses and placed them in the slides for use. After a day's work a sufficient number of fresh plates were coated to replace those exposed, and the latter were developed, fixed, washed, and squeezed into contact with sheets of the prepared transfer paper and reared up in any convenient place to dry, which they would do thoroughly before morning. Each negative was then stripped from its glass support and stored away in a portfolio, the glass being set at liberty to be cleaned and recoated. In this manner, though encumbered with no more than a couple of dozen plates, the ingenious artist possessed practically unlimited resources for the production of any number of pictures, his bottle of emulsion being renewable at a few days' notice by writing to England.

It was suggested at the time that the experiment was a risky one, and many old collodion “hands” expressed the opinion that after developing a good negative they would rather be troubled with the weight of the glass than jeopardise the safety of the picture by stripping it. That such fears are entirely unfounded is abundantly proved by Mr. Woodbury's success, and, indeed, so readily do the films strip, even when the glass is not previously waxed or French chalked, that we should have little hesitation in “attacking” negatives that have been in existence many years. Only one precaution is absolutely necessary, namely, to allow the transfer paper to become *thoroughly dry* before attempting to strip it, and also to observe that no heat is used to hasten the operation. Heat will do little harm *after* desiccation, but if applied before the gelatine has a tendency to melt and, penetrating the collodion

film, cement it firmly to the glass. Occasionally when very dry the film will exhibit a disinclination to leave the plate; in such cases, if it be left in a damp place for a short time, or be pressed in contact with a pad of very slightly moist blotting paper for a few minutes, or even if it be strongly breathed upon, the film will separate readily enough.

The negatives at this stage may be treated with wax or vaseline and used as paper negatives, when if a suitable paper has been used they will give as satisfactory prints as any other form of translucent *éclaté*. Or they may be retransferred to glass on the return home of the traveller, or converted into transparent "film negatives" printable from either side.

To perform the retransfer to glass, a plate of the latter material is cleaned and coated with a thin solution of indiarubber in benzole, or, better still, chloroform, and while the film of indiarubber is still "tacky" the collodion side of the stripped negative is squeezed into intimate contact and set aside to become thoroughly dry. Or, and for many reasons we prefer this plan, a fifteen to twenty-grain solution of gelatine, to each ounce of which a quarter of a grain of chrome alum has been added, is substituted for the rubber solution. In this case the glass plate is warmed and coated with the gelatine solution in the same manner as collodion, the surplus being drained off so as to leave an extremely thin and even film, which is then allowed to dry. When the retransfer is to be made, the negative as well as the prepared glass are soaked in cold water for a minute or two, squeezed into contact, and placed under gentle pressure for ten minutes; if the glass be then immersed in warm water the paper will come away, and after rinsing the collodion surface to remove all traces of gelatine the negative is ready for drying and varnishing. When indiarubber is used, the plate must be immersed in cold water for some minutes before using hot, or the paper will not strip evenly.

For making transparent or "film" negatives no better plan exists than to apply a thick coating of insoluble gelatine to the collodion surface, and after drying to remove the paper as before. This may be applied in a liquid form or in the more modern style as an insoluble sheet, the former being cheaper and more convenient though it takes longer. Prepare a solution of gelatine as follows:—

Gelatine (white)	1 ounce.
Glycerine	1½ drachm.
Water	6 ounces.

Dissolve the gelatine, and filter carefully. Prepare a separate solution of chrome alum, two grains in one ounce of water. Brush over the collodion side of the negative with a thin solution of indiarubber, about five grains to the ounce of solvent, and allow it to dry; this is not absolutely necessary, but it helps to waterproof the collodion film and so lessens the chance of the chrome alum penetrating to the layer of soluble gelatine. Next, turn up the edges of the negative to the depth of an eighth of an inch to form a sort of dish, and lay this ready upon a levelled and warmed glass plate. Have the two solutions of gelatine and chrome alum heated to a temperature of about 140° or 150° Fabr., and just before using mix them by stirring the chrome alum carefully into the other without creating unnecessary bubbles; let the mixture rest a little for any bubbles to separate, but carefully keeping up the temperature.

When the mixed gelatine solution is ready for use, pour it into the dish formed by the negative to the depth of a sixteenth of an inch or more and allow it to set, after which the whole may be hung up to dry in a current of air. No more of the chrome gelatine solution should be mixed than it is in-

tended to use up, as when it once sets it will not reliquify. The thick layer of gelatine will take some time to dry, perhaps from twenty-four to forty-eight hours or longer, in a moisture-laden atmosphere; when that occurs it is coated with a film of good enamel collodion, after which the negative is floated for three or four minutes, paper support downwards, upon cold water to soften the soluble gelatine. Then, laying paper side upwards on a sheet of clean blotting paper, go over the back with a sponge and hot water until the paper becomes quite loosened, when it is lifted by one corner and gently stripped away. The collodion surface is next gently washed with warm water to remove all the gelatine, a soft camel-hair brush being used if needful, and finally placed between folds of blotting paper to dry under pressure. When dry it presents the appearance of a thin transparent film of great toughness and flexibility—little liable to injury from any ordinary causes, and is capable of being printed from either side.

The description of the various operations may seem tedious, and the process a troublesome one, but in practice it is really not so formidable as it seems, the various advantages being taken into account. We treated some experimental negatives in this manner upwards of ten years ago, and for several subsequent years they knocked about in all sorts of odd places without apparently suffering much injury.

Such is what we may call the "transfer process," involving the employment of glass plates in the field. If, however, it be desired to dispense altogether with glass when travelling, the method becomes even simpler, for it is only necessary to apply the emulsion direct to the gelatinised paper in the first instance. This perhaps requires a little more skill than coating glass, at any rate at first, but with a fair amount of care and intelligence becomes easy enough even when large sizes are required. The chief *desideratum* is to have the transfer paper itself in a proper condition, and the following hints will probably assist in securing this.

When newly coated and dried, if the proportions of gelatine and sugar or glycerine have been suitable, and the coating and drying properly performed, the paper will be soft and pliable, and entirely devoid of any tendency to "crinkle" or curl into unmanageable rolls, though it will in all probability not lie perfectly flat. To make it do this, smooth the sheets out as well as possible with the hands, and place them in a pile under pressure between the leaves of a book in a large printing frame or in an ordinary screw copying press. A few hours of this treatment will take all or most of the "curl" out of the sheets, but should any remain a moderately warm but not hot iron may be passed over the back of each, a sheet of clean paper intervening. This will bring them to a condition for collodionising.

To coat with emulsion, the sheets, cut to convenient sizes, are pinned to a thin, flat board, a trifle smaller than the sheets, one corner of the paper—that at which the surplus is to be poured off—projecting well over the edge of the board. All four edges should be *slightly* clear of the board in order that the emulsion may not creep to the under side of the paper, say, about an eighth of an inch for the two sides and a quarter or three-eighths for the other two. A very handy arrangement where a practice is made of coating paper consists of a light board, suitably tongued and grooved, or otherwise clamped, to a perfectly plane condition, and provided with a projecting handle on the under side, after the style of a bricklayer's mortar board. This renders the coating of paper as easy as that of glass.

The emulsion is applied in precisely the same manner as to glass, and upon properly gelatinised paper flows with equal readiness. When the excess has drained off, and the film been duly "rocked" until "set," the coated sheet is detached from the coating board and pinned up to dry, which it will do in a few minutes.

It is far easier to coat a surface fifteen or sixteen inches square with collodion than with gelatine emulsion; hence there is no advantage in coating very small sheets separately, especially as the cut edges are free from any tendency to frill or detach themselves from the support, as in the case of gelatine upon glass. The size of the sheets should, therefore, be arranged accordingly, allowing a small margin for the pinholes caused in attaching the paper to the coating board and other defects at the edges. In this manner the cut sizes may be obtained absolutely perfect to the extreme margin.

This now forms a true "stripping" film to be used with any of the numerous forms of "film carrier," or it is possible that some arrangement might be made to adapt the sheets for use in some of the roll holders. After exposure and development, the negatives may be treated in one or other of the ways already described, only bearing in mind that if transferred to glass the image will be reversed. Perhaps the favourite plan for modern use will be to select a proper sample of paper, and to gelatinise it with a view to its remaining as the final support, or to utilise the flexible "strippers" when they become a recognised article of commerce.

We have described the various methods of manipulating the paper in connexion with collodion, and may finish by alluding to one or two applications which will readily present themselves. First, where reversed negatives are required for any special purpose, the gelatinised paper affords one of the simplest of methods. The negative is taken upon the coated paper, developed, and directly transferred to glass, or, if made into a "pellicular" negative will print either way.

For cloud negatives, too, the gelatine paper will be found particularly handy, whether the original negatives be taken upon glass plates or upon the flexible films, or whether the latter be utilised merely for copying and reproducing the originals. Finally, for composition or double printing, pellicular negatives made in this manner from the separate originals may be superposed in correct position, cut out with a pair of sharp scissors, and the selected portion from each duly mounted upon glass to form a combined negative. Other minor uses will, no doubt, be found.

The treatment in connexion with gelatine emulsion and plates is essentially different, and will form the subject of a separate article.

THE Copyright Convention, to which we have on several previous occasions directed attention, and which was finally concluded in September last, came into operation last week. Great Britain is a member of the Union, and an order in Council has just been issued reciting the provisions of the Convention entered into between this country, France, Germany, Spain, Italy, Belgium, Switzerland, Hayti, and Tunis. The effect of this instrument is to remove the disabilities inflicted on artists or authors in one country by priority of publication in another—a very important matter to photographers.

ONE clause of this international agreement is that "Authors of any of the countries in the union, or their lawful representatives, shall enjoy in the other countries for their works, whether published in those countries or unpublished, the rights which the respective laws do now, or may hereafter, grant to natives." The literary and artistic

works protected include books, pamphlets, dramatic works, music, paintings, sculptures, engravings, photographs, designs, lithographs, sketches, and, indeed, almost everything that can be classed under the head of "publication," and by any process of production. The agreement is most stringently worded, and we have little doubt that it will put a great check upon, if not an entire stop to, the wholesale piracy of English photographs which has hitherto been so extensively practised on certain parts of the Continent.

THE Board of Customs have just issued their regulations under the Fraudulent Trade Marks Act of last session, which are to come into force on the first day of next year. By Section 16 it is provided that, "All goods of foreign manufacture bearing any name or trade mark being, or purporting to be the name or trade mark of any manufacturer, dealer, or trader, in the United Kingdom, unless such name or trade mark be accompanied by definite indication of the country in which such goods were made or produced, shall be prohibited from being imported." From this it appears that the authorities intend taking active steps towards putting this important Act—as regards the importation of foreign goods bearing English names—into operation, so far at least as the Customs are concerned.

ENGLISH dealers who supply foreign lenses bearing their names, do not, as a rule, have the names engraved upon the mounts abroad, but have them put on here; the same with chemicals, paper, &c. These things come over with the manufacturers' labels on, which are frequently afterwards removed, and those of the dealers substituted. Of course the Customs' authorities can take no cognisance of this. One thing in connexion with this subject occurs to us: How will it be with photographic mounts? A very large proportion of those now used in this country are made and printed on the Continent, and, of course, they bear the name and address of the photographer who is to use them, and often, in addition, the name of the dealer who supplies them to him. When this is the case in the future, we surmise they will be arrested at the Custom House, and become forfeited, unless there is a distinct intimation upon each card that it was produced abroad. But if the mounts only bear the photographer's name and address, will they pass unchallenged without the intimation that they were manufactured in some other country?

AT a meeting of the Society of Arts last week, a paper on the subject of eggs was read by Mr. P. L. Simmonds, F.L.S.—and a very interesting paper it was. A large proportion of those attending the meeting had no idea as to the purposes to which eggs are put and the extent they are utilised in the industrial arts. They are used most extensively, and there is no real substitute for them, in calico printing, in clarifying wines, in gilding, in bookbinding, in dressing leather for bookbinders, and also for gloves. Our readers will not require to be told that they are extensively employed in photography. Mr. Simmonds mentioned that one establishment alone consumed two millions every year in the preparation of photographic papers. It may not be generally known that most of the egg merchants now break eggs for the purpose of supplying those who require only the whites, and those who use only the yolks; thus a great saving to the consumers is effected. Whites of eggs can now be purchased by the gallon, so can the yolks. It is usually imagined that the pastrycooks are the largest consumers of the latter; this, however, is not the case; the major portion of the yolks are used up by the dressers of leather for gloves. It was the late Mr. J. A. Spencer, we believe, who first introduced to the egg merchants the system of parting the whites from the yolks, and selling them separately to those who required the one and had no use for the other.

ALREADY we have had ample evidence in most parts of the kingdom that winter is at hand. Winter, apart from the lack of business, brings many inconveniences to the professional photographer, not the least of which is that pertaining to the water supply. To be "frozen out" of water, or to have burst pipes, particularly at the upper portion of the premises, is a serious annoyance in business. However, these annoyances may be averted if timely precautions be taken, or at least they may be reduced to a minimum; but, usually,

they are neglected until it is too late. If all the water pipes which are at all exposed are covered with three or four thicknesses of old felt carpet, and if out of doors this covering be supplemented with a few inches of stable manure, they will rarely be frozen, even in the severest winter. It is a good plan to shut the water off at the main on frosty nights, if care be taken that no water remains in the pipes by drawing it off at the lowest exits. To prevent the pipes freezing from the tank to the taps, the supply pipe from the cistern should be plugged up at night with a piece of metal tube long enough to reach above the surface of the water, and the pipe emptied by opening all the lower taps. In the morning the tube may be removed, for there is little fear of the pipes freezing when the water is constantly being used.

It is a popular belief that water pipes burst when they thaw; but this is an error, as the bursting is caused by the expansion of the water as it congeals, though the effect is not made manifest until the ice thaws. Therefore, whenever a pipe gets frozen, it should be carefully examined through its entire length, and if a fracture has occurred it can easily be discovered, and the evil averted by the plumber before the water thaws again and floods the place. In nine cases out of ten the inconvenience arising from frozen pipes may be avoided by a few precautions, if they are taken in time. No time should now be lost by those who have not already taken care of their water supply for the next two or three months, bearing in mind the old maxim, "Prevention is better than cure."

PROFESSOR FOREL is still continuing his researches as to the light-resisting power of water, his trials being made in the beautifully limpid contents of the Lake of Geneva. His method of procedure is to submerge chloride of silver papers at intervals of every ten metres, after sunset, and then to take them up at night after a day's exposure. Each piece of sensitive paper is attached at intervals of ten metres, and under suitable precautions, to a long rope. It was found that the depths where absolute darkness, or stoppage of actinic rays, was observed, varied according to the month. Strange to say, March allowed the light to penetrate the greatest distance—one hundred metres—while May and July respectively arrested it at the depths of seventy-five and forty-five respectively. It is evident, therefore, upon correlating this experiment with others on record, that the results obtained must be a measure, not of the intensity of the light in the months named, but of the turbidity of the water. However, Professor Forel intends to continue these experiments every two months for the space of a year.

At the same meeting some photographs taken at Greenwich with the Sheepshanks's equatorial on curved plates were exhibited. The object in taking these negatives was to ascertain the limit of the possible field for correct measurement. The general result arrived at was that negatives embracing a field of four degrees in diameter might be used where extreme accuracy was needed, but that approximately accurate readings might be obtained with a field of five degrees.

ONE great advantage of photographic over eye observations is that the personal element is, or may be, entirely eliminated. So important a factor is this, that at the same meeting a description was given of a machine devised by the Astronomer Royal for ascertaining the "personal equation," as it is termed, of those engaged in the work of the observatory. A table was also given of the errors made by each observer as shown by this apparatus, and which necessitated an equivalent correction being made to each individual record.

VERGARA FILMS.

WE are much pleased to find that, after much time spent in experimenting upon the preparation of negative films which should fulfil every requirement, Mr. Vergara has at length scored a success of a genuine nature.

For a long time, as our readers are aware, this gentleman has been indefatigable in his endeavours to substitute transparent paper for glass as a support for the negative film, and although success of a certain kind was achieved, yet were there always little, and at first sight

seemingly unimportant, things which prevented such success from being of an unequivocal nature. This led to his entirely discarding the basis formerly employed (paper rendered translucent by varnishes) and substituting instead a film of a gelatinous preparation, so altered in its nature that, while retaining its transparency and flexibility, it is yet as inert as glass in the presence of water and the chemicals requisite for developing and fixing.

The other day Mr. Vergara called on us, and submitted a large number of negatives taken on his new films, also showing us the supports previous to and after being coated with the sensitive emulsion. Proceeding to the dark room now connected with this office, a 10×8 film exposed that morning was developed with singular ease and unmistakable success. Transferred from the dark slide to the developing dish, it was first treated with water to ensure a uniform wetting of the surface, after which the developer was applied. Very soon the image appeared, and went on increasing in vigour until it was judged sufficient. Fixing and washing ensued in the usual manner.

The negative was now partially dried off by squeegeeing between folds of blotting paper, after which it was wrapped round a large extemporised cylinder of porous millboard, and covered with a couple of folds of stout bibulous paper, two indiarubber bands sufficing to retain the whole in cylindrical form. For lack of a better arrangement this cylinder was placed over the gas bracket in our office, and thus gently warmed. In an incredibly brief period of time the negative was found to have become dry. The whole operation from the commencement of the development to the negative being ready for the printing frame was much less than an hour.

Pellicular negatives of the class described will prove useful in many ways. Their lightness will appeal to those who carry with them a large camera, and trudge it over hill and dale in search of pictures; their thinness will render them useful to those who for mechanical printing or "process work" require a reversed proof, for nearly equally sharp prints may be obtained from either side of the negative; while their flexibility appeals to those who have a *penchant* for roller slides, but are disinclined to strip their films from a paper support. Mr. Vergara is entitled to credit for the persistence with which he has followed the trail until he has achieved deserved success.

ECHOES FROM THE SOCIETIES.

THE question box as an institution at the meetings of our societies is unmistakably a very valuable one, enabling, as it does, retiring and bashful members to bring their queries before the Society without personal discomfort. It is a pity, therefore, that the question box should run any risk of falling into disrepute in consequence of facetious individuals endeavouring to "play larks," as somebody seems to have been doing at Derby. "Will any member give the best mode of developing and the best developer to use?" asks the question box. No wonder it was "left over until next meeting." It is a case, I expect, of *tot homines, tot sententiae*.

Another conundrum, presumably from the same querist, is, "What is the action of the developer upon an exposed gelatine emulsion plate?" Now, that, to my mind, clearly depends upon circumstances. A less thoughtful man than the Secretary of the Derby Society might answer rashly, "To develop it," or "To bring out the picture." But I hold that it is not necessarily so, for the correct answer might be, "To fog it," or, again, "To show the party most closely concerned that his exposure tables are not worth a—well, the trouble he took in compiling them." I repeat that I consider the question is one impossible to answer off-hand with absolute correctness, hence, perhaps, the care with which the Secretary worded his reply. It "continued the action set up by light, and developed the latent image," he said. Mark, it is the latent image, not the plate, that is developed; but *is* development a continuation of the action set up by light? Some people say it is not.

But the Chairman evidently was not to be "done" by Mr. Secretary, so, in reply to another question, "Must the bromide in an emulsion be in excess of the silver salt or not?" he "hitched on to the job." After remarking that the question would be found answered in "one of the annuals," which he evidently did not, how-

ever, consider worthy of credence, he gave his own view. "If you do not get sufficient bromide in the emulsion the silver is lost, and it is the opposite if you get an excess of bromide." *Ergo*, if you use an excess of bromide you *gain* or *make* instead of *losing* silver. That is to say, from a plate maker's point of view, the more bromide and the less argent. nit. you employ the more argentum (=cash) you make. If that is Mr. Chairman's meaning, I don't think the game would last long. But perhaps he meant or said something else, and that is only what Mr. Reporter thought.

The report of the "technical exhibition," or whatever it is called, meeting of the Parent Society is interesting reading. To this meeting, from distant parts of the country, come strangers bent on seeing and hearing described the newest inventions of the year, but it seems to me that "reeds shaken by the wind" (the wind of interested exhibitors) are more to the fore. On going through the list I find that the greatest novelty, or the most important exhibit, seemed to be one which, according to the statement of a member present, was at least fourteen years old. Perhaps that is why it got a medal! Its turn had come round. These are the same old things one sees on the table year after year, including even "the only camera," &c. No wonder General Preston found cause for complaint! Why cannot the Society adhere to its own rules and refuse to allow any exhibitor, on the pretence of some paltry "improvement" (?), to bring up the same article year after year. An instantaneous shutter, which was shown there two, if not three years in succession, was said not to be made *for sale* but only *for exhibition*.

I notice a startling process brought before the members of the Bristol Camera Society by the Chairman, Dr. Arthur Richardson, who asked if any of the members had "tried the experiment of exposing a piece of plain glass in the camera to an object and developing the image by means of breathing on the same, as in the case of exposed carbon tissue." As no replies are recorded I presume it had never struck any of the members to try to dispense with films of silver bromide; they had all apparently been content to go on wasting money in silver, and gelatine, and pyro, and ammonia, and ferrous oxalate, when all that is requisite is "plain glass" and the breath of their own nostrils. Verily, we are advancing rapidly! But when was the process of developing a carbon print by breathing on it published? Perhaps Dr. Arthur Richardson will give chapter and verse.

The subject of the removal of hypo from prints arose in the discussion of a question from the box at the London and Provincial Association. Somebody of the "too literal" character wanted to know how to squeegee a print without tearing it. Such individuals should be cut off from the advantages of the question box, for surely they must either be attempting to play tricks or else their obtuseness is so great as to be hopeless. Certainly the individual in question is not likely to make much out of Mr. Ayres's straightforward and perfectly correct reply. The individual who is so fearful of tearing his prints would remove all danger, however, if he employed a piece of mackintosh cloth in the same manner as in squeegeeing a carbon print. The method of squeegeeing out the hypo solution by passing the prints through an ordinary wringing machine was published in *THE BRITISH JOURNAL OF PHOTOGRAPHY* over twenty years ago, as was also the plan of sponging each print singly, back and front, half a dozen times and changing into fresh water on each occasion. A simple and homely method I saw some years ago in use in a small studio in a country town seemed equally effective. The proprietor, who himself filled the various posts, from plate cleaner upwards, took his prints out in handfuls from the washing trough, "slapped" them down in a heap upon a flat board, and with a common "rolling pin" borrowed from the kitchen, and all the muscular force he could apply, rolled them nearly dry. Then, changing the water, the prints were put back to soak, turned over to separate them, and after an interval the rolling process repeated.

I have often complained of the unnecessarily diffuse and prolix manner in which secretaries of societies too frequently report perfectly familiar matters, possibly because they know all about them, while novelties are passed over almost in silence, because they want studying. As a contrast to this style of thing, I would refer to the report of a "hint" by Mr. H. N. Atkins, communicated to the Liverpool Association, on the subject of utilising the ordinary double

slides for paper negatives. The extemporised "film carrier" described by Mr. Atkins will prove of use to a large number of amateurs, and if secretaries would pay more attention to reporting such little trifles, and less to descriptions of demonstrations of commercial processes, their reports would be more readable and less like advertisements.

The question box seems to be constantly cropping up with me this week! At the London and Provincial Association a questioner wished to know how to reconcile Captain Abney's assertions with regard to the value of iodide of silver in the sensitive film with the claims made in favour of orthochromatic plates. When the anonymous questioner can show me that objects are reproduced in the camera by virtue of their *colour* alone, and without the intervention of *reflected white light*, I will tell him no reconciliation can be effected. Till then, or, at least, as long as things remain as they are, I shall side with Mr. Cobb, and prefer iodide to orthochromatic plates for landscapes.

At the same meeting Mr. W. H. Harrison stated his experience in photographing a wire rope cut clearly against the sky, and expressed himself unable to understand why backing the plate did not prevent the halation, which caused the rope to look twice as thick where it crossed some towers as where it had the sky for background. I would suggest as a reason that the defect was not halation at all in the sense usually understood, and for which alone backing the plate is a remedy, but that it arose from what Captain Abney, I think, called "lateral spread" of the image, a purely chemical effect caused by the particles of silver bromide strongly acted upon by light reacting upon adjacent particles which no light has reached. Portrait photographers know too well this defect, which shows itself by the spreading of white drapery, lace, or collars, into adjacent parts of the picture, even when they lie in the centre of the plate, where refraction is reduced to a minimum.

With regard to the responsibilities of plate makers recently discussed in these columns, I am inclined to agree with those who hold it would be practically impossible to make them responsible for plates alleged to be defective. As Mr. Ashman stated "experts" can always be brought to prove either side, and as a recent lawsuit proves when the conflicting evidence of experts becomes *too* bewildering the authorities "give it up."

That there is ample ground for complaint no one can deny, and that the responsibility of the plate maker reaches far beyond the mere value of the faulty goods supplied is equally true. But how is it to be brought home to him? Even in the extreme case quoted by Mr. Cooke in which a photographer had received plates with "all the films off the glasses" the maker could bring forward experts to prove that the result *might* be brought about by keeping the plates in a damp place, or a dry place, or a cold place, or a warm one, or as one expert more or less would not matter perhaps one might step up to support each atmospheric condition. "I would be a mighty small 'mighty,' but it *might* satisfy a non-scientific jury.

I myself received some years ago in a box of plates of my ordinary size and everyday shape one plate which differed from any I had ever seen before in having *five sides*: in other words, one corner, an area of about four square inches, had been broken off. I daresay *my* claim for compensation might have stood because the maker had not enclosed the broken piece—proof positive the breakage was his doing. Though—it has only just struck me—it would have been just as easy for him to swear that I had broken it myself and done away with the piece. Take it all round it is a difficult subject. MONITOR.

THE MAGNESIO-COTTON LIGHT.

FROM recent experiments I can testify that Dr. Piffard's discovery of the highly actinic and momentary flash of light emitted by a mixture of magnesium powder and guncotton is likely to be of great service to photographers.

In testing the light some difficulty may be found in procuring a supply of guncotton—at least of the highly nitrated or explosive variety which is best suited for the work. (The ordinary "pyroxyline" used in the manufacture of collodion answers very well, however.) The guncotton ought to be so made that when a tuft of it is laid on the palm of the hand and ignited, its conversion into gaseous products is so rapid and complete that the skin is scarcely

warmed, while not a trace of solid matter remains behind. Chemists—in this town, at all events—keep no stock of guncotton, as they say it involves them in possible trouble with the authorities, for the dynamite scare has not wholly passed away.

The preparation of guncotton is, however, so easy, that every photographer can readily prepare the article for himself. For this purpose he should purchase, say, a quarter of a pound of pure cotton-wool (price about 3s. per pound), and a couple of pounds each of strong nitric and sulphuric acids; the former costing 6d. and the latter 2d. per pound. In a well-glazed stoneware vessel capable of holding about a quart, place fifteen ounces of strong sulphuric acid, and then add gradually (stirring well) ten ounces of strong nitric acid. The mixture will make the vessel very hot, and some fumes will be given off. Cover the vessel over with a piece of glass, and place it in a dish of cold water, in which it may be left all night to cool down.

Next morning, weigh out half an ounce of cotton-wool, dry it thoroughly, pull it into half a dozen pieces, and with the aid of a stirrer made of a glass rod, immerse each piece of cotton-wool quickly and completely in the mixed acids, and leave it to soak for an hour or so. During this time the stoneware vessel should be kept as cool as possible, by changing the water in which it is immersed.

At the expiration of the time named, the cotton should be lifted out of the acids by the aid of a couple of pieces of glass rod, and placed in a small basin, where it should be well pressed, so as to free it from as much of the acids as possible. It must then be pulled out, and *quickly immersed* in a large vessel of fresh cold water; the water should be changed repeatedly—say, eight or ten times—until the acid is well washed out of the cotton, and this should be tested for with a piece of blue litmus paper, the colour of which should remain unchanged.

The cotton has now been changed from cellulose ($C_6 H_{10} O_5$) to guncotton ($C_{12} H_{14} O_4 (NO_3)_6$), a substance which contains a large reserve of oxygen gas, which it is capable of giving up to any oxidisable body brought into contact with it. If the body should have a high chemical affinity for oxygen the result of its combination with the oxygen contained in the guncotton will be the production of both heat and light.

Of the various metals, scarcely any have more affinity for oxygen than magnesium. This beautiful element has lately been much cheaper, and it can now be bought in the form of either "wire," "ribbon," or "powder," at the rate of half-a-crown per ounce, while there is every probability of the price becoming still lower.

In the form of a flat, thin ribbon, about one-eighth of an inch in width, magnesium has long been used in photography. It ignites readily at the flame of any candle, or even of an ordinary match, and yields an intensely white or violet-white light, possessing actinic power in a high degree. As it burns it unites with the oxygen of the air, forming a white powder, which is magnesium oxide ($Mg O$). Lamps have been devised to burn magnesium ribbon by Solomon and by Hart, and Lancaster sells a cylindrical reflector in the focal line of which a spiral of the ribbon is burnt. By this means magnesium has been instrumental in furnishing the means of securing many portraits at night. But the pictures so obtained which I have seen have been almost invariably "soot and whitewash," the shadows being extremely hard and black, arising from the fact that the magnesium ribbon when burning furnishes only a *point* of light of no appreciable dimensions.

It was a happy thought which led Dr. Piffard, of New York, a month or two ago to suggest the plan of mixing guncotton with magnesium powder, and then applying a light to the mass. The guncotton furnishes in abundance the oxygen needed to completely consume the magnesium, and the metal being in the state of powder can burn as a whole and simultaneously, thus spreading its flame—or rather flash—over a wide area.

A few days ago I consented, in a weak moment, to attempt to photograph a group of between forty and fifty young ladies who had undertaken, as amateurs, the performance of a certain operetta.

The only possible time came, and with it one of those gloomy December afternoons whose light was of so non-actinic a nature as to be absolutely useless for photographic purposes. What was to be done? The scenery had been specially arranged, the forty-two young

ladies had specially dressed, an indefinite number of friends were there to look on, and I dared not for a moment propose such a thing as "putting it off."

In these straits I bethought myself of what I have ventured to call the "magnesium-cotton light." Weighing out quickly a quarter of an ounce of guncotton, I dusted it over thickly with the magnesium powder and arranged it as a mass about eight inches long by two inches wide upon a piece of zinc, the edges of which were slightly turned up. The zinc plate was then laid upon a flat piece of wood, so that the hands of the person holding it should not suffer. I also provided a couple of pieces of cardboard, each measuring about four feet by three feet.

The "company" being arranged upon the stage (which was fifteen feet in width), I placed the camera in front of it, at a distance of twenty-one feet. The assistant holding the light stood on a chair about four feet to the left, and rather in front of the camera, and on either side of him other assistants held the curved pieces of cardboard which were to act as reflectors.

When all was ready the lens was uncapped (aperture $f/8$), the mixture ignited with a match, and a dazzling flame shot up, which had an apparent area of a square foot or more. The lens (Beck's rapid rectilinear, $8\frac{1}{2} \times 6\frac{1}{2}$) was instantly recapped. The plate (Thomas's whole-plate, extra rapid) developed with ease, and I send you a rough, untuned print herewith. Although the result is far from perfect, yet I consider the getting of any result at all on such a gloomy, misty December afternoon (after three p.m.) shows the new light to be a great acquisition.

I have since tried the magnesium-cotton light for portraits with good results, the roundness of modelling and the detail in the shadows being remarkable.

For single portraits, about ten grains of guncotton made into a little pad, and covered with about twice its weight of magnesium, will be found sufficient. This should be burnt at a distance of not less than seven or eight feet from the sitter. It is as well to illustrate the power of the light by making a "sham exposure" with a small quantity of the mixture, as a new sitter almost invariably closes his or her eyes the first time they are "under the light." I enclose a portrait of a young lady showing this effect, and invite editorial opinion as to "roundness" and "detail in shadows." It is an under-exposed bromide print, the only one I have at hand.

The person holding the light should keep his head well away from the magnesium-cotton, or he may get his face scorched.

The results of the chemical combination of the ingredients used are chiefly magnesium oxide (in the form of a fine, white powder), carbonic acid gas, and nitrogen. These products, of course, mingle with the air of the room, from which the magnesium oxide slowly settles down. It will probably, therefore, be best to burn the mixture in a lamp with a ground-glass front. I hope shortly to experiment in this direction, and will let you know the results.

W. JEROME HARRISON.

P.S.—I find that a mixture of lycopodium powder and magnesium, triturated in a mortar and blown from a tube through a gas flame, yields a very brilliant and momentary flash. Lycopodium is a yellow powder (the spores of a plant) which has long been used in a similar way in theatres for producing "flashes of lightning."

WHAT TO PHOTOGRAPH.†

UNFORTUNATELY, many who admire photographs are utterly destitute of the power of refined appreciation, and the consequence is, pictures possessing this quality (that of atmosphere) in a large degree are passed by as uninteresting, and the clear, sharp, non-atmospheric photograph is regarded as everything a photograph ought to be. There has been from time to time discussions as to whether atmosphere and out-of-focus effect are synonymous. For my part I think not. I look upon atmospheric effect in a photograph to be essentially a gradual reduction in the intensity of the dark portions, the lights and shadows becoming apparently more blended as they approach the horizon till they finally merge into the sky, still retaining their individual shapes and character. This is a very different thing to the effect of blurring by reason of the distance being out of focus. This merely gives a fictitious effect,

* Quite successful.—Eds.

† Concluded from page 790.

confusing the subject and rendering light, shade, and form into an inextricable tangle of fuzziness on one plane. This sort of thing may pass occasionally, and is even better, wrong as it is, than the map-like effect of a vacuum. The value of a properly-rendered bit of distance in a subject consisting chiefly of foreground can scarcely be over estimated. That little bit of distance is certain to attract attention more than any other part of the picture; therefore, in choosing a view to photograph, include some distance if possible, for as well as the additional interest excited, it acts as a foil to the nearer objects and throws them more boldly into relief. The point of view or station point is another most important matter in making a good picture; a few feet to right or left may make all the difference between artistic and inartistic rendering. Time is therefore not thrown away by moving the camera from one point to another in order to actually see the effect on the ground-glass, and choose the most preferable position. A view directly in front of an object is seldom so satisfactory as one taken a little to right or left of it. This especially applies to buildings where a view of the front, including a perspective view of the side, is almost always the most pleasing. With landscapes, supposing the tallest trees or other objects are on one side between mid-distance and foreground, a mass of shadow, or something that will take the place of it, should be on the other side in the foreground. This direction almost always holds good whatever the subject may be, and unless some arrangement of the kind is made the picture has a lopsided look that leaves an unpleasant impression. Coast scenes are very apt to have this effect, and the mind of the photographer is often considerably exercised in getting a proper balance. A figure may be posed to gain this end; but, unfortunately, a suitable figure is not always available. Placing a bush or some broken fencing removed from near at hand is apt to have an out-of-place appearance that seems exaggerated in the photograph when the subject can be minutely examined. There is a multitude of little differences attendant on things that have occupied one position for a length of time to those newly placed there. The various vegetable growths, grass, &c., are differently disposed, and never have that pressed down appearance that we generally see as when something is recently put amongst them. It is therefore best in all cases, if possible, to select such subjects that require as little as possible of artificial help, which at best is but a makeshift.

No natural object is more useful in picture making than water, from the merest puddle to the ocean itself. A small pool in the foreground will often redeem the whole composition. Water an inch deep will have as good and sometimes a better effect than if it was a fathom, by supplying a reflecting surface not so subject to be disturbed by wind or current, although in most cases if much water enters into the composition a perfectly mirror-like surface is not the best for pictorial effect. I was about to say that it was the worst, as very often it has a blank, unmeaning impression, whereas a slowly rippling surface in which the shadows are broken up is almost the best. A surface sharply ruffled by gusts of wind is, perhaps, photographically, the worst of all, it being represented as a blank, white space with neither depth or fluidity, more like a sheet of white paper, the ripples being so small that they are practically points of light that even with the most instantaneous exposure are always unsatisfactory. If it happens that the water is perfectly still, a few stones thrown in will make a visible improvement, for as soon as there is any motion of the surface the lights and shadows get broken up, and the water looks like water, and a much better effect is secured than if the surface remains absolutely undisturbed. This mirror-like reflection seems to some to be the very perfection of water rendering, and the cheerful, contented frame of mind I have often noticed, as they have shown me of these mirror-like representations with the remark, "You can't tell which is right side up, the water is so beautifully still," as if it was some great feat to make a picture that the right way up of it required some puzzling out. It may be all very well as a conundrum but not as a picture.

I believe there is much scope for photography in the artistic representation of groups of animals or poultry, for, with the exception of geese and swans, bird life is usually taken on a very small scale. Now, a direct picture, in which two or three specimens could properly fill the plate, and taken from a very low point of sight, could scarcely help to be attractive. Of course, artistic grouping goes without saying, but there are difficulties in the way; there is, no doubt, getting sufficiently near without observation is one, although with patience and management it may be done. There are certain times in the day when most animals, &c., are drowsy, and stand or lie about without much inclination to move. These are the times to be selected, and I do not think much difficulty would be found if anyone systematically set about it.

Hungry animals are generally restless, and the necessity to search for food gives them a rapid and unceasing action exceedingly objec-

tionable from a photographer's point of view. In the majority of instances such pictures are taken without any previous preparation; therefore, perfect success is very much a matter of chance. The plan often adopted of enticing by food just at the time the photograph is to be taken is, I fancy, a mistake, and has much the same effect as trying to keep a baby still by giving it sweets or biscuits under similar circumstances; it rather adds to the trouble than otherwise, as those having much to do with very juvenile juveniles can testify, and what photographer has not had his patience sorely tried by this same! In all we photograph, I would say as parting advice, cultivate simplicity and avoid spottiness.

EDWARD DUNMORE.

RECOVERY OF SILVER RESIDUES.

SEEING the prevailing discontent on the subject of the quantity of silver allowed for in the residues sent to the refiners, it is a matter of surprise to me that photographers do not make a practice of reducing their own waste and recovering the silver therefrom, for it is a metallurgic operation of the simplest character, and a pleasing one in performance.

I will relate an early experience of my own in this matter. I assisted in burning a quantity of spoiled prints and pieces of paper of all descriptions that were even slightly stained with nitrate of silver—the accumulation of some two or three years from a photographic establishment where a large quantity of work was continually carried on. There was quite a cartload of paper, which was burnt in the open air, and kept constantly turned with a pitchfork in order to get a brisk fire with as complete combustion as possible. There remained more than half a bushel of heavy, black ash, and the problem was how to get the silver out of this. I first stirred some of the ashes in a brassfounder's plumbago crucible at a high temperature, but could not by this means succeed in materially reducing the bulk of the ashes, in which combustion had apparently already reached its limit. To attempt to flux the ashes down would be impracticable on account of the enormous quantity of flux that would be required. I then bored a hole through the side of the crucible about an inch clear of the bottom, and conveyed a piece of gas pipe from the nozzle of a forge bellows to the hole in the crucible, in which I made a fire with a few large lumps of charcoal. When this was intensely ignited by means of the blast, I shovelled in the paper ashes, slightly damped to give them some coherence. The mass rapidly settled down as the paper now readily consumed under the direct action of the blast, and as I continued to fill up the crucible I occasionally threw in a small quantity of powdered nitre to serve as a flux. In less than an hour I had burned down the whole mass, and when cold there remained at the bottom of the crucible a nugget of silver weighing several pounds. (I cannot say the exact quantity, as the operation was carried out many years ago.) There was a cake of slag over the silver, which contained numberless small spherules of metal, which might have been recovered by pulverising and washing.

In a subsequent experiment I threw in with the paper a considerable quantity of "silver mud" which was also effectively reduced.

As to the outlay, this is quite inconsiderable, the chief item being the cost of the double bellows; but a complete portable forge may now be bought for three pounds, and one blacklead pot will last for this operation for any length of time.

F. H. WENHAM.

PHOTO-MICROGRAPHY.

[A Communication to the North London Photographic Society.]

I AM afraid the subject I have been asked to bring before your notice this evening may to some lack novelty as a thrice-told tale, but as I have been invited I cheerfully respond, hoping that I may be of use to some present in suggesting and assisting them to carry out what has proved to many a fascinating branch of the photographic art.

Photo-micrography is the art of making enlarged pictures of microscopic subjects by the aid of photography—the term micro-photograph being confined to such small photographs as need a microscope to render them visible in all their details. Photo-micrography may be regarded as taking over some of the work usually performed by the camera lucida, or any other appliance by which minute detail as seen through a microscope may be delineated. Many workers prefer the camera lucida for this purpose instead of employing the photographic process, and while the disadvantages and difficulties of both are well known, all must acknowledge that none are so physically immense as in that of photographing the subject of

many microscopical preparations. Amongst the greatest obstacles to the photographic delineation of microscopical detail is that arising from the varying planes of a subject possessing any thickness. This is not of much consequence in ordinary microscopical examination, as by practice and focussing up and down the varying planes presented to the eye of the observer can be justly estimated in regard to their sequential relations, and in making a drawing of them with the camera lucida these can be brought into harmonious combination, and a fairly representative picture produced. Not so with photo-micrographic delineation; it is candidly confessed that by this process only the front plane of the object can be reproduced in accurate sharpness, each succeeding plane increasing in want of definition till the rest are lost in one entire blur. This being true of even the very thinnest objects, it follows that the thicker the subject the greater will be the difficulty of obtaining any delineation worth looking at, to say nothing of its capability of conveying a correct impression of its nature and true character. Under these conditions only the camera lucida and the trained eye and hand of a skilful draughtsman can suffice to render an adequate representation.

These difficulties arise from physical causes, and will be found connected in a greater or less degree with all microscopical objectives alike, the only mitigation being afforded by using low-power glasses, so that provided the front plane of an object seen through one of these is sharply defined, there is not much falling off in the definition of several of the succeeding planes, certainly not sufficient to be offensive to the eye, but it gradually increases till the inevitable blur occupies the most posterior. These phenomena, which the lowness of the power enables us to detect and follow with facility, occur sooner in the higher powers, so much so that that plane behind the front immediately shows a falling off in definition, and the succeeding planes rapidly degenerate in indistinctness. This obstacle may to a great extent be minimised by employing the penetrability of the low powers and getting amplification by increasing the distance between the object and the sensitive plate. This method, however, must of necessity be limited in its applicability. This art has been practised by many, both in this country and on the Continent, since photography was first discovered, and considering the advances made in optical science it is discouraging to see how appreciably small is the progress towards perfection as displayed in the photo-micrographic examples exhibited. I should like to see other objects than echinus spines and sections of wood and such like worked at—these are comparatively easy to do; but I hope that when this branch of photographic science captivates by its fascination a few more enthusiasts that an advance may be made all along the line.

The apparatus employed for the purpose of obtaining photo-micrographs has varied slightly in outward detail, and a reference to the *Journal of the Royal Microscopical Society* for June, 1887, will show by illustrations the various instruments favoured by different workers. Some employ the eye-piece, and others do not. Those using the eye-piece may get sharpness over a very circumscribed disc, but I favour the instrument without the eye-piece, as for my class of work I do not wish to be limited to size, for in exhibiting pathological and anatomical subjects it is desirable to show as much as possible of the relationship of the different parts. If you wish to confine yourself to such small and complete subjects as diatoms or bacteria taken with the highest known powers, then it is not of much consequence to do more than photograph a small portion of your subject, just sufficient to show the character of the detail, when the eye-piece may be an advantage; but if your fancy lies in the direction of photographing whole insects or large sections of a histological character, then the eye-piece becomes a hindrance and is better dispensed with. This being the principle upon which I have worked I may now call your attention to the construction of the apparatus you see before you, which has enabled me to do fairly good work without much difficulty.

Those of you who have on former occasions seen the apparatus I devised for my first work will now see that I have modified it in one respect, but in one only. You may remember in the original arrangement I employed an objective, which, being screwed into a movable brass plate, occupied somewhat of the position of a lens in an optical lantern, the object to be photographed being held in a vertical movable stage which was capable of being actuated in focussing by a long micrometer screw; this, together with my oil lamp, included in an oblong lidless box placed on its side, constituted the home-made but very efficient camera. By means of this arrangement images of microscopic objects could be projected on to a card and made available for purposes of instruction or for drawing diagrams, and, of course upon a small scale, the image projected on to a sensitive plate could be photographed. I did very satisfactory work with this form of camera, as the album on the table can testify to; but I needed some further elaboration in the direction of condensing and centering

the light when using powers higher than one-fifth of an inch. About that time I was in communication with my friend, Mr. Walmsley, of Philadelphia, who kindly sent me this photograph of the arrangement he employed. I saw its applicability to my wants, and Messrs. Beck, who had made this for him, made one for me, being about the third of this character made by them. I have substituted this for my former apparatus of vertical stage and objective, retaining every other feature of the deal box and sliding baseboard, and I find it works with the greatest comfort and satisfaction to me—being steady and free from vibration, giving plenty of light with every provision for modifying it where desirable. With this short introduction to an old friend which has lately put on a modified face, I will pass on to a brief sketch of the light employed, and say a few words on focussing and exposure.

The light employed by me is from a microscopical lamp known as Beckett's—this is more than is sufficient for all powers up to one-fifth of an inch, above that it would be desirable to have one more powerful, but so arranged as to be capable of modification, because detail and sharpness is greatly depreciated by too much light. The oil I employ is a paraffin known as Strange's crystal oil, in which I place a piece of camphor about the size of an ordinary Spanish nut to the reservoir of paraffin; this dissolves readily and imparts a more actinic colour to the light. I find in practice that a larger quantity is unnecessary, besides soon coating the inside of the chimney with a yellow deposit. It is always advisable before commencing work to wipe out the chimney with a cloth moistened with spirits of wine so as to remove this deposit, and under all circumstances to start fair each night under the same conditions, because any variation in these might throw you out in your judgment of the right exposures. A plano-convex condensing lens is necessary, and should always be used with the plane side towards the object to be photographed so as to render the light rays parallel. The lamp should be lighted and placed in the apparatus for about five minutes before beginning operations, that every part may be warmed up and subsequent expansion of the brass work be moderated, if not checked altogether.

Focussing the Object.—The light being as accurately centred as possible, the object may be arranged on the white focussing screen, and that part selected which it is desired to photograph. Being able by this arrangement of mine to see the focussing screen with the greatest ease, this selection can be made without any difficulty, and a certain amount of rough focussing can be done. The white screen can now be removed, and the glass focussing screen may be substituted. Many suggestions have been made relative to the character of this screen, as ground-glass is out of the question where fine and complicated detail has to be sharply focussed. That which commended itself to my judgment as being applicable to this purpose has been described by Mr. Walmsley after the following manner:—A sensitive plate being exposed momentarily to daylight is developed to a very slight extent, and not sufficient to give any considerable density. After washing, fixing, and drying, it is to be immersed in a bath of mercuric chloride till it is whitened. This makes a very efficient screen, but is not so satisfactory in my hands as the clear glass I use after this fashion: An old plate may be cleaned, and some fine lines, made by the very light draught of a writing diamond, may be drawn across it at short intervals, a set being also drawn at right angles to these; it is thus roughly divided into squares. This surface must always be placed next the object. To enable us in the semi-darkness of our room to distinguish this surface from the back, it is well to affix to the edges of the back some narrow strips of postage-stamp bordering, which will be sufficient to indicate the difference. The object being illuminated, and having been roughly focussed on the white screen, may now be looked at through the glass plate and focussed till its details are as clearly defined in the focussing glass as are the scratches on the plate; as these are approximately on the same plane as the gelatine film we may be satisfied that we shall get a tolerably sharp negative. If we adopt the plan first suggested for making this focussing screen, we may get the focus absolutely on the right plane if the plates are all coated to the same thickness; but the difficulty of seeing the detail of a pathological subject through even the slight opacity of such a screen is a hindrance to sharp focussing, and, therefore, does not recommend itself strongly for this purpose, but might answer for coarser detail.

T. CHARTERS WHITE.

(To be continued.)

COPYING.

YOUR answer to "A. Z. (Worcester)," induced me to repeat the experiment I made, and which I roughly described in my article in the *JOURNAL* of 11th November under the section "Lantern Slides." My

object now was to try for both an enlargement and reduction, thus covering the copying a subject the same size. The following is the result :—

Enlargement.—Camera, $7\frac{1}{2} \times 5$; lens (Dallmeyer's wide-angle rectilinear), $7\frac{1}{4} \times 4\frac{1}{2}$, screwed inside the camera, thus reversing the lens; height of subject to be copied, 3 inches; distance of subject from front of lens, $5\frac{1}{8}$ inches; ditto of focussing screen from back of lens, $14\frac{1}{2}$ inches. *Result.*—Enlarged to $6\frac{3}{4}$ inches.

Reduction.—Camera, lens, and height of subject, the same; distance of subject from front lens, $10\frac{1}{4}$ inches; ditto of focussing screen from back of lens, 7 inches. *Result.*—Reduced to 2 inches.

I did not photograph either, not thinking it necessary. Many who have not a copying camera, or whose camera does not extend sufficiently, will find a great advantage in this arrangement. I do not claim that my measurements are mathematically correct, but they are very close, within an eighth of an inch, I believe.

GLASS STEREOGRAMS.

In renewing the binding paper on some of these, taking off the covering glass to examine, and wiping the clear glass edges, I happened to touch the print, and to my surprise found it covered with a very thin layer of a powdery nature, that came off easily by use of a piece of soft washleather without the slightest damage to the print; on the contrary, it brightened it. I suppose it to be an oxide of silver (?). This is, perhaps, worth mentioning, as there must be many of these older glass stereograms in existence, and the possessors may think them to be fading. One or two that had been thinly varnished before the covering glass was put on were all right, and so were those I have of Breezes's peculiar productions.

HYDROKINONE.

Examined by microscope, and polariscope, and micro-spectroscope. The two samples mentioned in my last do not essentially differ under this examination. The samples contain few, if any, well-defined crystals; some portions have no defined shape, but appear as agglutinated masses; but both polarise well. If there is any approximate form it appears to be hexagonal. Micro-spectroscopically, I made the following notes: Bands of well-defined black lines running across the spectrum; spectrum bright and clean when stage of microscope removes object, showing there was no dust in the slit; lines more distinct and density increased by throwing them out of visual focus; the black lines divided at irregular intervals by open space, or spaces of the breadth of two lines, and sometimes more; there appears some slight but ill-defined absorption in the red end of spectrum. The examination was simply microscopical, and for polarisation and micro-spectroscopically. The effect of polarising through the spectroscope is very curious.

APPARATUS.

A very useful piece can be made by buying two cheap deal dressing-tables (about 5s. each), and fastening them one on the top of the other. The under one may be with or without a drawer as may be desired, but the upper one without a drawer. If a slip of wood is nailed round the bottom of the legs of the upper one a very useful tray is formed. It is very light, and can be used either as a camera stand for indoor use, cutting a slot in the upper table to put the screw of the camera through, or it forms a good Sciopticon stand. A wooden arm with half a dozen joints holds a negative or print at any distance or angle required for copying. W. T. F. M. INGALL.

LANTERN SLIDES.

[A Communication to the Manchester Photographic Society.]

THE method of making lantern slides or transparent positive pictures on glass, to be exhibited by the projecting lantern, has occupied the attention of photographers from a very early date in the history of that branch of art and science, the first to suggest such an application to the lantern being one of our late townsmen, Mr. Dancer.

It is not my intention to wade through the history of the various processes which step by step have developed into the splendid results at the command of every lantern exhibitor of the present day, nor do I propose to state any fancy formula that is as difficult to compound and understand as it is when decocted to obtain the results fore-shadowed.

The preparation of a sensitive plate that will produce all the colours of the rainbow, and a magic developer that will, without the addition of that all-important restrainer, brains, produce results of surpassing beauty, are not any part of my task to-night. Those persons who have much time at their disposal may profitably occupy a portion of

it by making lantern plates; but before doing so I would advise them to experiment first with collodio-bromide emulsion, gelatino-chloride, and gelatino-bromide, which are the leading dry plates that can be obtained from commercial houses noted for excellence of production in every respect. By doing so they will become familiar with the good and bad qualities of negatives varying in density and subject, and numerous experiences will be passed through which will be of great value later on.

After thus experimenting I would further advise the study of such books as Captain Abney's and Dr. Monckhoven's on emulsion. When you have made yourself acquainted with the instructions on coating, drying, and chemical formula, select some well-trying method, and, without adding or taking from the one selected, make up your mind not to change until you have patiently given the one in hand a fair trial. You must not expect to find a royal road to success, or go through without failures and mistakes. These will teach you more than all your successes.

I am probably like most of you, with little time at my disposal; it is therefore of primary importance that in all these experiments the apparatus and the methods adopted must be the most convenient. In introducing to your notice the making of lantern slides, or the production of enlargements by the aid of artificial light, I do not wish it to be inferred that I prefer or advocate it in preference to daylight; but I do maintain that to me it does hold out advantages which I cannot obtain from daylight. It may be when I am at liberty the sun is not in the brightest of moods, or, if pouring forth his beams of brightness just when I have got all fixed, by the time the first exposure is made I am interrupted by some friend calling in, which puts an end to further progress, with the discouraging fact that at some future day I must start again under new conditions with regard to actinic power of the natural source of light.

It is with the object of reducing this uncertain element in the process, coupled with the convenience of being able to work any night with a standard light, that I have experimented with gas, oil, lime, and the magnesium light. After giving all these a fair trial by direct and reflected light, assisted by condensers and reflectors of various forms, I have given the preference to the magnesium light as being the most convenient, and by using a certain number of grains in proportion to density of the negatives I can depend on a certain amount of light, which cannot be said of the other systems named. Artificial light enables you to deal with defective negatives, such as those with one side of greater density than the other, caused by uneven coating, or where you have great contrast, such as thin foreground and bright distance. These effects can be considerably improved by moving the light a greater number of times over the dense portions of the negative.

For very thin negatives I prefer to use either gas or a weak-coloured orange glass, placed about one inch from the negative, and behind the ground-glass when using magnesium.

The magnesium ribbon I have found most suitable is much thicker than that usually sold, and weighs one grain to the inch in length. I cut this into lengths of two, three, and four inches, and for very thin negatives use two grains for good printing negatives, or what I call my standard three grains, and if a little above pitch, four grains; and it is only when I am dealing with very dense and unsuitable negatives for lantern slides that I use daylight.

The development of lantern plates and positive enlargements can be accomplished with either ferrous oxalate or alkaline pyro solution. The tone or colour of pictures can be modified by the addition of acids, carbonates, chlorides, and citrates of soda, potash, and magnesia. For further information, I would refer my hearers to THE BRITISH JOURNAL OF PHOTOGRAPHY, page 522, 1887, and to Swan's and Fry's lantern plate developers. The developer I shall use to-night is compounded of—

1.	
Potassium oxalate	480 grains.
Ammonium chloride	4 "
Distilled water	3 ounces.
2.	
Ferrous sulphate	120 grains.
Citric acid	60 "
Distilled water	1 ounce.

The apparatus you will have an opportunity of examining. There is nothing new about it, and, although appearing an expensive arrangement, it was cheaper than constructing a special camera, as I was already possessor of the camera, which only required mounting on the board which supports it, and allows of any amount of adjustment to various sizes of lenses and negatives for either enlargement or reduction.

J. SCHOFIELD.

Our Editorial Table.

PHOTOGRAPHY SIMPLIFIED.

London: MAWSON & SWAN.

This is a practical treatise for the use of amateurs or professionals, and as stated on the title-page it contains useful hints to beginners on the selection of apparatus and on general practice. It is the third edition, and has been considerably revised and enlarged.

The field embraced is one of considerable extent, and it is refreshing in these days, when gelatine reigns supreme, to find a chapter devoted to the ever-useful wet collodion process, concerning which we have nothing but good to say, except in the employment by the author of that hateful and incorrect term "redeveloping solution," by which of course is meant *intensifying* solution—a term that we grant is time-honoured, but capable of being reformed. Still, the chapter on wet collodion will be welcome in these days when so few, of the many manuals, take cognisance of anything but modern processes.

For the beginner in photography the work will be found specially useful, as the different subjects, though necessarily briefly treated, go sufficiently into working details to enable any one of ordinary intelligence to grasp the subject in hand without recourse to personal tuition, a point in which most of the existing books fail, being either too technical or presupposing an acquaintance with the science which they themselves ought to impart.

Scarcely any department of photography is left untouched, and it is not necessary to say in connexion with a firm so well known in every branch of science as Messrs. Mawson & Swan that the instructions are concise, practical, and useful.

One minor fault strikes us, namely, the binding up with the other matter of a series of useful labels, which to be of use must be abstracted, and possibly injure the stability of the binding; but if these when required are carefully cut out not much harm will be done.

SUTER'S PORTRAIT APPLANAT.

MR. J. R. GOTZ, 19, Buckingham-street, Strand, has afforded us an opportunity of critically examining some of Suter's latest optical productions, especially in the domain of lenses of the applanatic form, but having angular apertures greatly exceeding those associated with objectives of the rapid doublet class. Of these a description of two will suffice.

The larger is one of about ten inches focus, and has an aperture so great as to equal $\frac{1}{55}$, which, we need scarcely say, fits it for every class of portrait work in the studio. With the stop No. 2 of the Society's standard, the lens works with a high degree of rapidity. With smaller stops the area of sharp working, combined with depth, is increased, until at last it becomes a 12×10 objective, its short tube and the pronounced form of the lenses admirably adapting it for the transmission of a pencil of light at great obliquity to the axis. The diaphragms are placed in such a position that the projections are quite free from distortion, and the relation of each lens to the other such as to ensure freedom from a flare spot. The trade designation of the lens is the *D. Rapid Applanat*, No. 1.

The second lens is of much smaller dimensions, having also a smaller angular aperture. It has a focus of six inches, and is intended either for detective camera purposes, or as an element in the stereoscopic camera.

We are informed by Mr. Gotz that M. Suter is indebted in no small degree for the large aperture he obtained to employing some of the recently introduced glass of Professor Abbe. As hinted above, the apertures in the diaphragms are regulated according to the standard of the Photographic Society of Great Britain. The definition is all that can be desired.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST Tuesday night, at a meeting of the above Society, held at 5A, Pall Mall East, London, Mr. James Glaisher, F.R.S., President, occupied the chair.

The minutes of the last meeting having been read,

Mr. J. G. B. WOLLASTON said that supposing a member objected to the nomination of a candidate for membership, he wished to be informed what rule that member should follow to get the balloting for that candidate put separately.

The PRESIDENT replied that he always stated beforehand that if there were a sufficient number of black balls he would then have each candidate voted for separately.

Mr. WOLLASTON stated that he had formally objected to one of the candidates at the last meeting, and had given his protest to the Assistant Secretary before the meeting began.

The CHAIRMAN responded that the protest should have come to himself. He knew nothing about it.

Mr. E. COCKING, Assistant Secretary, said that he had not the slightest recollection of the matter.

Mr. WOLLASTON replied that he wrote his protest in ink on a piece of paper in the presence of the Assistant Secretary and then handed it to him.

Mr. COCKING responded that he had been unable to find it among his papers.

Mr. WOLLASTON added that when he found at the last meeting that candidates were, nevertheless, to be voted for *en bloc* he wrote a note to the Hon. Secretary, Mr. Donkin, on a postcard he had in his pocket, saying that there must be a mistake about such and such a name. No notice was taken thereof; he therefore thought that the persons balloted for at the last meeting were not duly elected.

Mr. W. E. DEBENHAM said that they were unduly elected because that name about which there was a protest was not taken separately.

The PRESIDENT then took a show of hands as to the signing of the minutes, and there was a large majority against their being signed.

The PRESIDENT remarked that he had never heard of a case of the kind before; if the meeting said that those minutes were not to be confirmed he would leave the chair and never enter it again.

Mr. SAMUELS said that at the last meeting the President had turned up the balloting box and said that there were no objections to the candidates whatever; if he (Mr. Samuels) had objected to any candidate he should have put in a ball on the "No" side. He submitted that it was a proper election.

The PRESIDENT added that there was no protest before the meeting and no black ball in the box; he, therefore, declared those minutes to be correct, and if the meeting said that they were not correct he replied that "they were."

Mr. WOLLASTON stated that as he had made his protest he was satisfied.

Another show of hands about signing the minutes was taken; two only voted against their being signed; they were confirmed accordingly.

The following new members were then elected:—Mr. Samuel Bourne, Miss E. Boyer Brown, Lieutenant A. H. Corrie, R.E., Mr. Horace L. Field, Miss Grumman, Messrs. Walter C. Johnson, H. Chapman Jones, Eustace H. Turner, and Alfred Werner.

The PRESIDENT announced that the retiring officers and members of Council were himself, Captain W. de W. Abney, Messrs. W. S. Bird, W. Bedford, W. Cobb, Cadell, A. Cowan, and Leon Warnerke. Nominations for the filling of the vacancies must be sent in not later than Monday, January 23. He added that at the meeting on January 10 stereoscopic appliances and work would occupy the attention of the Society, and he hoped that members would bring objects of interest in relation to the subject.

An adjourned special general meeting was then held to continue the revision of the rules of the Society.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday night, December 8, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. A. Cowan presided.

The CHAIRMAN exhibited a still stronger example than on a previous occasion of the positive left upon glass after fixing and then dissolving off the negative image in boiling water; the positive was so powdery that he doubted if it contained any gelatine.

Mr. A. HADDON thought the explanation to be that the pyro spent its energy in developing the blacks, therefore could not render the gelatine below them insoluble in water; in the other parts it acted with undiminished vigour, therefore the gelatine in contact with the glass beneath became insoluble and gathered there more or less silver from the rest of the image. He believed, from the amount of friction necessary to remove the positive image, small though that friction was, that the positive contained a little gelatine.

Mr. C. HEINRICH TRINKS was of opinion that it contained no gelatine.

Mr. A. MACKIE exhibited a camera devised by Major Durnford, which, he

said, could be fitted up readily in thirty seconds, could be turned easily on its side, shut into small space, and was of ingenious make.

Mr. W. M. ASHMAN said that the arrangement for turning it on its side was either a copy of Scovill's plan or Scovill's was a copy of Major Durnford's.

Mr. MACKIE replied that Major Durnford claimed no novelty in that respect. Mr. A. P. HIGGINS exhibited a camera bellows he had made of an artificial "leather cloth" costing 2s. 3d. a yard; the bellows cost him 2s. altogether for materials.

The CHAIRMAN remarked that the stuff was called "leatherette."

Mr. ASHMAN stated that a member of the Association had made a 12x10 camera out of *Times* newspapers, and was using it daily. The solid parts were made of paper pasted together; the dark slides were of the ordinary kind, bought in London.

Mr. WALLACE asked the cause of the "superficial toning" of silver prints, adding that on soaping the prints with flannel some of the colour came off on the fabric without visibly reducing the image.

Mr. TRINKS, Mr. ASHMAN, and the CHAIRMAN, expressed the opinion that by toning it was impossible to entirely substitute gold for silver in the finished print.

Mr. ASHMAN thought that the described effect might be due to dust settling on the prints while they were left about.

Mr. WALLACE responded that the colour was evidently from the print itself.

Mr. ASHMAN thought Mr. Wallace to be in error.

Mr. HADDON supposed it might be finely divided gold deposited by subsidence from an old toning bath.

A question in the box asked whether the best lantern screen could be made from linen, calico, or "union."

The CHAIRMAN thought unglazed union to be the best if the screen had to be folded, otherwise glazed was the best.

Mr. TRINKS had found paper to make the best screen; the more dead-white the surface the better.

Mr. HADDON thought that a glazed surface should never be used.

Mr. W. M. AYRES liked a dead surface, slightly woolly.

Mr. C. H. COOKE exhibited some platinotype prints.

The HON. SECRETARY announced that two members of the Managing Committee, Mr. W. M. Ashman and Mr. H. M. Smith, had resigned because of approaching absence from London.

Messrs. H. M. Hastings and Edgar Clifton were then unanimously elected to fill the vacancies.

CAMERA CLUB.

On Thursday, December 8, Mr. A. PRINGLE read a paper on *Photographic Residues*. Mr. S. B. Webber was in the chair.

Previous to the reading of the paper Mr. FERRERO explained an ingenious piece of mechanism he had added to a roller slide for automatically registering the number of exposures made.

The Hon. Secretary handed round an album of Mr. J. S. Blanckensee's, containing photographs taken chiefly on the Cornish Coast.

A new print washer, invented by Mr. A. Kellar, of Cardiff, was also exhibited. In this the prints are inserted into a perforated cylinder or drum, which revolves slowly in a large trough of water, the revolution being actuated by the dropping of water from a tap upon a wheel which is attached to the cylinder. Its action was much admired.

In the course of his very practical and yet amusing lecture, Mr. PRINGLE described the best means of recovering silver from the first washing waters and cuttings of silver papers, and from hypo baths, gold from old toning solutions, and platinum from platinotype paper and platinotype developers. He also exhibited some of the apparatus employed and performed an experiment.

Mr. W. ENGLAND showed some interesting apparatus and described his methods of procedure.

The CHAIRMAN gave particulars from a record he had kept of the exact gold savings effected from his old toning baths.

The discussion was further carried on by Messrs. Welby, Hussey, Ferrero, the Hon. Secretary, and other members.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

At the meeting held on December 6 at Myddelton Hall, Islington, N., Mr. J. Traill Taylor, President, in the chair, Messrs. J. P. Mears, W. M. Ashman, and C. M. Griffiths, were elected members of the Society.

The PRESIDENT read a letter from Mr. H. M. Smith, announcing that that gentleman was leaving London, and in consequence thereof was compelled to resign his post of Hon. Secretary and Treasurer.

Mr. J. HUMPHRIES felt sure that all the members would regret losing the services of Mr. Smith as their Hon. Secretary and Treasurer. Mr. Smith had held the office of Hon. Secretary since the first institution of the Society, under the title of the North London Amateur Photographic Association, and had performed his duties with great skill and energy. It was not too much to say that the Society was indebted for its present prosperity mainly to the labours of Mr. Smith. He would, therefore, move, "That the Society, in accepting the resignation, desires to express regret at Mr. Smith's retirement and to thank him heartily for the services he has rendered."

Mr. J. OAKLEY seconded the resolution, which was unanimously carried.

Mr. SMITH, at a later period of the evening, having been informed by the President of the resolution, said he felt great sorrow at having to resign his post. He should not, however, resign his membership, and hoped from time to time, during his visits to London, to be present at the meetings. He thanked the members for the kindly way in which they had expressed their appreciation of his services and also for the assistance they had rendered him in the performance of his duties. He trusted that the spirit of friendliness which existed throughout the Society would continue, and that its present prosperity would increase.

The PRESIDENT presented a bound copy of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1888, for which he was thanked.

Mr. A. MACKIE, in exhibiting a camera, said that it was invented by Major

Durnford, whose name was well known in connexion with an ingenious little piece of apparatus known as the "Right-about-turn shutter." It was a whole-plate camera, and was remarkably light and compact, the measurements being 9 3/4 x 8 x 3 inches, all projections included. There were no loose parts of any kind, and the tripod head was part of the baseboard. The camera simply set up would allow of a variation of focus from three to nine and a half inches, but, by an exceedingly ingenious and simple arrangement, the baseboard could be extended to allow a focus up to seventeen inches. There was a novel method of obtaining both vertical and horizontal swing to the back, and also an easily and rapidly worked arrangement for setting the camera on end for upright pictures. Major Durnford claimed, Mr. Mackie said, that the camera might, when its working was understood, be brought into action in thirty seconds; but he would demonstrate that Major Durnford had modestly overestimated the time required.

The camera was examined with great interest, and the ingenuity of its action was much appreciated.

Mr. A. P. HIGGINS showed a platinotype picture which he had soaked in aqua regia, the image, however, was but slightly reduced.

Mr. J. Jackson passed round a print on alga paper.

Mr. T. CHARTERS WHITE then delivered a most interesting lecture on *Photomicrography* [see page 792], and at its conclusion gave a practical demonstration of the method of working with his apparatus, a very good negative being produced of the tongue of a blowfly. In the discussion which ensued,

The PRESIDENT asked whether Mr. White found it necessary to make any allowance for the over correction of micro-objectives for chemical focus.

Mr. WHITE did not make any allowance, and had experienced no difficulty on that account in working with objectives up to one-fifth of an inch.

The PRESIDENT explained the construction of an apparatus by means of which stereoscopic effects might be obtained. He also stated that pictures might be obtained which could be mounted and viewed as stereoscopic slides by making two negatives illuminated by oblique light from opposite sides. Another method was to take one negative with half the objective, the other half being covered, the other negative being taken by covering the half of the objective used for the first negative. Stereoscopic effect could also be obtained by tilting the slide slightly, a second negative being obtained tilting the slide to the same degree but in the opposite direction.

Mr. WHITE, referring to the difficulty of centering the light, said that the eye of *dytiscus marginalis*, being a group of minute lenses, required absolute accuracy in this respect, and any deviation was very apparent from the direction of the shadows. The difficulties of photographing bacteria, which Mr. Pringle had successfully overcome, arose principally in the lighting. He found it a mistake to have too strong a light, and for ordinary purposes Bockett's microscope lamp was sufficient.

Mr. HUMPHRIES said that those who felt inclined to take up this branch of work need not be deterred by the fear that the apparatus must necessarily be expensive. An ordinary two-guinea microscope would do all the work of a more expensive instrument, the only disadvantage being that a little more time must be spent and more care taken in obtaining the adjustments. To work successfully it was necessary to have some knowledge not only of the microscope but of the object, so that its distinctive features might be brought into prominence. He would recommend beginners to choose for practice a well-marked diatom, such as *arachnoidiscus*.

The PRESIDENT said very good micro-photographs of objects not requiring high powers might be made with ordinary photographic lenses of short focus, the little combination lenses used for postage stamp portraits being quite suitable.

A hearty vote of thanks to Mr. White terminated the proceedings.

The next meeting will be held on December 20, and will be a technical meeting.

NORTH SURREY PHOTOGRAPHIC SOCIETY.

At the last meeting of the above Society, held on December 7, at the Greyhound Hotel, Dulwich, there was a full attendance of members and many visitors. Mr. James occupied the chair.

Messrs. J. Thomson, F.R.G.S., and Herbert Starnes were elected honorary members of the Society.

It being a lantern night, no formal communication or paper was read, but several important matters of business were considered.

It having been found that Wednesday evening was inconvenient to some members, it was decided that the night of meeting be changed to Tuesday.

The present place of meeting being found to be also inconvenient to some, Messrs. Crossthwaite and Senior were deputed to ascertain if a suitable place of meeting could be obtained in Norwood-road, which was found to be the most convenient centre, and to be of easy access from West Norwood,ulse Hill, Herne Hill, and Dulwich Stations.

Mr. J. THOMSON, who had been requested by the Society to act as Judge in the competition for the Hon. Secretary's prize, then gave his report. This prize was for the best set of six prints from negatives taken during this year. Having remarked on the high order of all the prints sent in, Mr. Thomson said that it was not without difficulty that he had decided to award the prize to "Achromatic," whose prints showed both great artistic merit and technical excellence.

The CHAIRMAN, having opened the envelope containing the name of "Achromatic," announced that Mr. Lewis Wolf was the winner of the prize.

Mr. Wolf's prints, which were handed round, consisted of two albumen, three platinum, and one bromide, and it was a subject of much comment that the bromide print, which was on Eastman's "A" paper, could not be distinguished from the three platinum prints either in tone or quality.

Mr. CROSSTHWAITE announced that he would offer a prize of the value of one guinea for the best set of six lantern slides, to be sent in before the first meeting of the Society in March.

Mr. BUXTON MORRIS also announced that he would offer a prize of one guinea for the best set of six prints from negatives to be taken during the next season, and Mr. THOMSON supplemented this prize by a second of one guinea for the best single print of those sent.

Mr. W. H. WALKER, in commenting upon the work done by the Society during the year, said that it compared favourably with that done by the older and larger societies, and he congratulated the members on the interest they had shown in matters pertaining to the fundamental principles of photography, and offered a prize of one guinea for the best paper on any subject pertaining to the technique of photography.

The business meeting was followed by an exhibition of lantern slides contributed by members and others. Among those deserving special mention was a series of instantaneous views by Mr. Fincham, which were of exceptional quality. Some slides by Mr. Dresser were interesting from the fact that the negatives were drop shutter exposures on Eastman strippers in a detective camera, and were taken in a dull light during the month of November. A number of American slides lent by the Camera Club were much admired. In all two hundred and seventy slides were put through the lantern.

Mr. Myer was elected Chairman for the next meeting, on December 21, when a paper on *Silver Printing* will be read by the Secretary, and the Society adjourned.

A NEW SOCIETY—BARNET.

ON Monday evening, the 5th instant, there was inaugurated at High Barnet a Society in connexion with the ancient Grammar School of the town under the title of "The Barnet Elizabethan Photographic Society."

A meeting was held for the purpose of bringing together present scholars, old boys, and friends, some of whom are already photographers. The Head Master, the Rev. J. Bond Lee, M.A., took the chair and efficiently directed the business of the meeting, being unanimously voted President.

A Committee was appointed to draft rules and regulations, who, supported by a substantial members' roll, will doubtless make the Society a thorough success.

Mr. T. SAMUELS sketched concisely the past and present state of the art, and the benefits arising from a union of workers, basing his remarks upon a practical experience of thirty years' standing. In his exposition he was assisted by Mr. A. MCKENZIE, who kindly put his lantern at the disposal of the young Society, and by its means were exhibited some of the possibilities of modern photography, including a fine series of micro-photographs, local objects of interest, Scandinavian views by an old boy, &c., which appeared to awaken the enthusiasm of all gathered within the mediaeval precincts of the quaint old dining hall.

CHESTER SOCIETY OF NATURAL SCIENCE. PHOTOGRAPHIC SECTION.

THE second meeting of the session was held in the Lecture Theatre, Grosvenor Museum, on Thursday, November 24, when the CHAIRMAN (Mr. E. W. Parnell, F.C.S.) delivered a lecture on *Paper Negatives and Stripping Films*.

In the course of a very interesting paper the various forms of apparatus used for holding the negatives were described, an Eastman-Walker roller slide being sent round for inspection; the exposures and various methods of development were detailed at considerable length. The films were then referred to, specimens of the earlier and the latest films being shown; the methods of using these were then demonstrated, at the close of which a large number of paper negatives, oiled and plain, films, and prints, were then sent round for examination.

A hearty vote of thanks was given to the Chairman for his interesting paper. THE SECRETARY then announced particulars of the Exhibition to be held in Liverpool in March next by the Liverpool Photographic Society.

THE third meeting was held in the Lecture Theatre on December 1, taking the form of an exhibition of negatives, prints, and lantern slides. A large number of plates were sent in, also prints on silver, bromide, platinotype, and Rivot's self-toning papers.

Lantern slides lent by Messrs. A. W. Beer, of Birkenhead, and P. Okell, of Bowdon, were very much admired.

There was a good attendance.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

THE ordinary meeting of the above was held in the Free Public Library, Hamilton-street, on the 8th instant.—The retiring President (Mr. J. A. Forrest) in the chair.

Messrs. J. A. Sinclair, J. L. Mackrell, W. Wilkinson, B. W. Moore, and Bardsley, were elected as members of the Association.

The annual competition prints were handed round for exhibition, including Mr. J. H. Day's prize one, for which a silver medal was awarded by the Judges, and which has been selected by the Council for enlargement up to 15×12, as the annual presentation picture, to be printed in platinotype and carbon, there being considerable difference of opinion amongst the members as to which was the most artistic and suitable process, the warm and cold tones of each having their respective admirers.

The remainder of the evening was devoted to an exhibition of slides, Mr. F. Evans manipulating his oxyhydrogen lanterns. Mr. C. B. Reader was represented by a number of scenes in Devonshire; Mr. P. Lange by a fine collection of slides from negatives on stripping films taken in the detective camera, illustrating "boat drill" on board a Cunard steamer, street scenes, &c.; the Secretary (Mr. G. A. Carruthers) by views in the north of Ireland; Mr. F. N. Eaton by scenes in North Wales printed on wet collodion plates toned with platinum. Mr. Evans had a collection of statuary lent by Mr. Archer, Liverpool. Messrs. Forrest, Lupton, Cornish, Latimer, and Mackrell, were also represented by work done in different localities.

In order to encourage members to produce good lantern slides, Mr. Evans placed at the disposal of the Council a silver and bronze medal for a competition to be held at the February meeting for the best set of four slides, all to be printed from the same negative, but each to be of a different tone, preference to be given to the set having the greatest variety of colour.

A vote of thanks to the lanternist terminated the proceedings at a late hour. From the third annual report of this Association we learn that at the close of the year 1886 the roll book showed a list of fifty-four members, twenty-four new members have joined during the current year, and there were nine resignations, &c., leaving sixty-nine members now on the books, and that the Treasurer's account shows a balance in hand to the credit of the Association of 117. 2s. 10d.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

THE usual fortnightly meeting of the above Society was held in the Technical Schools, Bridge-street, on Thursday, the 8th inst.,—Mr. E. H. Jaques (Vice-President) in the chair. Sixty-four members were present.

The minutes of the last meeting were read and confirmed.

Messrs. W. T. Horton, Walter Griffiths, and R. Norris were elected as members, and Mrs. Hart and Messrs. E. Fowler, J. A. Richards, and E. Marlow nominated for election.

THE HON. SECRETARY read a letter from W. Griffiths (enclosing two plates which showed the image after exposure and before development) in which he wrote the following observations:—"Having long ago observed that ordinary dry plates change colour on exposure to daylight, I lately put one or two behind negatives in ordinary printing frames and exposed them to daylight (November). A few seconds produced the image you see herewith and no amount of light after that would deepen the image; in fact, I gave one an hour and it came out just the same. It was observed at our meeting on November 10 that the phenomena frequently occurred, and was not uncommon after a long exposure or a very bright light, such as a window, was thrown upon the plate. I am inclined to think the effect can be produced at will by observing these conditions. It seems to me a question whether pure bromide of silver has the property of darkening upon exposure to light, or whether a trace of some "printing out" substance be present in the film, such as chloride of silver, which would account for the result. Gelatine probably contains sufficient common salt to produce the effect, though how it escapes elimination in the washing of the emulsion I cannot account for. I have kept some of these exposed plates about two or three weeks and the image is quite distinct now, and I expect would keep indefinitely." Discussion on the matter was postponed till such time as Mr. Griffiths would be present.

A number of exhibits were shown, notably early prints from collodio-bromide plates and instantaneous pictures, 1863 (Sayce), by W. J. Harrison, carbon prints by W. Curtis, instantaneous pictures of Buffalo Bill's company, by A. Leeson, and a very compact and useful washer made by Fell & Co., Wolverhampton, by J. F. Pickard.

The remainder of the evening was devoted to a lantern display by Mr. Charles Pumphrey, which consisted of a large number of scenes taken during a tour in the United States and Canada. He afterwards showed numerous pictures of flowers and ferns, and then exhibited the same which he had tinted and coloured by hand, much enhancing the appearance on the screen. A very effective picture was one of skeleton leaves and plants, &c.

NEWCASTLE PHOTOGRAPHIC ASSOCIATION.

AT the ordinary and special meeting of the Newcastle and Northern Counties Photographic Association, which was held on the 13th instant, Mr. P. M. Laws, the Treasurer, presented a rough statement, showing that, notwithstanding the abnormal expenses for the present year, the Association was still on a sound financial basis, and only required the active co-operation of the members to place it in as good a position as ever.

After the regular business was disposed of, Mr. J. P. Ginxon, of Hexham, in the name of the members, presented Professor Herschel, the President of the Association, with a handsome album filled with photographic views contributed by the members. Mr. Gibson alluded to Professor Herschel's distinguished position and name in the scientific world and his researches appertaining to photography, and expressed the general regret at his removal from this district and the severance of his connexion with the Association, of which he has been a member from its foundation and president for three years, and for which he has worked so ardently and disinterestedly.

Professor HERSCHEL, who had been kept completely in the dark as to the testimonial, expressed his gratification at the unexpected compliment, and also his pleasure at the form which it had taken. He desired to say how much he regretted his unavoidable retirement. He wished the Society every success, and trusted he would be able to come amongst them occasionally, when he felt sure he would not be received as a stranger.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

THE ordinary meeting of the above Society was held in the Society's Rooms, Masonic Hall, on Wednesday December 7,—The President, Councillor Firth, in the chair.

Mr. A. S. PLATTS then read a paper on *The Doctoring of Negatives for Printing Purposes*.

THE SECRETARY showed a negative that had been varnished on the back with a matt surface, and described how simple it was to work a cloud on it with a stump and a little crayon.

A lantern-slide competition was arranged to take place on the first Tuesday in March, the first and second winning sets to become the Society's property. Mr. Shields presented his last year's winning set, also an extra half-dozen.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—On Thursday, December 22, a paper will be read by Mr. Norman Macbeth on *The Construction and Requirements of Portrait Art*.

Correspondence.

Correspondents should never write on both sides of the paper.

A REVOLVING FOCUSING GLASS.—A TRANSPARENT SUPPORT FOR FILMS.—
A NEW ROLLER SLIDE.—THE AUTOCOPIST FOR PHOTOGRAPHIC PRINTING.
—A NOVEL MODE OF OBTAINING FACSIMILES.—M. BALAGNY AND HIS FILMS.
—LANTERN VIEWS.—PHOTOGRAPHIC WASTES: HOW MANAGED IN FRANCE.

M. THOUROUDE exhibited a focussing glass, which he had been using for some years to focus photo-micrographical objects. It may be remembered that in a former letter I spoke of M. Aimé Girard's idea of the focussing glass oscillating during the operation of focussing, which, in his opinion, was a great advantage. M. Thouroude thought it well to show us that this idea was not new, and that he had employed it upon a better principle. His ground-glass is in form a disc embedded in a sheet of brass. Through the centre of this disc is a hole, in which a steel axis has been fixed and centred to a point. The glass disc can now be turned by a twist of the fingers, will spin round like a boy's top, and will revolve for a length of time if the axis be well centred. The brass frame is placed upon the microscope, the rays of light pass through the hole D, and the image is designed upon that part of the disc which is over the hole D. The disc is then made to revolve, and the object focussed. This operation is much easier and truer than if a fixed ground-glass had been employed, said M. Thouroude, because the best ground-glass is formed of opaque and brilliant facets, which deviate the rays of light. When the ground-glass is not stationary, this fault is eliminated. A discussion took place as to whether the ground-glass could not be replaced altogether by means of an *oculaire* (eye-glass), as adapted to a camera by M. Vidal. M. Thouroude replied that the system of the eye-glass was excellent, but it was dangerous for the eye of the observer.

M. Alexandre Nowicki presented a new film, which I imagine to be formed of celluloid. It has all the qualities for a support for the gelatino-bromide film. It is transparent, thin, flexible, insoluble (in the developer), and can be manufactured in lengths of several yards. M. Nowicki dips this film into the gelatino-bromide of silver emulsion in such a way as to coat the two surfaces. In developing, this double coating prevents curling. A band was shown containing about twenty half-plate-size portraits. A great progress has been made, and will be a joy for amateurs having roller slides.

M. Mendoza presented a new roller slide, similar to the one I described in a former letter presented by M. Carquero. M. Mendoza has adopted a dodge of making an incision in the centre of the paper or film. When another view is required the drum is turned; at length the incision comes in contact with a lever which enters the hole, the drum continues to turn, and an indicator or hand on the side of the apparatus then shows that the film is in its proper place. This arrangement is very simple, cannot get out of order, a mistake cannot be made, and it does away with all complicated ratchet work on the roller slide.

M. Vidal, in the name of M. Raymond, Director of the Society L'Autocopiste, presented a number of fatty ink proofs, which had been obtained by a slight modification of the above apparatus. Great praise is due to M. Raymond for placing in the hands of the public a simple machine by which photographic proofs can be printed in fatty ink by using a simple press, the same as employed for taking the copy of a letter.

M. X— came forward, and said that he desired to draw the attention of the members to a communication made to them in 1882, and which had been passed over without, he believed, due attention, as nothing had been heard of experiments having been tried, &c. He placed before the members a number of negatives and positives obtained by the said process, which consists in obtaining from a negative another negative, from a positive a positive—a process of great value to photographers, to obtain a double or *facsimile* of all their negatives. This gentleman then cited the method he employed, which, he said, was first thought of by Capitaine Biny. A gelatino-bromide of silver plate is taken (whether or not it has been exposed to light is indifferent). This plate is plunged into a four per cent. solution of bichromate of potash. It is allowed to remain there to get impregnated with the potash salt, which takes about ten minutes. The plate is then allowed to dry. The plate is now exposed to light under a negative or a positive; the exposure is the same as for a phototypic plate. When the image upon the bichromated surface is sufficiently visible, the plate is taken from the printing frame and well washed in order to eliminate all the bichromate which has not combined with the gelatino-bromide of silver in the film. In a running stream of water fifteen minutes is amply sufficient. The plate is laid upon a black velvet cloth, glass uppermost, and exposed for one second to full light. The plate is then taken into the dark room, and plunged into the developing solution composed of ferrous oxalate. The development is slow but sure, and in a given time an exact *facsimile* of the *cliché* type will be obtained. Naturally the image is reversed, and consequently in a right position to be employed for fatty-ink printing. When the image is sufficiently developed, the plate is well washed and fixed in a solution of hypo-sulphite of soda. The elimination by the hypo takes more time than for an ordinary plate. The chemical action is as follows:—When the plate thus prepared is exposed to light under a negative, the blacks of the *cliché* preserve the prepared surface from the chemical action of the light, whereas the rays passing through the

whites or transparent parts of the negative render the bichromated gelatine insoluble in those parts. The insoluble gelatine therefore imprisons the silver bromide, and prevents the action of the developer. The contrary takes place on those parts protected from the light: the potash salts dissolve out, and the iron salts operating upon the silver bromide form the photographic image. When dry the plate forms a relief or mountainous appearance: the blacks form the hills and the whites the valleys; and what is to be remarked is that the blacks or hills refuse to take the printing ink, whereas it is the whites which receive it. With a little practice, said M. X—, any degree of intensity can be obtained upon such plates, and with care and intelligence an ordinary negative can be replaced by a first-class *cliché* far superior to its parent.

M. Balagny, the apostle of films, exhibited some new films which can be employed either in obtaining proofs on albumenised paper, or used to be printed from with fatty ink. This gentleman showed the members a number of proofs in fatty ink and in silver salts taken from the same negative. I believe myself that the future of photography is in this kind of preparation; that is to say, a thin film of gelatino-bromide so spread upon paper that it may be left on or taken off at will. The operator is in this case complete master of his *cliché*. He can take a proof from it when upon the paper, or he can transfer it to a glass plate, from which he can take it if he wishes to procure fatty ink proofs, or he can thicken it by doubling it with a sheet of transparent gelatine. Although this is done, I would not advise it, as I maintain it spoils its value for fatty ink or other printing which requires a reversed image. M. Balagny deserves praise for the progress he has made in photographic films. Being a man of fortune, he has devoted his whole time and much money to the advancement of photography. It is not general, such tenacity in rich men, and when we find it we must applaud.

M. Molteni, as is his wont, amused and instructed the members by a lantern exhibition, showing off the value of certain hand cameras to obtain *souvenirs* when on a tour.

Much has been said on refiners, and the unsatisfactory returns sent in by those tradesmen to those who have been, as they think, too confident in their honesty. In fact, our able Editor was obliged to write a leader on the subject, if not to defend, at least to make the supposed wolf a little whiter than he is taken for. I will now try to describe as clearly as possible how this reduction of photographic wastes is done in Paris, and give some advice to my readers, by which I hope they may for the future find good return for their money. I say with the Editor, Keep the gold and silver wastes completely apart! Mix together all chlorides and sulphides, but do not let the least particle of silver go to the refiners in the form of silver bromide; dissolve this salt out by the old hypo-sulphite of soda baths, and precipitate it by sheet zinc or into sulphide of silver. When a sufficient quantity of residues are obtained burn them down in an old iron pot until they turn to red-hot dust, pass through a fine sieve, and break up the lumps, and pick out any foreign matter, such as old glass, brass pins, &c. This is now ready to be taken to the refiners. I write the previous day to Messrs. Lyon Alemand to prepare me a crucible for such a weight of waste to be ready by nine o'clock in the morning. I take my waste to their foundry; the sample is weighed—say, eighteen pounds. I now know what I have to pay—5*fr.* 5*0* per pound = 7*fr.* 6*0*. The waste is put into the crucible in my presence, and I sit down and read my journal during the operation. The crucible and its contents are taken out of the fire, and left to cool, during which time I go to lunch. On my return the crucible is broken up and the *lingot* taken out. The silver is then put into another crucible, and melted again and poured into a *lingotière*. I pay my 7*fr.* 6*0*, and give, as is the custom, one franc to the workman in charge of the furnace. I then take the *lingot* to an assayer's, who in half an hour's time gives me on a bulletin the weight of pure silver contained in the *lingot*. A number is punched on the latter which coincides with the number on the bulletin. I have only to take the *lingot* to a banker or silver merchant, who reckons up its value, taking the exchange price of the day for pure metal as a basis. If I desire I can take the *lingot* and convert it into silver nitrate at my leisure. I have always found a gain in selling the *lingot*, and purchasing the silver salt.

59, Rue des Batignolles, Paris.

PROF. E. STEBBING.

RESIDUES AND REFINERS.

To the Editors.

GENTLEMEN,—I was pleased to read your article *Photographers versus Refiners*, but I can quite agree with your correspondent "Ebbw Vale" that the refiner is making a good thing of it.

I recently sent to an advertising firm one pound of mixed silver residues (sulphide, chloride, and ash) carefully collected, dried, and sifted to a fine powder free from rubbish; 7*fr.* 6*0* was allowed for this. Another refiner has on several occasions allowed for the same description of residue 1*fr.* 9*0* to 1*fr.* 11*0*.

For two ounces and one drachm of gold residue carefully prepared, refiner allows 1*fr.* 7*0*. Refiner No. 2, for same kind of residue, allowed for two ounces and two drachms 3*fr.* 16*0*.

It is very uncomfortable to think that after all the dirty work and trouble of collecting these residues, it is simply to put the value into the pocket of a stranger, who also makes a charge on pretence of melting, &c.

In these hard times photographers ought really to get the full value for their residues, and not be treated like a burglar who may take plate and jewellery to be melted down.—I am, yours, &c.,
H.
December 6, 1887.

CHROMATE OF SILVER.

To the EDITORS.

GENTLEMEN,—With reference to Mr. W. K. Burton's detailed and valuable article in the ALMANAC for 1888 on *Chromate of Silver*, I would venture to draw his attention to a paper by M. Paul Roy, of Algiers, printed in *Le Moniteur* for 1881 (and reprinted in your ALMANAC for 1882, page 221), on *A Chromate of Silver Emulsion*. M. Roy bases his process on his discovery that "gelatine containing chromate of silver in emulsion coagulates in presence of an excess of alkaline bichromate." He, however, only used the red chromate as a means of getting an emulsion of a haloid silver salt by the addition to the silver chromate of alkaline bromide, iodide, or chloride. The emulsion so obtained is "of the greatest delicacy, and will pass entirely through the paper filter." Roy thought the chief advantage to be the ease with which the precipitate could be washed, as it was spongy.—I am, yours, &c.,
W. JEROME HARRISON.

Science Laboratory, Icknield-street, Birmingham.

A NEW DRUG.

To the EDITORS.

GENTLEMEN,—Permit me to draw the attention of photographers to a newly manufactured drug, which I think may possibly be found of very great value to them. It is called phospho-citric acid, and is made by Messrs. Hassall & Co., York-road, King's-cross, its principal use being for the Aerated Company's drinks. It is made only in the fluid state, as I suppose it cannot be crystallised; as every fluid ounce by measure is equal to one ounce of crystallised citric acid, it will be found very convenient to use.

Its advantages over the plain citric acid are many: first, it never turns mouldy or ropy, no matter how dilute its solution may be; then it is perfectly pure and free from contamination of lead, often found in the plain commercial acid. It is cheaper than the latter, the wholesale price being only 10d. to 1s. a-pound, so that it could be sold retail at from 1d. to 1½d. per ounce. The amount of phosphoric acid in it is very small, not quite one grain in every ten ounces—the real quantity by analysis being 1·9 grains in twenty ounces. Now, if this has no injurious effect in a developer, the phospho-citric acid ought to be a far better preservative to add to pyro than the plain acid, which always turns mouldy in solution in warm weather.

To those photographers who use temperance drinks when working in hot studios, it makes splendid lemonade, which will also assist their brain after the worry of troublesome customers; while to those who prefer a stronger drink, a little mixed in their Scotch or Irish makes a very piquant grog.—I am, yours, &c.,
FRANCIS G. ELIOT.

Kingston-hill, Norbiton.

"NEW METHOD OF ALKALINE INTENSIFICATION."

To the EDITORS.

GENTLEMEN,—If Mr. B. J. Edwards will kindly turn to the BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1880, he will see that I contributed a short article on the subject of alkaline intensification before fixation by means of a concentrated and well-restrained redeveloper, and I therefore think that Mr. Edwards has inadvertently misnamed his article in the new ALMANAC for 1888, as I am sure that he will allow I was before him in suggesting the method in question for intensification purposes.—I am, yours, &c.,
A. GIL DE TEJADA.

THE "PERFECT" PHOTOMETER.

To the EDITORS.

GENTLEMEN,—With respect to the photometer alluded to in your JOURNAL of December 9, page 779, we beg to inform you that this instrument is the invention and manufacture of J. Decoudesor, of Paris, and we have had stock for sale some time; moreover, it is but a modified copy of Warnerke's actinometer, and the principle of its use is clearly pointed out by J. H. Storey and W. O. Roper in the BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, 1884.—We are, yours, &c.,
MARTON & Co.
December 10, 1887.

WRIGHT v. WRIGHT.

To the EDITORS.

GENTLEMEN,—In your issue of the 2nd instant the report of the above case is not correct. It states "there were to be a dozen cards for 15s. 6d., but when the cards were finished the plaintiff refused to accept them, and defendant gave back 10s." &c. This is not correct—the proof only was finished, and finding it impossible to satisfy him, as he demanded to be taken without any extra charge until he was satisfied, although the only complaint he made was because one of the children was slightly compressing the lips, I returned the 10s., deducting 5s. 6d. for the proof as I did not wish to have any further trouble with him, and thinking that

would satisfy him. Had I known it would not, I should have finished the dozen and let him sue for the whole amount.

The above correction in your next issue will greatly oblige.—I am, yours, &c.,
W. EDWARD WRIGHT.

1, Sebert-road, Forest Gate, E.

P.S.—As a matter of fact, I finished a print from another negative, finding the first did not satisfy, so that he had two proofs, and only one was charged for.
W. E. W.

ATTACHING CAMERA TO STAND.

To the EDITORS.

GENTLEMEN,—In your ALMANAC of 1888 W. H. Harrison mentions an invention for simplifying the fixing of the camera to the stand by a bayonet arrangement, but forgets the name of the inventor of the same. I have much pleasure in informing your readers that I am the inventor of the said invention, which I had the pleasure of showing at the Camera Club some time ago.—I am, yours, &c.,
J. E. BROWN.

26, Bowling-green-lane, London, December 14, 1887.

[The bayonet method of attaching a camera to the stand was in use in New York years before the Camera Club existed.—EDS.]

THE AMATEUR EXHIBITION.

To the EDITORS.

GENTLEMEN,—In your notice of our Third Annual Amateur Photographic Exhibition, you appear to be under a misapprehension, which we trust you will allow us to point out, as the remarks based upon it may tend to prejudice the value of these Exhibitions in the future. We refer to your allusion to "Artemus Ward's army, in which every man was an officer," and your statement that every exhibitor has received either a medal, a money prize, or honourable mention.

It is quite true that every exhibitor whose work is hung upon the walls has been the recipient of either a prize or commendation; but it is necessary to explain that these successful competitors form only a small proportion of the whole number of amateurs who have sent in pictures to the Exhibition, want of wall space debarring us from hanging any subjects but those selected by the Judges as being the most meritorious. This will be at once understood when we state that the total number of photographs sent for competition amounted to over 4000, out of which only 270 have been framed and hung, the remainder being on view in portfolios arranged according to their respective classes.—I am, yours, &c.,
S. CLARK, Secretary.

London Stereoscopic and Photographic Company, Limited,

December 12, 1887.

[Our statement was based upon a careful perusal of the catalogue and of the pictures on the wall. We are pleased to learn that such a degree of success has attended this Exhibition. Before we are done with it we shall also examine the rank and file in the portfolios.—EDS.]

Exchange Column.

Will exchange whole-plate portable camera, by J. B. Dancer, for good lens or offers.—Address, C. J. EMENT, Walton, near Ipswich.

Buttonhole camera, will exchange for stereoscopic lens by Ross or Dallmeyer. Difference adjusted.—Address, J. MORRISON, 73, Earl Howe-street, Leicester.

A whole-plate portrait lens, by Lerebourn, and a cabinet lens, by Sawyer, will be exchanged for rapid rectilinear or doublet.—Address, W. BOND, Bank Plain, Norwich.

Wanted, 12×10 or larger-sized camera in exchange for fifty-inch bicycle (Singer's National Challenge).—Address, J. MORRO, Deveron-villa, King-street-road, Aberdeen.

Wanted, stereoscopic camera with pair of portrait lenses in exchange for achromatic microscope and slides. Value adjusted.—Address, H. C. PARLOW, 55, St. Aldate's, Oxford.

Will exchange oil painting, size, 20×24 canvas, in gilt frame, for whole-plate portrait lens, group lens, posing chair, or other accessories.—Address, S. BAYNTON, 6, Queen-street, Coventry.

Wanted, Dallmeyer's or Ross' short focus cabinet portrait lens; exchange, Rudge's rotary tricycle, and give part cash if required.—Address, W. E. LEEK, 11, Iron-market, Newcastle, Staffordshire.

Wanted, a quarter-plate Meritole, 1887 pattern if possible. Will exchange '230 rook rifle with about one hundred cartridges and microscope magnifying thirty diameters.—Address, T. H. HALL, 42, Sutherland-square, London, S.E.

Wanted to exchange, microscope, by Dancer, with five powers, polariscope, and other accessories, in mahogany case, for half-plate camera, lens, and slides. Cash adjustment if necessary.—Address, J. G. M., 23, Hall-street, Nottingham.

12×10 Universal lens by Hunter & Sands, rolling press, plate, 14×10, whole-plate burnisher and books; wanted, 12×10 Ross' rapid symmetrical or Dallmeyer's 12×10 rapid rectilinear, also 12×10 burnisher.—Address, W. H. SEDGWICK, Sedburgh.

Will exchange half-plate single lens, several JOURNALs, and a Reeves's mahogany box of thirty-six water colours, for a whole-plate or larger camera or a half-plate rectilinear lens. Difference adjusted.—Address, A. G., 2, Park-place, King's-road, Windsor.

Wanted to exchange, fine compound microscope, by Dancer, of Manchester, with five powers, polariscope, and other accessories, in heavy mahogany case, for half or whole-plate camera, lens, and slides.—Address, J. G. MARTIN, Hall-street, Sherwood, Nottingham.

Wanted, whole-plate outdoor camera, quarter-plate or larger rectilinear lenses, carte or cabinet lens, detective camera, or offers, in exchange for handsome old-fashioned bronze repoussé plaques, thirty-nine inches diameter, and smaller.—Address, HEMERA, St. Leonard's-on-Sea.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED:—

- J. Gibson, Penzance.—*Photograph of the Lizard lights at night.*
 G. A. Dean, Douglas, Isle of Man.—*Three photographs of the Bishop of Sodor and Man.*
 J. Schmidt, Belper.—*Three photographs of Hon. F. Strutt.*
 R. Watson, Hull.—*Photograph of Yorkshire County Football Team. Photograph of Durham County Football Team.*
 J. Squibb, Bridgewater.—*Photograph entitled "Convalescence."*

- F. D.—Apply direct to the Company or order through any gasfitter.
 V. C. B.—Diluted nitric acid will prove the best agent for cleaning the opal glass.
 T. BRECH.—The modified potash developer prepared as directed will suit the plate named.

AN AMATEUR (Newcastle-on-Tyne).—We are going to treat the subject in a special article soon.

CAPT. C. M. HARRISON.—Thanks for your note. As requested, we do not make its contents public.

E. H. EARL.—When about to photograph by the magnesium light the focussing should be effected by gas or candlelight.

T. PINDAR.—We have not yet come across the article, but will do so in a week or two hence, when preparing the index.

W. S. A.—Details of the collodion transfer process are given at page 307 of the last edition of Hardwich's *Photographic Chemistry*.

Y. Z.—1. See the shutter described in our new ALMANAC at page 499.—2. We must decline to offer an opinion relative to spirit photographs.

HENRY WALLIS.—Replace the silvering on the damaged portion of the mirror by covering it with tinfoil upon which a little mercury is afterwards poured.

JAMES PAIUS (Fargo, Dakota).—The incandescent gas burner may be used in a lantern for enlarging purposes, but it is not sufficiently intense for an entertainment.

A PHOTOGRAPHIC COMPANY.—We have been asked if the "Company" to which reference was made in a sub-leader in our last issue was that of R. W. Thomas & Co.; to which we reply—Certainly not.

B. R. BRADEN.—The carbon prints springing off the support before the transfer paper is applied no doubt arises from their being allowed to become too dry. Avoid allowing the prints becoming abnormally dry.

W. SOUTHWELL (Blackpool) sends us two excellent stereoscopic views of an interior with figures, a tribute to the information imparted by the articles on stereoscopic photography in the ALMANAC for 1887.

ETHEL CONSTANCE MAY.—We have practically tested the production you designate "A," and can speak very highly concerning it. There is nothing to be apprehended regarding its possible perishability.

B. S. asks: "Supposing a painting be made from a photograph before it is registered, can the painter be proceeded against after the photograph has been copyrighted?"—The painter cannot be proceeded against.

W. GRIFFITHS.—The most powerful form of limelight burner is the mixed jet. But the light of magnesium aided by a suitable reflector will prove more convenient for illuminating the map. It is very much more actinic than the limelight.

H. J. M.—1. In our ordinary practice with the ferrous oxalate developer we do not employ sulphite of soda.—2. See what was said at the meeting of the London and Provincial Association in our last week's issue respecting hyposulphite of soda. There are many hypo eliminators each claiming to possess special advantages. All of them are good when properly used.

C. I. CALLOW writes: "I have heard that a camera has been patented which will photograph colours in their own tints. My impression was that even if colours could correctly be photographed it must be owing to the chemicals employed in coating the plates. I should be glad if you know of such a camera or plate."—The camera and plates alluded to belong to the photography of the future.

PHOTO.—Acts of Parliament are sometimes inconvenient, but this cannot be helped. The Poisons Act was framed to prevent the indiscriminate sale of poisons by unqualified persons. Those you name come within the Act and can only be legally sold under certain restrictions. The shopkeeper who sells them, except in conformity with the Act, of course renders himself liable to the penalties.

NEW CLUB (Edinburgh).—A five-inch condenser will prove rather small for a 5 x 4 negative, unless you are content with only a portion of it, say, a circle of four and a half inches diameter, or probably rather less, unless the condenser be a very fine one indeed. There is no objection to employing a thirteen-inch focus lens to produce the enlargements, irrespective altogether of the focus of that by which the negative was taken.

T. A. W. complains that he has attempted to reduce some wastes and used the flux recommended by us some time back, and has only got the metal in a honeycombed or semi-metallic state.—The reason is that the heat was insufficient or it was not continued long enough. Our correspondent should now add a little more flux, and fuse again with more heat, and give plenty of time. When the mass is well liquefied a little borax dropped in will assist the operation.

A. G. CORNELL.—The reticulated appearance in the film of which you complain arises from the collodion being made with solvents of insufficient strength. Methylated ether and methylated alcohol will do quite well for making collodion for enamelling prints, provided they be of the requisite strength. If the former have a specific gravity of .720 and the latter of not less than .825 they will do very well, but they ought not to be much weaker than this to give satisfactory results.

S. V. T. asks: "1. Can a photographic firm copyright a photograph as their own property if actually posed and manipulated by an operator during the time he is in their employ?—2. Would the operator have any direct or indirect interest in the photograph necessitating an assignment from him before copyrighting?"—In reply: 1. It must be registered as the production of the one by whom the picture was made.—2. If he has assigned his copyright to another he has no further claim.

J. RING (Greymouth, N.Z.).—We regret we can give you no definite information on the subject. The piece of unfixed paper reached us of a deep brown colour, and the fixed piece as well as the two prints badly marked and mottled by contact with it, accelerated no doubt by damp. So much are these stained that no straight marks are discernible. If the marks were caused by the rods upon which the paper was dried we should expect that a careful examination would show them before the paper was sensitised, also that they would make their appearance more or less on every sheet. Can they be due to a slight scum upon the bath that the paper is sensitised in?

C. T. M. writes: "I have just had the misfortune to break in three clean pieces a negative of some value to me (as it is the photograph of a house now in the course of demolition and consequently cannot be reproduced) before obtaining a print from it; can you tell me of any method by which I can obtain a fairly good print from this, not showing any lines where the glass is broken?"—Bind the edges with slips of paper applied wet, so as to shrink when drying and thus hold the pieces close together; then apply a paper backing to the negative. Now take a transparency by contact printing and scrape out the markings showing the cracks; from this take another negative, or you may print on paper from the original broken negative when thus prepared.

FACILE writes: "Can you help me in the following matter? I have mounted prints in optical contact with glass and found no difficulty in making a black margin by means of Brunswick black; can you tell me any means by which a similar effect in colour can be obtained? Ordinary paint 'strikes,' and if mixed without oil, but with jappanners' gold size or turps only, it dries dead, and no gloss like the black. Would it be any use mixing the dry colour with a varnish, or would this have the same drawback as oil? If I could get at the composition of Brunswick black the road would be clearer, but no one seems able to tell me."—There are several formulae for Brunswick black. This is a good one:—Melt two pounds of asphalt in an iron pot and add hot boiled oil one pint; mix thoroughly, and allow it to cool somewhat, then stir in two quarts of oil of turpentine. We should advise our correspondent to try the effect of mixing the dry colours with different varnishes.

T. V. writes: "I. I am a constant reader of your JOURNAL and have not found any mention made in it of the use of dextrine as a mountant for photographs; is there any objection to its use?—2. Could you explain the cause of the following? I pose a model, say, two feet from a vertical mirror, in order to get a full-face as well as a profile portrait with a portrait lens; in the focussing screen both figure and reflection look 'sharp,' as also does the frame of the looking-glass, and I proceed to take the portrait; when this is produced the object is well defined, so is the frame of the mirror, whereas the image on the glass is 'blurred,' as if out of focus. What is the cause of this, and what the remedy? It seems to me that the image or reflection on the mirror is not, in fact, at a greater distance than the surface, and, therefore, than the frame of the looking-glass, so if these are in focus so ought the image to be, notwithstanding the fact that this last seems not two but four feet from the sitter.—3. Are 'gelatino-chloride' plates for transparencies (or is Dr. Liesegang's gelatino-chloride paper) capable of development by ferrous oxalate developer in the same or similar manner as, say, Eastman's or Morgan's gelatino-bromide paper, after, say, two seconds' exposure to diffused daylight? In that case, given a dull November day when printing for toning bath takes six hours' exposure, only two seconds would be required to expose for development. Is this so?—In reply: 1. Dextrine is not a good material for mounting photographs. Most commercial samples are acid, and acid mountants should always be avoided.—2. There may be two causes for the unsharpness of the reflected image, the first arising from the reflection from both surfaces of the looking-glass, and the second from the lens not possessing the requisite penetrating power, for the image is not on the surface of the mirror but as far behind it as the sitter is in front of it.—3. Gelatino-chloride plates are generally used for transparencies. The paper in question is not intended for development but for printing out. Gelatino-chloride paper suitable for development is an article of commerce.

THE JENNINGS'S FUND.—The following additional contribution has been received:—Mr. James Swift, 11. 1s.

A NEW SOCIETY.—A Society, "The Photographic Assistants' Club," has been formed in Glasgow, the Secretary being Mr. William Anderson, 6, Drummond-street.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, December 21, 1887, will be *The Relation of the Quality of Negatives to the Quality and Permanence of the Silver Prints*.

* * The pressure on our space is so great this week that we are compelled to leave over the continuation of the Amateur Photographic Exhibition and articles by Marston Moore, W. H. Harrison, F. G. Eliot, &c.

No. 1442. VOL. XXXIV.—DECEMBER 23, 1887.

HOME-MADE STRIPPING FILMS.

WE now come to the last and most difficult application of the gelatinised transfer paper, to the production of stripping films of gelatine emulsion. The greater difficulties arise in consequence of the solubility of the transfer coating in the medium, which keeps the upper layer liquid during the process of spreading, a condition which does not prevail when the latter consists of collodion, and also in the danger that exists of the chrome alum used to harden the sensitive film when dry penetrating sufficiently into the underlying gelatine to render it partially or wholly insoluble, and so defeat the object in view by permanently cementing the picture to the paper support.

These difficulties, of course, exist equally whether the work be performed on a large or a small scale, though, probably, they make themselves felt with greater force under the latter conditions, owing to the absence of systematic arrangements for combating them. On the commercial scale, and when the "films" are coated by machinery and in continuous bands, the careful adjustment of the temperature of the emulsion and of the speed of the machinery serves to render the process practically automatic, and relieves the operator of all anxiety as well as the necessity for the exercise of the most perfect combination of rapidity, accuracy, and care in manipulation, which alone serves to ensure success or failure when the work is done by hand.

Thus, on the large scale, a band of paper previously coated with an even layer of soluble gelatine is passed, tightly stretched, at a regular speed through a trough of alumed emulsion, which is kept with comparative ease at a uniform temperature, sufficient to keep it fluid without being high enough to retard its setting beyond a certain time. Thus, as the coated paper leaves the emulsion trough, the sensitive layer remains liquid during the period the band occupies in travelling a certain distance, when it sets, the back flow during the interval it remains fluid being perfectly regular, and the ultimate coating uniform in thickness. Variations in the temperature of the emulsion or of the atmosphere sufficient to modify the period of setting, and, consequently, the interval of back flow, may be compensated by altering the speed of the machinery, and thus a practically even coating is maintained for any required extent of time or surface.

While the hand operator is deprived of these aids to uniformity, and is compelled to trust to his own manual dexterity and acuteness of observation, it must be borne in mind that he is not bound to the unvarying exactitude that is indispensable on the commercial scale. Coating a single sheet at once, either by floating or otherwise, he may work in a more leisurely manner, and take time to study the varying circumstances of

temperature and fluidity of his preparation, and should any hitch occur the consequence will scarcely be so disastrous as in the case of a mishap to the coating machinery. Still, the difficulties are such as to call forth all the intelligence of the most careful worker.

He has two main points to bear in mind, namely, that the transfer surface of the temporary support is soluble (more or less) in the warm emulsion, and that the latter sets rapidly when its temperature falls below a certain point, and that it cannot be reliquefied by heat in order to equalise an uneven or imperfect coating. Thus there are two reasons why expedition and dexterity are absolutely essential, for if the sheet be floated and re-floated to secure an even coating, the chances are that the soluble gelatine will be sufficiently attacked by the warm emulsion to produce unevenness of the under side of the film; while if it be attempted to equalise the layer of emulsion by other means, there is every probability of greater irregularities arising from the premature setting of the latter. Add to this the fact that the longer the emulsion remains warm and liquid the stronger is the chance of the chrome alum diffusing itself by absorption into the layer of soluble gelatine and rendering it insoluble through a portion of its thickness. Bearing these circumstances in mind, the operator may proceed to work.

Reverting for a moment to the preparation of the transfer paper, we may repeat that when it is made for the express purpose of gelatine stripping films the coating of soluble gelatine may be thicker than for collodion purposes, in order to afford the best possible chance of at least a portion of its thickness next to the paper support remaining soluble, in case any accident should occur to cause the chrome alum to penetrate it injuriously. Again, for reasons that will be touched upon presently, it should contain a full quantity of glycerine, or other hygroscopic material, to preserve its pliability to the utmost, without injuring its keeping qualities, or causing it to exert any deleterious action upon the sensitive film to be placed in contact with it.

Beyond these small matters, there is nothing in the preparation of the transfer paper for gelatine stripping films in which it differs from that prepared for collodion, but its after condition is of far higher importance as tending to promote speed and success in the application of the coating of sensitive emulsion. When dry it must be perfectly smooth and free from wrinkles or obstinate tendency to curl. Clearly, it is impossible to float, or otherwise coat evenly with emulsion, a stiff, uneven paper surface, without first rendering it pliable by damping, which, in this case, is quite out of the question, so that every precaution should be taken in the preparation of the

paper to ensure its proper condition. It is here that the utility of the glycerine makes itself apparent, as by adding a proper quantity to the gelatine solution the coating, when dry, remains perfectly pliable, like soft leather, without exhibiting the slightest tendency to tackiness.

Paper coated with gelatine so prepared curls very slightly on drying, and if the sheets be laid one on top of another and kept under slight pressure in the flat state every appearance of unevenness will rapidly vanish, and in this state the paper is in perfect condition for coating with emulsion either by floating or any other method.

The amateur or small consumer, working upon a moderate scale and for private use, will naturally consider it to his interest to make his product as perfect as possible. That being so, we strongly recommend as an additional refinement, though not as a necessity, to coat the paper with collodion before applying the emulsion. The trouble is comparatively slight, and the result is to more completely isolate the two layers of soluble and insoluble gelatine, and so preserve the integrity of both, while the negative after stripping is already provided with a protective coating of collodion. After collodionising the paper must be again dried and placed under pressure, or it may even be necessary to roll it up, coated side outwards, in order to counteract the tendency to curl in the opposite direction.

The emulsion needs no special preparation except that a small quantity of chrome alum is to be added to it in order to render it insoluble after drying. The quantity will vary with the kind of gelatine employed, the harder kinds requiring less than the softer, and being more difficult to manipulate into the bargain, as some of them will suddenly curdle or solidify in a most unaccountable manner with even the smallest quantity of alum present. It must be remembered that the alumed gelatine sets at a higher temperature than before the alum is added, and that when it has once gelatinised it is impossible to satisfactorily reliquefy it by heating. Therefore the chrome alum in weak solution should be *stirred* into the emulsion almost at the last moment before coating, and the utmost provision made for keeping up the temperature to a proper point.

We now come to the coating of the paper with emulsion, and we shall presume that the operation is to be performed with single sheets of moderate dimensions, not necessarily cut to the exact size required for use. Sheets measuring up to from thirteen to fifteen inches in longest dimension are almost as easy to handle as smaller sizes, and give no more trouble or anxiety, while they will cut up into two, four, or more smaller ones; besides, it is easier to keep up an equable temperature with a large bulk of emulsion than with a smaller quantity.

Floating will no doubt be generally selected as the most convenient method of coating, and no doubt justly so. If the paper be in proper condition nothing is easier than to lay it down quickly and smoothly upon the surface of the emulsion without enclosing a single bubble, and to raise it again evenly and steadily is equally easy. But then comes the question of what next to do with it.

It is not safe to hang it up immediately to set and drip at the same time, as the alumed gelatine is apt to gelatinise in an irregular manner, and to run in lumps, or break away from the paper by its own weight, unless it be applied at exactly the proper temperature and under carefully considered conditions, as in machine coating. It is therefore desirable to lay it down as quickly as possible in a horizontal position to set, and if the slab or bed upon which it is laid be slightly warmed to prevent

sudden chill, the evenness of the coating will be improved. If provision can be made for keeping the emulsion liquid for some seconds or half a minute, time will be permitted for searching out and removing chance irregularities, such as air bubbles, and the delay in setting under the circumstances will do little harm to the under layer. Dry gelatine, as is well known, dissolves but slowly in hot water, where that which is already swelled liquefies almost instantly under slight warmth. In a level position, then, the slight softening of the surface of the soluble gelatine can do little harm, though in a hanging position, or if the sheet were to be much moved about, it probably would.

If a levelled hot plate be placed at the side of the coating dish, each sheet in turn may be lifted by one edge from the emulsion and drawn steadily over the edge of the plate, and then left while the next sheet is being floated, after which it may be drawn on to a cold slab on the same level to set, and make room for another.

Instead of floating, the sheets may be coated by pouring a measured quantity of emulsion on to each while laid in a horizontal position. This plan, perhaps, has advantages on a small scale, requiring less emulsion and less care in keeping up the temperature. The coating should, however, be performed on a hot plate, or the emulsion is almost certain to chill on application. One disadvantage exists, namely, the tendency of the paper to "cockle" under the combined effects of warmth and moisture, and if this occur before the emulsion has set the result is fatal. If it occur later, it matters not.

The drying of the paper presents no special features, and once dry, if kept so, there is no reason why it should not preserve its quality as long as ordinary films. If, however, there be any great delay in drying, or if the paper be subsequently stored in a damp place, there is a strong chance of the chrome alum from the layer of emulsion reaching the soluble gelatine, and so ruining its stripping properties. With expeditious drying and careful storage, however, this cannot occur.

The method of using the stripping films has been already described, so nothing further need be said here on that subject.

THE GENESIS OF THE ROLLER SLIDE.

II.

RESUMING our remarks from page 689, we continue by giving a description of the latest development by the inventors of the Eastman-Walker roller slide or roll holder, being that which is now known as their 1887 model. It will be seen that it differs in several details from the original one, the construction of which is now too well known to require repetition here.

The metallic frame of the original, or 1885 model, is re-

placed by wood, light yet rigid. In this frame is fitted the various rollers and mechanism, both the back and front being detachable therefrom, as shown in the accompanying cut.

Apart from this, or rather as a consequence thereof, the key by which the rollers were rotated so as to shift the paper, and which formerly had to be removed every time access to the interior was desired, is now a fixture to its special roller and need never be disconnected. When not in use it folds down, and lies flat against the top of the roll holder.

There is also another improvement. In the first model the progress of the paper or other flexible negative material was indicated audibly by four sharp clicking sounds made during the winding, the fourth one intimating that a fresh surface had taken the place of that which had been exposed. In the new one the progress is indicated to the sense of sight, a small, unpretentious, and simple, yet surely working piece of mechanism on the top revealing with unerring accuracy the stage of progression, which, when completed, also appeals not alone to the eye but also to the ear, by a click. Both this and the erected key are shown in the accompanying cut of the completed slide.

Although we have personal cognisance only of the two models mentioned, Mr. Walker informs us that another was introduced in 1886, which differed from the original in respect of the movement which was attached to the back being disconnected and having a visible indicator, but retaining the metallic frames for holding the rollers. Both of these are now superseded by the last model, in which are combined all their good qualities without any of those which might be open to objection. It is not so wide as the others and is much lighter.

The adjoining figure shows the back of the case removed

and the method of inserting the spool or roll of negative paper. We conclude this brief description by showing a transverse section of the internal parts in which the ingenious automatic

tension rollers are seen. The roll holder both in conception and mechanical execution is a beautiful specimen of work of the highest class.

MR. H. TRUEMAN WOOD is announced to read a paper on *Photography and the Printing Press*, at the meeting of the Camera Club on the 12th proximo. Many of the principal "process" workers have promised to lend specimens for exhibition, so that there is likely to be an interesting collection of photographs and photogravure work.

We learn from the *London Gazette* of Friday last that the partnership heretofore existing between Messrs. Alexander Lamont Henderson and William Middleton Ashman, photographers, of Amersham-road, New Cross, S.E., has been dissolved by mutual consent, Mr. Henderson carrying on the business alone. Mr. Ashman, we understand, joins Mr. H. M. Smith, and these gentlemen will carry on business in the provinces under the style of Smith & Ashman. Both of these gentlemen will be much missed in London photographic circles. Mr. Hedley Smith has been the Hon. Secretary of the North London since its formation, and much of its success is owing to his energy and ability; he is also an active member of the various other London photographic societies. Mr. Ashman, besides being Chairman of the Council of the Photographers' Benevolent Association, has long taken a most active part in several of the London societies, and contributed much to their interest by his great practical knowledge.

We direct attention to an Exhibition of Photographs, Lantern Slides, and Photographic Apparatus, to be held in the Crystal Palace, commencing on February 20, 1888, particulars concerning which will be found on another page. We are informed by the Executive Committee that already such progress has been made and such encouragement received as to ensure the success of the Exhibition, which is to be on a large scale, and free from some of the drawbacks associated with other exhibitions, especially with regard to the judging.

THE death of Thomas Annan, of Glasgow, deprives photography of an able artist and the world of an honest man. For many years he pursued, with singular success, the profession of photographic artist in Glasgow. The excellence of his work, more especially in the reproduction of paintings, obtaining for him wide and most honourable distinction. Cultured, and with great natural taste for art, he loved the society of artists, and was never so happy as when endeavouring to faithfully translate some masterpiece into monochrome through the medium of his camera. Honourable in feeling, and fastidious in taste, he was utterly intolerant of shams, and of everything below the best. It was natural that he should have felt dissatisfied with the uncertain permanence of silver prints, and been one of the first to introduce carbon printing, and that, later, he should have gone a step further in the direction of permanent printing by taking up photogravure. In this connexion he was associated with Mr. Swan, the inventor of the incandescent electric lamp and of carbon printing. Almost a giant in stature, and with a handsome, clear-cut face and a brilliant eye, Mr. Annan was altogether a noble type of man. One who knew him intimately says:—"He was the personification of truth, and the soul of honour." Mr. Annan was born in 1829, commenced business as a photographer in 1857, and died December 14, 1887.

Our contemporary, the *Athenæum*, can never be said to indulge in an undue bias in favour of photographic processes, its opinion upon which, when questions of art are to the fore, being usually most unequivocally expressed. But in a recent criticism upon a certain book of travels, as it may be termed, it says of the illustrations (which the author of the work, Mr. A. J. C. Hare, states to be "with few exceptions" from his own sketches) that, "judging from the revelations of perspective, and from our knowledge of the photographs of the principal buildings of Paris and its outskirts, we fear that we must pronounce a larger portion of them to be obviously from photographs than Mr. Hare is willing to admit." We should like to know what our readers can make out of this paragraph—a compliment or the reverse, or any meaning at all.

MANY formulæ have been given at sundry times in these pages for making sizing liquids for preparing the surface of albumen or carbon

prints to receive colour more readily than the untreated surface permits. But we have been told, as, indeed, has also been before published in these pages, that many artists use no other medium than that supplied by nature, when the tongue is passed over the glossy surface. It is worthy of being noted, however, as "tinted" photographs have so frequently been shown to be wanting in permanency, that chemists recognise as a fact admitted that there is present in saliva a substance that is capable of acting upon the photographic silver image under certain conditions; in fact, that sulphocyanide of potassium is present. So much of this compound, indeed, is there to be found, that a process has been devised for testing the state of the health by the amount of this salt contained in saliva, this amount being gauged by the colour produced upon the addition of a persalt of iron. Hence it is no way unreasonable to suppose that the moistening the surface of an albumenised print by the tongue may lead to chemical changes of an injurious nature.

At the last meeting of the Physical Society a conversation upon prisms of some interest to photographers was held. It may be remembered that the late Dr. Draper used bisulphide of carbon prisms in some of his spectroscopic researches, an ingenious arrangement being devised, as has been explained by us, for counteracting temperature effects. At the meeting referred to Mr. H. J. Madan described a new refracting liquid capable of taking the place of bisulphide—phenyl-thio-carbimide. It is colourless, has a high boiling point, and a specific gravity of 1.35; its refractive indices for the A and G lines being 1.639 and 1.707 respectively. It is thus seen to be very similar in this respect to the bisulphide; but it is stated to be free from many of the risks and inconveniences attaching to the use of the latter in prisms. The dispersion at the blue end is very remarkable. A polarising prism had also been made with the new liquid, and it gave an angle of twenty-five degrees.

We learn from the Report of the New York Pharmaceutical Association that a factitious glycerine has been put on the market. This substance contains no glycerine at all, nor does it possess any of its qualities; hence, if it should be sent to or made in this country, it may find its way into photographic laboratories, to the undoubted discomfiture of the worker. This sophistication consists of a saturated solution of sulphate of magnesia (Epsom salts) with about fifteen per cent. of glucose. Its taste would be sufficient to detect it, however, not to speak of chemical tests.

A DISCUSSION of great importance on the question of halation arose at the last meeting of the Royal Astronomical Society, from some remarks made by the Astronomer-Royal. Referring to previous statements made at the last meeting regarding the use of curved plates for producing star photographs, as described in these columns, he now gave more complete details of the work. A four-inch objective of sixty-inch focal length, specially corrected for photographing, was employed, and the plates on which the star pictures were taken were curved to "the theoretical curvature of the field of least confusion, the radius of this curvature being about half the focal length. The plates are six inches square, and cover an angle of about five and three-quarter degrees. Images were thrown upon the centre, a little distance away, and upon the edges, and photographed in these positions. A very remarkable appearance was produced with the images a little away from the centre." As one goes further from the centre the image of the star spreads out. It is winged something like a kite; as the exposure is increased the figure fills up a little, you get something of an approach to an oval form; as a matter of fact, with the object glass we have been using, the circle of least confusion seems to be really not a circular patch, but a cross representing the two diameters of a circle at right angles. Captain Abney contributed some of his own experiences, and pointed out the erroneous results obtainable by neglecting the thickness of the film, which in gelatine is so great compared with collodion. The Astronomer-Royal admitted the cogency of Captain Abney's remarks, but thought that,

after bearing in mind possibilities of halation from chemical phenomenon and optical distortion from reflection at the back of the plate, the effects described were connected more with optical phenomena, and he especially pointed out the opposite effects obtained by photographing within and without the focus. Mr. Ranyard described what we consider an observation of greatest value. He stated that part of an image of a star may be cut off by platinum foil placed on the plate during exposure, and "the star's image does not, as far as I can make out, spread under the opaque platinum foil." Mr. Common made also some very valuable additions to the discussion, having a similar bearing to the last. This is a subject of such capital importance that we may return to it at a future time.

COLLODION LANTERN TRANSPARENCIES.

MANY complaints are heard from amateurs who prepare their own lantern slides from collodion emulsion, that they are unable to produce them absolutely free from veil and with the highest lights represented by perfectly clean glass. Occasionally I have had shown to me even by "experts" in the process samples of this kind of defect, which have been sufficiently puzzling to evade all attempt at explanation. Sometimes it is a case of an old and well tried formula with equally trustworthy chemicals that suddenly proves at fault; at another it is a sample of previously proved emulsion that in an equally mysterious manner goes back upon itself, and refuses to give the immaculate results it has hitherto produced, and then, perhaps after a brief interval, the fault disappears as unaccountably as it came. Of instances in which a new formula is tried for the first time and found wanting, though in other hands it has proved quite satisfactory, or where new materials have been employed, I say nothing, for in such cases it may at least be inferred that the causes are traceable to the method of working or to unsuitability of the chemicals, as the case may be. A few hints on some of the least suspected causes of veil may therefore prove useful at this season.

In the first place, I may say that the defect I have to deal with is not in any sense fog, that is to say fog caused by the action of stray light upon the emulsion or films, or by abnormal reduction of the silver haloid by chemical means. It is rightly described by the term I have applied, and for negative purposes would be by many operators considered an advantage rather than the contrary, tending as it does to give transparency to the shadows and general harmony to the picture. But for lantern purposes the emulsion must be uncompromisingly clean and above suspicion.

I may just allude in passing to one or two causes which I do not include in this category, though they may, perhaps, be so classed by some of those who have recognised them. First of these is the pyroxyline itself, which is not unfrequently the cause of a more or less marked opalescence in the transparent portions of the film, owing to its unsuitability to the purpose. Many samples of "high temperature" cotton, as well as extremely low temperature papyroxylines, exhibit this peculiarity in a marked degree; indeed, with regard to the latter, notwithstanding the general fact that as a rule papyroxylene gives a far more structureless film than ordinary pyroxyline, I have found it far easier, by slight variations in the strength, proportion, or temperature of the acids in the process of manufacture, to produce this opalescence when operating on paper than with cotton. It is little consolation to the lantern-slide maker to know that such samples are very frequently of the highest possible quality for general emulsion work, or that the opalescence disappears on varnishing the film, and in a great measure when it is moistened; his only remedy is to change his pyroxyline.

Another prolific cause of veil is dirty glass, or perhaps I should rather say, improperly cleaned glass. Some samples of French chalk used in polishing the plate seem to leave an impalpable film upon the glass which exercises a reducing action upon the silver bromide in much the same manner as smears and irregular polishing marks without French chalk do; but in this case the reduction is extremely slight and perfectly even, resulting in a fine veil between the collodion film and the glass and quite invisible on the surface. This is more common in cold and damp weather than the opposite, so perhaps atmospheric condition may be the real cause. A similar result is also

sometimes obtained when a substratum of indiarubber, albumen, or gelatine, is employed, so perhaps the safest plan is to trust to a perfectly pure surface of well cleaned glass.

It is scarcely needful to say that over exposure is one of the most certain methods of veiling the image, that is to say, over exposure not properly checked in development; in the production of warm tones it is necessary to expose very much longer than the time absolutely required to impress the image, but bearing this in mind the developer is suitably restrained to compensate. Over exposure can, therefore, scarcely be classed as an "unsuspected" cause of veil, and yet to a certain extent it is. For instance, we will suppose that an abnormally long exposure has been purposely given; when the plate is developed the operator in order to be on the safe side employs a proportionately augmented quantity of restraining bromide, resolved to err on the side of clearness rather than of veil. The result is that the image is slow in appearing, but when it does come it proceeds regularly and evenly, the high lights beautifully clean, and, in fact, everything seems as it should be.

The details in the high lights long in making themselves seen, are at last there, but the image is not strong enough generally, so a little more ammonia is added to the developer or a fresh and stronger batch is made and applied until the needful vigour is attained. Still everything seems perfectly right, the sky and high lights retain the clean, pearly blue tint of the unexposed plate, the image clearly marked out in a creamy colour verging between brown and red, not a suspicion of fog. The plate is fixed, and as the unaltered bromide clears away the high lights stand out clear and black in comparison with the rest of the picture against the dark background of the sink. It is not until the picture is critically examined against the light with a piece of ground-glass intervening, or after being dried is laid carefully on a sheet of white paper, that the presence of a faint veil becomes evident, but there it is in spite of the precautions.

"In spite" of the precautions! It is those very "precautions" that have caused the mischief, or rather the misapplication of the precautions. If, instead of "piling on" the bromide at the outset, a moderately restrained solution had been used to commence with and used until all but the very finest details were out and *then* the strong dose of bromide together with more ammonia had been added, not only would development have been more rapid, and the image have had better gradation and vigour, but the veil would have been entirely absent. It may appear paradoxical to say so, but that veil is the result of *under exposure*; the strong dose of bromide applied at the wrong time has to a certain extent converted the really over exposed plate into the reverse.

I will try and explain as briefly as possible. All who have used alkaline development in connexion with collodion plates know well how much more powerful and how different is the action of restraining bromide as compared with gelatine. A collodion plate that has received a normal exposure may be developed and intensified without the use of bromide at all, which is possible with but few gelatine plates when liquid ammonia is used. If it be used at the commencement of development its quantity must be exceedingly small, though at a later stage very much larger proportions may be added with impunity. In the early stage bromide not only attacks and destroys the finer details of the undeveloped image, but also deprives the more robust portions of their power of acquiring density; in fact, the over use of bromide at the commencement of development induces in a properly exposed plate precisely the same characteristics as those of under exposure.

In the case I have cited of an abnormally over-exposed plate, the chief force of the attack of the powerful dose of bromide is felt and borne by the half tones and finer details in the lights; while these are being "felt for," or coaxed out, the bromide is hard at work—augmented and reinforced now by that liberated from the reduced silver bromide—undermining the image already formed, and robbing it of its power of gaining strength—not as in the case of gelatine, allowing the better exposed parts time to acquire density while the half tones are held in check. Thus it happens that in bringing out the details of the picture the plate is strained to its utmost limit as regards the quantity of ammonia it will bear, and when more has to be added in order to bring up the density something must happen, and that something is veil or fog. But mark that even now it is

invisible before fixing, for the strong solution of bromide keeps the surface of the film clean, and the veil commences at the back.

But if development be started with a moderate proportion of ammonia well but not over restrained with bromide, a second and stronger solution being ready at hand, a thin image is developed with great rapidity, and instantly the amount of detail that experience teaches to be correct has made its appearance, the second or intensifying solution is passed over the plate to check it and allow it to gain strength. With bromide of reasonable strength the visible image suffers but little comparatively, the main check being on the undeveloped portions; therefore by suddenly increasing the proportion of restrainer after the picture is nearly formed we gain the end in view—clearness of lights—without unnecessarily interfering with or slowing the general development. But in any case it is injurious to use too much bromide.

As I have already said, the gradation of the picture will be better and more vigorous; it is remarkable how an extremely feeble and apparently flat image on collodion if produced by the first application of a weak alkaline developer will behave upon treatment with a stronger solution. In the first image there is perhaps little difference between the strongest and weakest portions, but upon applying a solution containing twice the original proportion of ammonia the better exposed parts leap away as it were from the feebler—in a manner scarcely comprehensible to one who is wholly accustomed to gelatine plates. Intensification in this manner is so rapid that if the proper proportion of ammonia be not exceeded there is no chance of fog from forcing or straining the development, as in the other case.

I am presupposing, of course, an emulsion or film that is in perfect condition, for if there be any weak point in its character almost any method of development will find it out. But whether good or bad originally, the "forced" system of development will make a worse mess of a plate than proper or reasonable treatment.

There is another source of veil to which I would call attention in these days of warm tones and long exposures, namely, the source of light employed. There can be no question that gas or lamp light is far the best to use for general purposes; it is well under control, and the length of exposure is not excessive, at least for contact printing, even when the warmest tones are desired. Daylight at this time of year does not present any very great dangers even in contact printing, but magnesium, which is now absurdly cheap, does, if not used with judgment. For contact printing, I should therefore always recommend gaslight, while for camera work circumstances will have to decide the choice. With tolerably sensitive plates there will be greater safety from foggy and weak pictures in the less powerful light than in daylight or magnesium.

But quite independent of the risk of mere over exposure when employing daylight or magnesium, there is also lying hidden another of the "unsuspected" causes of veil. This is to be found in the higher "penetrating" power daylight and magnesium possess as compared with gas. I was shown some time ago a number of transparencies printed by contact, and which were intended to serve as the text for a sermon on the deterioration of collodion emulsion with age. When newly made, but a few weeks previously, it had worked to perfection, giving beautifully clean lights; but now all the results showed a thin veil, slight it is true and nothing that would have been noticed except in a lantern slide. I suggested that the negative might be too thin, but was met with the reply that the same negatives had answered perfectly well with the *new* emulsion.

My reason for this suggestion was, that the margins of the plates which had been protected by the rebate of the printing frame were perfectly clear, while the highest lights of the pictures all showed veil. On further investigation I found that my friend had only recently been using magnesium where previously gas had been his means of illumination. Here was at once the solution of the mystery. How few modern negatives are sufficiently dense in their highest lights to protect a sensitive bromide plate from the action of magnesium light, only those who have made the experiment would perhaps believe. Let those who have not already done so test the matter for themselves.

It is clear that if the densest portions of a negative are not *opaque* to a given light that a certain amount of action must take place, and I

the result of that action in the case of a lantern slide is veil. Where such occurs it cannot be altogether remedied by any modification of development without affecting the rest of the picture also. So employers of magnesium light had better be warned in time.

In conclusion, I would give a word of advice to those who are more accustomed to gelatine than collodion dry plates, namely, to use plenty of light in developing. The collodion image is far more difficult to see than that on gelatine, but it is at the same time infinitely less exacting in the matter of the colour of the light it will bear with safety. I have no doubt "canary medium" and similar risky fabrics (for gelatine) might be used with care; I employ, myself, glass coated on both sides with collodion containing in each ounce eight grains of cotton and thirty grains of aurine. This I find perfectly safe, but if any gelatine person should feel nervous he may add a thickness of yellow paper.

W. B. BOLTON.

THE PRESERVATION OF SILVERED PAPER.*

No. 13.—Mr. Jex Bardwell (THE BRITISH JOURNAL OF PHOTOGRAPHY, 1870, page 544) says, "The following formula will keep the paper for three or four days in perfect condition without washing or fuming:—

Silver nitrate	480 grains.
Water	16 ounces.

Dissolve and add a few drops of ammonia, then add ammonia nitrate one ounce. The sheets are to be laid on blotting paper, and the excess of solution is to be removed." *Remarks:* The function of the ammonia nitrate is not obvious to me, but my inference is the same as that I drew from extract No. 12.

No. 14.—Mr. Antony (THE BRITISH JOURNAL OF PHOTOGRAPHY, 1871, page 24), says, "When alum is used in the silver printing bath the paper keeps far better in hot weather."

No. 15.—The Editor of the JOURNAL (1871, page 35) says, "The silver solution will take up only a very minute quantity of alum." He does not allude to the keeping qualities of the paper.

No. 16.—The Editor thinks (THE BRITISH JOURNAL OF PHOTOGRAPHY, 1871, page 48) "The value of the method chiefly depends on the combination of silver nitrate with silver sulphate, the latter saturating the liquid." I have no remarks to offer and no inferences to make upon the last three paragraphs at present.

No. 17.—Mr. Engleman (THE BRITISH JOURNAL OF PHOTOGRAPHY, 1871, page 138) advises washing the paper and fuming it. He says he has "kept such paper for months with impunity." My inferences and remarks have been already given in conjunction with a previous extract.

No. 18.—The Editor (THE BRITISH JOURNAL OF PHOTOGRAPHY, 1871, page 348) says, "Mr. Carey Lea has found that by simply adding tartaric acid to the silver bath paper excited on such a solution will remain white and in otherwise good condition for seven weeks after preparation." I have at present no remarks to offer and no inferences to draw upon this matter.

No. 19.—Mr. Carey Lea gives his method of preserving paper in THE BRITISH JOURNAL OF PHOTOGRAPHY for 1871, page 351. He says it "keeps perfectly for seven weeks," and should, he says, "be kept in a dry atmosphere." He also advises the use of gelatine and glycerine. *Remarks:* I fail to see the use of deliquescent and hygroscopic substances if the paper must be "dry."

No. 20.—Mr. Homersham (THE BRITISH JOURNAL OF PHOTOGRAPHY, 1871, page 512) expresses approval of Mr. Lea's method of preserving paper by the use of tartaric acid. He advises that the paper be kept in a wooden box with a closely fitting lid.

No. 21.—Mr. Wilkinson (THE BRITISH JOURNAL OF PHOTOGRAPHY, 1872, page 141) advises that citric acid and ammonia be added to the printing bath. He says the paper keeps white for a "considerable time."

No. 22.—The Editor (THE BRITISH JOURNAL OF PHOTOGRAPHY 1872, page 376) says, "Formerly we were satisfied with the supposition that the organic substances present caused a slow reduction of the silver nitrate. We believe that the yellow or yellowish-brown colour of the kept printing paper is not due alone to the reduction of the silver nitrate."

* Continued from page 758.

No. 23.—Mr. Antony (THE BRITISH JOURNAL OF PHOTOGRAPHY, 1872, page 478) advises:—*First method:* Floating on silver solution, then on water, then on an aqueous solution of alum. Thus prepared he says the paper keeps absolutely white for four months after preparation. It requires fuming before being printed on. *Second method:* "Float the back of the sensitised paper for a short time on a five-grain bath of oxalic acid. No fuming is required." *Third method:* "Use thirty-five-grain silver bath. Add two grains of citric acid to each ounce of solution. Add ammonia, and dissolve nearly all the precipitate with nitric acid."

With this last extract ends the roll of notes upon which by sheer accident I have laid my hand. I will defer my further observations till they have appeared in print. In the meantime I hope to find further manuscripts relating to this matter, and particularly those of D. WINSTANLEY.

COLOURING AS APPLIED TO PHOTOGRAPHY.*

It was my original intention to go straight ahead into the various methods of colouring photographs in *natural colours*, but find it would be impossible to do the subject sufficient justice in the limited space that may be allotted to me between now and the new year. Therefore, this branch must remain untouched until the old year will have run its length, and a brighter time, I hope, may come to all of us, both photographically and socially. I think, therefore, all things considered, we may gain advantage by giving one parting glance at the past, as regards the treatment of photographs worked in monochrome, whether they be enlargements or otherwise, before quitting this subject for a more advanced branch.

As a workman requires first-rate tools to turn out first-rate work, so we must provide ourselves with suitable materials, if we wish to produce our work in like manner, of the first quality. I will assume, therefore, that we are provided with Winsor & Newton's colours and brushes, &c., and a bottle or two of Newman's sizing preparations, gum water, &c., and with, say, a 24 x 18 enlargement (carbon) on our easel, we are ready to start work. Let our subject be an elderly man, with well defined features and grey, almost white, hair. The figure three-quarter, as in such cases all our knowledge of working in monochrome can be called into requisition.

Our first task will be to *prepare* our enlargement, which we do as already laid down, thus securing for ourselves a surface that will easily receive the colour we place upon it. We cannot be too careful in this matter, as much of the comfort we will have while working will depend, to no small extent, upon the condition of the carbon film. If imperfectly prepared we may have no end of trouble before we gain a satisfactory result.

Another point which should be constantly borne in mind by photographers generally, and more especially by those who expect good results attained at moderate prices, is the printing. On the depth of the print must naturally depend the general *tone* of the picture. Thus if the print be "*too dark*" the picture, when finished, will present a rather heavy appearance, while, on the contrary, if printed "*too light*" it will have a *washy* effect. As I said, this more strongly applies to cases where the artist gets but a moderate price for his work. It is needless to say that any effect *can* be gained by a good artist almost in spite of the defects in printing, but it must be at the cost of much time and labour. In a dark print the shadows will require such a lot of *rubbing down*, as will necessitate a very considerable amount of working up afterwards to restore its brilliancy. In a like manner with the print which is *too light* the lack of brilliancy and "*go*" must be obtained by hard work and much expenditure of time. Therefore, I say, it should be thoroughly understood by the printing department that a certain class of print *must* be sent out or it will be returned as useless. It is scarcely fair to throw all the unnecessary trouble on the poor, struggling artist's shoulders, when, by a firm and distinct order to the printing department it can be easily obviated. I know some photographers who are *very* particular upon this point and will never send an imperfect print, be it too light or too dark, to their artists, but return them and have others of proper density produced instead. This is as it ought to be, but I regret to say I know of many more photographers who will not go to this trouble, but content them-

* Concluded from page 759.

selves with "It will be all right when worked up!" The photographers who adopt this latter system have never worked up carbons themselves nor do they know the nature of them, and their ignorance in regard of the extra labour given to the artists must plead their excuses. I must say, however, that men who understood the work, but who have never viewed the matter from this point before, have seen the justice of it when I, as a worker, have advanced it for their consideration.

From all this it will be seen that in *rubbing down* we should be very careful to remove as little of the *brilliance* of the photograph as possible, and so economise our labours. The shadows which may lose their clearness and beauty in *rubbing down* (if same has been properly done) may be restored by the application of a glaze of medium or gum water. If, however, the *rubbing down* be carried *too far*, they will require a considerable amount of *working up* to make them as they should be. For the producing of lights where shape or definition may be required, erasers mounted in cedar should be used. They can be brought to a point and worked as one would work a crayon. Even a pattern can be suggested, if not completely worked out, on the background, &c.

Having, therefore, paid such attention to the preparing of the surface of our picture as will enable us to work with ease and at the same time preserve all the brilliance in the shadowy details, we can proceed to work the figure. Many artists start with the background, still I think it better to begin with the head. Having advanced the treatment of the head to a certain point then take the background and draperies, &c., and finish them. This done, return to the head and finish it. On consideration, I think many reasons will suggest themselves why this method is the more advantageous of the two. We are more likely to secure softness and delicacy and certainly a better degree of finish generally.

The first portion of the head upon which our attention should be bestowed is naturally the forehead. To this feature (if I may so call it) the most essential quality is breadth, and our efforts in working upon it should be directed towards attaining this effect. The intellectual endowments of the original may be greatly flattered or maligned by our treatment of this feature, and there is really more *likeness* in it than many people think. If ever we deviate from strict adherence to nature, it should be to compliment it rather than offer it an insult. Therefore, as I said before, we must so work the forehead as to endow it with breadth. Needless to say the *formation* should be strictly preserved, and not, as might occur through inattention, be lost in our endeavours to produce *roundness*. As before laid down the strokes of the brush should mostly run in a horizontal direction, not too much so, nor even to such an extent as to attract the eye to the fact that they *are* so; nevertheless, the fact of their being horizontal will give breadth to the feature.

The eyebrows come next and are very important, and require a good deal of judgment in their treatment. On their prominence depends much of the expression, not only of the face generally, but more immediately of the eyes as well as the shape of the forehead. In cases where the forehead is rather square and heavy, the brows are always very prominent; this fact will almost always necessitate giving the eyes the effect of being rather sunken. Care should be taken lest we should accentuate this fact, for it does not add to the general or favourable appearance of the face that the eyes should be thus discounted.

From the eyebrows we come to the eyes. On the expression of the eye or eyes, as the case may be, will depend in very many cases the success of the whole picture. As in life the eyes fix the attention, so it is in a picture. In a portrait where the eyes are uninteresting we will never find satisfaction. But, where we succeed in endowing them with expression and motion, we almost command success for our portrait. With all this, however, they must be *soft*, nothing will save them otherwise; nothing is more objectionable than *hardness* in their treatment. They may have *expression*, even when they are *hard*, but the latter quality will prevent their ever appearing pleasant; and a pleasant portrait should ever be the result an artist seeks to produce. Considerable expression can be imparted to the eyes by the thoughtful treatment of the eyelids. A few delicate touches on the upper lid, suggesting the presence of the lashes, will do much to enhance the beauty of the eye. I say these touches must *suggest* the presence of the lashes because it would be ruinous to thoroughly

define them. Their presence should be, as it were, indicated or expressed by a soft shadow.

The nose, although a very important feature, is not so very difficult of treatment. Care must naturally be taken when placing the *high light* upon it or else we can very easily falsify its shape. We must also rigorously avoid making a straight line of light down the ridge of the nose, for such produces a most *lifeless* effect, to say nothing of its being unnatural. It is comparatively an easy feature to work upon, demanding only a little care and judgment to secure success. Be sure never to let the cavities of the nostrils be too black in comparison to surrounding parts as the effect would be fatal. Force can be imparted to the nose or *vice versa* by strengthening or reducing the cast shadow down its side. In strengthening this, however, never make it *too dark*.

Next comes the mouth, a most important feature, second only to the eyes. There is no feature which holds more fully the gift of expression, and therefore demands considerable skill to ensure success in its treatment. Often the light will catch the lower lip in such a way as to really disfigure it. This must be altered, and a soft effect secured instead. The photographer, in many instances, is powerless to avoid this ruinous and shapeless diffusion of light, often resulting from the skin being dry or cracked. As it spoils the expression of the mouth it must be reduced to proper proportions, and treated in such a manner as to add to the pleasant expression of the portrait. This can always be done by trying to raise the muscles of the face wherever it is practicable. Shadows falling from the nose should be raised, also those formed at the corners of the mouth. A portrait may be wonderfully benefited by a judicious treatment of these points.

The chin is not a very troublesome feature, but still requires care in its treatment. If treated badly or thoughtlessly it may deprive the face of much of its power or firmness. It requires more thought than skill in manipulation. Of course, in the cases where men have heavy beards and moustaches, the mouth and chin will not require our aid. We will have, instead, to strengthen and give force to them, and in so doing, which applies also to the hair on the head, avoid all approaches to minute detail. If we were to attempt the latter, in all probability *wiriness* would be the result. All hair should be treated in masses.

The hair should be worked in *masses*, the lights being put in with an eraser. This in many cases will be sufficient, but if *not*, a few touches of the brush charged with Chinese white will add considerable *brilliance* and power to the general effect. Great care and judgment should be used in treating this portion of a portrait, as it is an essential that it should possess a certain amount of *power*, and yet not lose its quality of *softness*.

Having worked up the face satisfactorily by a judicious intermingling of *hatching* and *stippling*, we have the background and dress to finish, which must be treated in a broader style. A free, open *hatch* being, perhaps, the most effective, and also calculated to enhance the value of the face. In many cases the dress will not require more than a few touches here and there to remove some slight blemish, and a glaze put in the shadows to give them a little extra force. Patterns are often worked into the background with the eraser, which will give an air of elaboration to the work and yet keep in harmony with the rest of the picture.

After having worked up the dress and background, &c., it may be found necessary to do something more to the head, but it can only be to repeat what has already been laid down until you get the desired result—a harmonious whole. Great taste can be shown in monochrome work, and, with the exception of crayon drawing, perhaps, nothing can show more completely the mastery which an artist has achieved over the delicacies of light and shade, than a really good monochrome.

REDMOND BARRETT.

THE LONDON STEREOSCOPIC COMPANY'S EXHIBITION.

SECOND NOTICE.

RESUMING our notice, we have first of all to observe that it is very pleasant to see so many ladies coming out as exhibitors. During our visits several ladies have been present, and from their remarks it was easy to perceive that they possessed knowledge of the art. Their criticisms on the works of the sisterhood seemed to be free and outspoken, yet did we not hear any one so much as attempting to pull another to pieces. Photography is veritably a great humaniser.

Of a frame of nine pictures by Miss E. G. Stone (35), while none are below the average, *At Gulval, Cornwall*, is the best. Her *Well, Gulval*, would have been much better had it not been for the rather stiff posing of two figures. Her *Bridge over the Stream* seems, when looked at from a distance, to be marred by a pronounced horizontal line across the picture, but which on a nearer view is found to be a prostrate trunk of a tree, which is the bridge. All that is wanted to render this a very charming picture is a more oblique view of the "bridge."

Miss Maude Sulwan (*Six Marine Views*) has been very fortunate in one of her pictures, a boat with a number of figures. The others, too, are good. The *Morning Bath* of David Lewis represents a group of cattle in the water. The leaning of a doorway, *In the Mosque, Futtehpore*, by F. L. Cox, renders it uncertain whether this is a freak of the Indian architect or arises from the camera not having been levelled; but otherwise it is a well-executed picture. Three views by the Rev. H. B. Hare, *The Cooling Stream, Thirsty Moments*, and another, possess a softness and delicacy that charm the spectator. The *Sport in Many Lands* of Sir Robert and Miss Harvey arrest attention from the subjects—animals quite unknown in this country, except through treatises on Natural History. Of the exhibits of W. H. Banks, *Street, Meiningen*, will be considered his best. H. Hood Daniels's *Spring and Summer*, while dismissed by the Judges with a "highly commended," are certainly much more deserving of a medal than many others thus favoured. Concerning two pleasant outdoor scenes by Captain Brown, three pictures by the Countess Oriola, two by A. James, and two by Mrs. West, we have nothing special to say. The last-mentioned are of average excellence, the others are entitled to rank a little higher, especially one by A. James, *The Keeper's Cabin*, and another. Concerning a frame of nine pictures by Lieut.-Colonel Hooper the figures in all are naturally and artistically posed, in this respect being probably the best in the Exhibition. Their technical merits are also high. The *Amateur Photographer* of Rev. F. C. Lambert (two children playing at portrait taking) provokes a smile. *A Labourer's Luxury* (W. Adcock) is a large portrait of a man thoroughly enjoying a pipe of tobacco—a solace, no doubt, well earned.

Several imposing pictures are exhibited by J. T. Hopwood. What a pity this artist had not some good genius at his elbow when trimming his prints, to have advised him to take an inch or more from off his foregrounds, especially those of *Ketton Hall, Kirby Hall*, and *The Courtyard*. This would have rendered them as faultless as his *Avenue, Ketton Hall*, than which nothing can be finer, unless it be his *Jack*, which is perfect.

Several pictures are exhibited by George Davison, all of them above mediocrity. His *Fishing Village Group* is cleverly posed, but his *Who so Contented as He?* carries the palm.

Four pictures, *Elderline Lock* and others, by Miss C. Wrigley, attest this lady's skill with the camera. Such also may be said of a frame of instantaneous and other views adjoining, by E. A. Gollidge; *A Wayside Rest* (C. Smerdon Roe), several views by H. Manfield, and four Indian views by Dr. Wellington Gray. The last-mentioned are attractive subjects, but the intensification of the negatives has been carried too far, causing the lights and shadows to be so vigorous as to suggest hardness. Above the average are Cyril S. Cobb's *Riva Lago di Garda* and an *Interior of a Church*, also the *Jersey Cattle* of J. T. Hopwood.

Mrs. Brian Hodgson, in her frame 65, gives promise of better things before long; and in 71 Miss E. G. Stone shows that she has an eye to a good pose.

We have more than once named J. T. Hopwood, who has taken highest awards in various classes; his *Winter and The Music Room, Ketton Hall*, are truly magnificent works. The *Exeter Cathedral* of Harry Tolley shows that the cold tone which suits so well many of the exhibits of this artist is not best for every purpose. A much warmer tone would have better suited the subject named. This applies also in some measure to three pictures (76) by Dr. Vos, which are otherwise excellent.

Miss Miles has admirably managed her *Two Studies* of horses, and Mrs. Edward Penton has made the most of a subject (*A Worcestershire Harvest Field*) not very attractive in itself.

PHOTO-MICROGRAPHY.*

Exposure.—With this begins our real difficulty, and only several trials can enable us to arrive at the correct time to give, for it not only varies with the objectives used and the distance the plate is from the object, but is also governed by the colour of the object.

* Concluded from page 793.

For instance, take a brown insect, or parts of an insect, and it will be found impossible to photograph more than its outline. Its brown chitinous skin presents a barrier no actinic rays can pierce. Better results can be obtained if the insect has been decolourised by long immersion in turpentine; but although its brown has been reduced to a yellow, this affords but a slight amelioration of the difficulty. Insects may be bleached as white as paper by being steeped in a mixture of chlorate of potash and water to which a few drops of hydrochloric acid has been added, but while this bleaching fluid removes the whole of the colour, it destroys the whole of the internal structure, and so robs the photograph of half its value and beauty. Again, exposure is dominated by the staining of a tissue. Staining processes have an immense value to the histologist, as by their means the elements of a tissue can be differentiated in a manner which the highest power objectives are unable to accomplish. But staining may be of two characters. There is the selective staining, by which the nuclei of a tissue, or its growing parts, are, as it were, picked out from those parts which are formed, and in which no active functions are in operation. Now, this, however valuable to the microscopist, is detrimental to the photographer, for it is, to say the least, not pretty to see a photo-micrograph of an anatomical or pathological subject dotted all over with the stained nuclei. Luckily, staining may be made general, and it is in this direction we may look for aid in our operations. In this way an unstained section, whether of an animal or vegetable nature, if cut as thin as our previous observations show to be necessary, is so diaphanous that it will not throw an image on the screen, and the subject and the background are so much alike that there is no contrast between them in the resulting negative; but if the section be stained with a general stain it removes this disability, the image of the object being retarded in proportion to the colour and depth of the stain, while the background gets its full exposure. Stains vary in colour, and their influence on exposure and this variation must meet with due consideration at our hands. In practice, I find the blue stains, especially if pale, and the logwood stain, if too lavender, do not give that retarding action necessary to get a good negative, even with the shortest exposure, the image being buried in one uniform density. — Carmine stained preparations give very good results. Bismarck brown stained preparations give good negatives, and do not require such a long exposure as many would imagine. It is of very little use to be guided by tables of exposure in this branch, as they can, at best, be only used as an approximation to correctness, and practice and judgment are the only guides upon which the beginner can rely; but the table given by Mr. Walmsley, and which I have before quoted from Nos. 13, 14, and 15 of THE BRITISH JOURNAL OF PHOTOGRAPHY for 1885, will furnish a very reliable guide for those who take up this class of work for the first time, but after that the student should draw up tables for himself, to be modified according to circumstances.

The plan I have adopted for ascertaining the magnification of an object is simple and accurate enough for all ordinary work. The sliding baseboard carrying the sensitive plate is marked off roughly into five divisions of about half a foot distance apart. An object exactly one-sixteenth of an inch was chosen, and its image was projected through the lowest power objective intended to be employed, and being focussed on the screen, its dimensions were taken at the first division by means of compass and rule, and its amplification determined accordingly. The sliding base was moved through all its divisions, and the same performance gone through for each of the objectives employed. Now, if the object which we know to be one-sixteenth of an inch is magnified at the fifth division to four inches diameter, we call that $\times 64$, and so on for all the objectives and for every class of subject. Thus having, as we have done, determined on the magnification in diameters which every objective will give at every division of the baseboard, we are enabled to tabulate these and hang up the table near the apparatus.

There is one thing this apparatus in its present form cannot do very comfortably, and that is, photograph opaque objects. It might be made to do that, however, by widening the baseboard, and some day it may be further modified to accomplish this. This class of work requires more attention than I can give it, so I must perforce leave that to others, but I dare say I shall some day feel inclined to add to the apparatus some arrangement by which the light from the lamp can be thrown on to opaque objects or the light from two lamps of differing intensity employed.

Then, again, I might be expected to say a few words relative to the use of orthochromatic plates for photo-micrography. I have used these, both purchased and made by bathing in erythrosine, and except in double stained sections of plants, have not obtained sufficiently marked results to induce me to get these plates in preference to the usual ordinary kinds.

I have, in these few brief remarks, touched on the cardinal difficulties which beset the path of the photo-micrographer. These may be, to a limited extent, removed, so that they are less obtrusive, by the concentration of many minds on the task, but they can never be entirely overcome on account of the physical laws involved in their production. In the meantime, however, many of them may be lessened by proper attention on the part of the preparers of microscopical objects by their mounting these as flat as possible, by particular attention to necessary reduction in thinness, and the selection of suitable stains. Thus, insects mounted entire, without pressure, and rendered perfectly transparent, are beautiful objects, and eminently suited for examination with a binocular microscope, but are perfectly useless for photography; while, had they retained their transparency and been mounted flat, they would, at least, have conveyed an idea of their form in a photograph. Again, sections are either too thick, not flat, or unsuitably stained. Some sections I recently examined presented in miniature all the beautiful undulations of some rolling downs, instead of that absolute flatness which would ensure a sharp photograph. We may expect an improvement in this department of the photographic art only from the combined operations of the histologist, who knows what is required in photo-micrography, and the photographer, who knows something of the normal characters of the histological elements. It is at present useless to trust to professional mounters, who do not know, or do not care to know, the conditions necessary to the making of a successful photograph, and who ought to be, at the same time, in the possession of the knowledge of microscopical anatomy to enable them to put up suitable subjects properly. As an illustration of what I intend to convey, take some of the sections of tongue frequently met with; they usually present a confused, broken up mass of muscular fibre with here and there a piece of glandular structure, and crowned with a range of unimportant papillae. Now, such a section would be a far more instructive agent if it had been made through a filiform or a fungiform papilla. I need not multiply instances, this one will suffice to exemplify my meaning. Section cutters should always endeavour to include in their sections some important element of interest, then, if cut thin enough and suitably stained, a photograph full of instructive detail will be the result. Life is not long enough for one man to devote his leisure moments, snatched from the business of bread winning, to every branch of this interesting work; therefore, from personal experience, I plead for this division of labour.

T. CHARTERS WHITE.

ON NEGATIVES AS AFFECTING THE PRINTING.*

THERE are many who think that provided the negative will give sufficient contrast from light to shade with a full amount of middle tints that it must necessarily be a good one. That this is by no means the case with gelatine negatives I hope soon to show.

I have lately had my attention called to the fact, that in printing from two negatives which took about the same time in the frames, and gave equally good results in contrast and middle tints, the print from one looked flat, and if the slightest overdone, the high lights appeared fogged as if it had been exposed all over to the light, while the other was clear and round, and even when over printed still retained its good qualities. Upon examining the negatives I found that No. 1 was thin, such as would have frightened an old collodion operator, but was sufficiently non-actinic to print strong and vigorous, while No. 2 was very much denser, more resembling a collodion negative in colour, and, as I before mentioned, took about the same time, or if anything rather less than the other in printing.

Upon inquiry I found that all of the No. 1 class were developed with pyro and ammonia, while the No. 2 were developed with pyro and the carbonates of either one or both of the fixed alkalies. It would seem from this as if the carbonates of soda and potash with pyro gave much better negatives for printing than those in which ammonia was employed; but I have lately had numbers of plates quite equaling the No. 2 both in appearance and good printing qualities, which I knew were developed with pyro and ammonia. In seeking as to the cause of this I find that these latter had had the development carried on much farther than in the No. 1, and the whole of the non-actinic colour discharged by soaking for a few minutes in diluted sulphuric acid, half an ounce to a pint, as recommended by Messrs. Morgan & Kidd.

There is no question that however this non-actinic colour may assist the density of the negative, it is at the expense of all rotundity and clearness of the prints, so that in all cases it is advisable to be discharged. Now the point to arrive at is this, Is this colour due to the action of the ammonia or the pyro, or is it only in the use of a caustic

* Written for ALMANAC, but received too late.—Eos.

alkali? that is, would it also occur if the solutions of oxides of sodium or potassium were employed? and would the carbonate of ammonia be better than the liquid?

This latter is commonly used, not so much on account of its cheapness as that it is supposed to require less exposure of the negative plate than any other, and also that the development is quicker finished, but possibly if first-rate negatives are studied the extra trouble it gives to make them good printers will not be found to be much in its favour. It is also very certain that the more sensitive plates are much more liable to produce this strong colour in development than the less sensitive ones, so that it is better to use these last for general purposes, and only use the others for special occasions where great rapidity or work in rooms or studios is required.

FRANCIS G. ELIOT.

HISTORICAL NOTES ON THE OPTICAL LANTERN.

[A Communication to the London and Provincial Photographic Association.]

My first invitation to read a paper before a photographic society having emanated from this Association, it is a pleasure to respond this evening to that honour. The announced title of my memoir was *Lanterns and Lantern Slides in the Nineteenth Century*, but now that the paper is finished, it contains some information of earlier date, hence that title acts as a kind of bed of Procrustes, and either the title or the paper must be cut in two to suit each other, therefore a new heading has been chosen. The details about the optical lantern collected to bring under your notice this evening are historical rather than scientific.

The history of the optical lantern, the "magic lantern" of our younger days, has yet to be written, for to my surprise, after beginning to investigate the subject, I have been unable to discover a single book devoted to the history of the instrument, and the complete story will have to be gathered hereafter from scattered works on optics, from encyclopædias, and from certain old trade catalogues of opticians which may chance to have escaped the ravages of time and pipe-matches. A few books, or rather pamphlets, worth perhaps about a shilling each, exist, devoted to descriptions of special forms of the modern instrument. The following notes represent the results of such small research as could be made within the past week or two among records of the past, and they may serve to roughly indicate to the real historian of the future the general nature of the path he will have to traverse.

One reason of the paucity of the literature of the optical lantern is that, up to recent times, the instrument has been regarded merely as a means of amusement. In the English Patent Office it is not entered under the heading of Optics, and he who would discover patented inventions related thereto, will find it classed by the Government under "Toys." The earliest patent taken out in relation to the lantern bears so late a date as January 14, 1860, by Mr. Willoughby Smith, of Atlantic Telegraph celebrity.

The magic lantern was invented by Athanasius Kircher in the year 1646. There are speculations that it may have been known before his time. Some have ascribed its invention to Roger Bacon, who, in his *Discovery of the Miracles of Art, Nature, and Magic*, written about the year 1260, displays knowledge of the uses of lenses. Others have speculated that it may have been known to Egyptian hieropphants, because they understood the properties of concave mirrors. Cellini, who died about 1570, describes spectres which had been seen in ascending smoke, and it has been said that these must have been produced by an optical lantern. All this is but speculation. The one thing which can be clearly seen by us when peering into the mists of antiquity, is that Kircher gave the first clear description of an optical lantern, and was personally proud of its invention, see *Ars Magna Lucis et Umbrae*, Athanasii Kircheri, in decem Libros digesta, Rome, MDCXLVI. In his preface to a portion of this book devoted to optical instruments, including some peculiar cameras among other things, he says that they are not the work of the Devil, but the result of contemplation. He adds that he has to tell of one of the rarest secrets of nature, that it will excite admiration in the minds of spectators, that nobody has done anything of the kind before, that he made the first experiments before any one else knew anything about the matter. Other people sometimes promised rare, wonderful, and unheard of things which afterwards proved all wrong, but what he had to tell would prove all right. Evidently the worthy priest, for priest he was, stood upon excellent terms with himself.

Kircher was born at Giessen, near Fulda, Germany, May 2, 1602. He was, when a boy, educated in the College of Jesuits at Fulda, and in the course of his ecclesiastical career resided at Cologne, Coblenz, and Mayence. In 1635 he was Professor of Mathematics at Vienna; subsequently he went to Rome, where he died November 28, 1680.

Kircher's lantern contained a plano-convex bull's-eye condenser, a double convex lens as the objective, and a conical oil flame as the source of light; the slide was placed between the condenser and the light. Messrs. Carpenter & Westley have a diagram of Kircher's lantern in their possession. Kircher was a voluminous writer; the titles of his books form a long catalogue. He prided himself on his skill in deciphering hieroglyphics. A student, one André Muller, did some scribbles on a parchment and forwarded them to Kircher as antique records; the unsuspecting *savant* replied that they were true hieroglyphics, and sent Muller the translation.

Leonard Euler, the mathematician, invented the modification of the optical lantern for exhibiting images of opaque objects, and he described it, with a diagram, in one of his published *Letters to a German Princess*, dated January 8, 1762. It consisted of a lantern with a tube and double convex lens in front, and at the back, opposite the lens, was a kind of saucepan lid, which held the object to be projected. In the lantern were two opaque screens, or wings, behind each of which was a lamp with a large wick. The lamps illuminated the object, and the wings screened the lights from the lens. He says: "I have contrived in this box two side wings for the reception of lamps with large wicks, and in each wing is placed a mirror to reflect the light of the lamps on the objects. . . . The ordinary magic lanterns, however, are not constructed in this manner, and serve to represent no other objects but figures painted on glass, whereas this machine may be applied to objects of all sorts." To magnify a fly to the size of an elephant, he recommends that the rays of the sun shall be concentrated upon it by a "burning glass," to give sufficient illumination. This treatment, we may surmise, would be bad for the fly.

In the *Dioptrica Nova*, by William Molyneux, published in 1692, is an engraving of a magic lantern, in all respects the same as that of Kircher—a simple oil flame, a plano-convex bull's-eye of great curvature, and a double convex objective. Molyneux calls it the "Magic Lantern, sometimes called the *Lanterna Megalographica*." He speaks of it as a well-known instrument, made by "common glass-grinders," and he states that in some of the instruments a reflector is used instead of the lenticular condenser.

For about 150 years little or no improvement was made in the original instrument of Kircher. Towards the close of the eighteenth century, Dr. Gravesande, a Dutch man of science, described a magic lantern containing a four-wick lamp. The oil from the lamp traversed a horizontal pipe carrying the wicks. The flame was made up of four little flames, which by touching one another made "one square flame two inches wide." A concave reflector behind increased the illumination. This lantern had a five-inch double convex condenser. The objective consisted of two double convex lenses; the diameter of the one next the light was three and a half inches, and was of considerable convexity. The front lens of the combination was smaller and flatter, and was placed three inches from its neighbour. There was a diaphragm between the lenses, and the information was published that unless the diaphragm "be just where the rays intersect, it does a great deal of mischief." For additional information about this lantern see *A Complete System of Opticks*, by Dr. Robert Smith, Professor of Astronomy at Cambridge, and "Master of Mechanicks to His Majesty," 1784. Five years after this, in the year 1789, Argand invented his lamp. Before this date the optical lantern was necessarily an imperfect kind of instrument, unless sunlight were used as the illuminant. The solar microscope was invented by Nathaniel Lieberkuhn, of Berlin, in 1738.

With the exception of the step described by Gravesande, all the great improvements in the optical lantern have been made within the last one hundred years; before that time illuminants were too feeble. If I remember rightly it was Charles Lamb who described our forefathers as persons who "walked in the dark, groping."

Phantasmagorical effects were first seen in London in 1802, at the Lyceum; their advent is thus described in *Chambers' Journal* of April 28, 1849:—

"In 1802, a French gentleman, a M. Philipstal, astonished crowds of people in London by an optical exhibition which he entitled the Phantasmagoria. It was a soul-appalling spectacle to those who had hitherto been ignorant of the wonders of light and shade. The spectator was a room where no light but that of a dismal oil lamp, hanging in the centre, was admitted. On the assembling of the audience, this lamp was drawn up into a chimney, and a pitchy gloom overspread the place. Presently the soft and mournful notes of sepulchral music were heard, and a curtain rose displaying a cavern, on the frowning walls of which were depicted the forms of skeletons and spectral figures. The music ceased; the rumbling of thunder was heard in the distance. Gradually it became louder, until at length vivid flashes of lightning, accompanied with peals apparently of the deep-toned organ of the skies, gave all the impressions of a tremendous storm. The thunder and lightning continued at their height, when suddenly a small cloud of light

appeared in the air; it gradually increased in size, until at length it stood revealed a ghastly spectre, around whom the lightning gleamed in fearful reality. Its eyes moved agonisedly from side to side, or now turned up in the sunken eye-socket, the image of unutterable despair. Away, back to the dim abyss from whence it came it was seen swiftly to retire, and finally vanished in a little cloud, the storm rolling away at the same time. Then came other phantasms, some of which rushed up with apparently amazing rapidity, approaching the spectators, and again as rapidly receding, to return clothed with flesh and blood, or in the form of some well-known public personages. After a display of a number of similar apparitions, the curtain fell."

If the man were still living who wrote the foregoing harrowing description of a magic lantern entertainment, and were to apply to the *Daily Telegraph*, he would probably be engaged as a leader writer straight off. How the narrative reminds us all of early days at the Polytechnic, when from the depths of the yawning cavern the bloodthirsty ogre expanded into view, amid the crash of gong and the roll of drum, while Mr. J. L. King, who governed these terrible powers, steadily controlled the incantations without being the least bit frightened; he ruled the whirlwind and the storm, unmoved and serene he stood amid all the horrors of a Walpurgis night.

Phantasmagorical effects, it is scarcely necessary to state here, are produced by means of a translucent screen, behind, and to and from which, a lantern is run upon rails; as it approaches the screen the figure represented diminishes in size; as it recedes from the screen, the apparition increases in size but diminishes in brightness. To equalise the illumination various devices have been invented, among them the interposition of a varying number of curtains. The objective has to be moved in its tube as the lantern advances or recedes, so that the image shall always be in sharp focus upon the screen. Some operators have been clever enough at private lantern displays to manage all the motions of the camera and its parts without additional automatic appliances; their plan in old days was simply to tuck the lantern under one arm, and go to work. With a modern three-wick lantern the temperature would, under such circumstances, be objectionable.

Before lantern objectives were constructed capable of giving a flat field upon the screen, the designs to be exhibited were in some rare instances painted upon concave instead of flat pieces of glass; these old concave slides are now great curiosities.

The oldest manufacturers of magic lanterns in this country are Messrs. Carpenter & Westley, of 24, Regent-street, London. Philip Carpenter began the making of lanterns in Birmingham about the year 1803, and subsequently the late William Westley, who was born in 1807, entered his employment. In 1827, shortly after the removal of the business to London, William Westley rejoined his employer, first as foreman, than as partner; lastly he became the principal. He died at the beginning of this year, 1887, and was buried in Highgate Cemetery. Philip Carpenter was the uncle of the late Dr. W. B. Carpenter, the physiologist; the latter is said to have acquired his taste for scientific pursuits from the interest he took as a boy in the lanterns and lantern slides of his uncle. When dissolving views were invented, about 1836, by an Italian, whose name I have been unable to obtain, and, it is said, by Henry Childe, independently of each other, Dr. Carpenter wrote to Messrs. Carpenter & Westley, asking how they were produced and giving his own theory; he did not guess that two lanterns were brought into play. That letter is still in existence. When dissolving views were first invented, William Westley put them before the public, but the method of their production was kept secret. William Westley raised lantern slide painting to a fine art; he selected the best artists and encouraged them to improve by paying them twice the usual fees for their work, with something in addition for any exceptional specimen of skill. Among the best slide painters he employed may be mentioned Thomas Kearnan, the best slide painter of architectural subjects who ever lived; he died in 1872. Another was Henry Childe, who claimed the invention of dissolving views; he was clever at scenic effects, such as rippling water, summer and winter, eclipses at sea, and so on. Another was S. H. Baker, the best man who ever painted landscapes on glass for the lantern. J. Smith and Thomas Clare were other noted slide painters of the past, so also was Charles Simpson, a miniature and portrait painter by profession, who subsequently became blind. Lastly, C. Constant, the painter of comic slides, should be remembered; he has made himself immortal by devising the world-wide famous slide of the sleeping man swallowing endless processions of rats. All these painters have departed this life with the exception of Mr. Baker, who now occupies a high position in connexion with the Birmingham Society of Arts. Kearnan and Simpson were interred by the late William Westley in the same grave in Brompton Cemetery.

Messrs. Carpenter & Westley introduced the crescent form of dissolver, in which a crescent was cut out near the circumference of a circular disc; it gets rid of the shadows on the picture cast by opaque dissolvers. Philip Carpenter, the founder of the business, materially helped Sir David Brewster in the invention of the kaleidoscope. A few days ago I had the pleasure of meeting in the establishment a nephew of each of the founders of the firm, from whom the particulars herein given in relation to its history were obtained. They have about 12,000 slides on the premises, some of them by departed artists, whose productions they will not now part with on any terms, and all people connected with the lantern trade agree in telling me that photography has killed lantern-slide painting as a fine art.

W. H. HARRISON.

(To be continued.)

THE CRYSTAL PALACE PHOTOGRAPHIC EXHIBITION.

AN exhibition of photographs and apparatus will be held in the Crystal Palace, commencing Monday, February 20, 1888. We make such an extract from the rules and regulations as will enable our readers to become acquainted with the conditions under which they may exhibit.

All goods or pictures for exhibition must be delivered, carriage paid, on or before Saturday, February 11, 1888, addressed to the Executive Committee, and bear, in a distinct manner, the name and address of the sender, together with the number of table or space assigned to the exhibitor. The committee reserve the right to refuse any exhibit, without stating any reason for so doing.

No exhibit shall be removed until the close of the exhibition, immediately after which each exhibitor must pack and remove his goods at his own expense. The executive reserve to themselves the right of doing whatever they may consider necessary, at the expense of the exhibitor, unless this regulation is strictly complied with.

No sales shall be allowed to take place during the exhibition, nor may photographs of the Palace or grounds, or any part thereof, be taken, but orders may be booked for duplicates of any exhibits.

In the apparatus division, tables or floor space will be provided for exhibitors 16 ft. by 12 ft., which will be subdivided to suit requirements into spaces of 16 ft. by 6 ft. or 8 ft. by 6 ft., for which a charge will be made of 1s. 6d. per square foot. No exhibitor will be allowed to transfer any portion of the space allotted to him, or to allow any other than his own duly admitted exhibits to be placed thereon, without the consent of the committee.

In the art division a fee of 2s. 6d. per frame (irrespective of size) will be charged. No Oxford frames will be admitted.

Photographs coloured by artificial or mechanical means will be excluded, except under class C, section 4.

Reasonable care will be taken to protect exhibits, but neither the directors nor the Executive Committee will be responsible for any loss or damage arising from fire, accident, or any other cause.

A non-transferable admission ticket will be supplied to each exhibitor, and, in the apparatus division, to an attendant where necessary, which will pass the holder into the Palace without payment on each day of the exhibition.

No exhibitor will be allowed to display his goods or name-board (which must in every case be placed longitudinally with the nave), to the annoyance or detriment of other exhibitors, and the directors may require the removal of any obstruction, or anything which in their judgment contravenes this rule.

No substance of a dangerous or explosive nature shall under any circumstances be exhibited.

Awards will be made in each class, provided the judges deem any exhibit or exhibits of sufficient merit. From the decision of the judges there shall be no appeal.

All correspondence and inquiries to be addressed to the Executive Committee of the Photographic Exhibition, Crystal Palace, S.E.

Applications for space must be made as above, and the forms filled up and returned before Saturday, February 4, 1888.

Regulations and other information respecting the competitive lantern entertainments which will take place during the exhibition may be obtained from the committee.

These regulations, with one or two omitted, are signed by S. G. Buchanan Wollaston, W. H. Hyslop, and J. F. Peasgood, who form the Executive Committee.

Space does not permit us this week to give the divisions and classification of the exhibits. These in our next.

NOTES FROM ABROAD.

(From our Special Correspondent.)

V.

BELGIUM AS A FIELD FOR THE CAMERA.

IN my last some particulars were given about Louvain, the capital of South Brabant; the city now contains but 35,000 inhabitants, whereas, in the days of its glory in the fourteenth century, it had 140,000. Its history dates back to the Roman period. The country surrounding it is flat, and its chief photographic subject, the City Hall, has been much "done" by photographers; in London it is represented in commercial lantern views. The chief thing I saw in Louvain, of interest to a professional photographer, was one likely to take his breath away, namely,

the following announcement in some of the shop windows:—"Carte-de-visite 1s. 3d. per 100, in ten minutes." Gradually, however, the light may dawn upon him that the name of *carte-de-visite* for a photograph is a stolen one, and that it originally meant what it says, namely, "visiting card."

To Liège, a distance of between forty and fifty miles, the country is gently undulating, and cultivated to its utmost capacity of production by peasant proprietors. Here and there a gentleman's chateau is seen, with grounds, and sometimes ornamental waters, of moderately limited extent. Liège, the chief seat of the iron trade of Belgium, lies down in the valley of the Meuse, and the railway approaches it down a long, steep, and expensive incline. No city is more labelled in English guide-books than Liège. It is almost invariably described as a place of fires and forges, surmounted by a grimy canopy of smoke. The *Practical Guide*, published by Trübner & Co., is dated 1887. Its editor says:—"The primary feature which distinguishes these 'Guides' is—They are altogether based on personal experience. . . . They indicate nothing that has not been personally verified." Of Liège it says: "Iron foundries, for firearms, printing presses, steam engines, &c., flaming in all directions. . . . To Namur, 1½ hr. or steam." In this book the words "or steam" are always employed to denote steamboats. As a matter of fact the steamboats between Liège and Namur have ceased to run for at least five years, and instead of Liège being a place of flames, forges, and iron foundries, I saw in it neither flame nor smoke. Bath and Brighton are more smoky than Liège, doubtless because the Belgians burn their fuel in a rational manner, do not waste three-fourths of the heat up the chimney after paying for it to the coal merchant, neither do they waste the unburnt fuel called "smoke," and at the same time pollute the atmosphere therewith. The region of fire, and smoke, and forges is at Seraing, a few miles up the river from Liège. The latter is a beautiful city, laid out with boulevards, gardens, squares, and ornamental waters, with an atmosphere so clear that, when photographing in the middle of the town, the cottages on near and distant hills would come out sharp and crisp in the picture when the weather is fine. At the end of September, when fires were coming into use, I saw no haze due to smoke. An average London atmosphere is pea-soup compared to that of Liège. So much for guide-books, for the one just quoted is not an exceptional case, but makes most claims to extreme accuracy. The editor has a lively style of writing.

Among the chief features of Liège, from a photographic point of view, is the Palace of Justice, built in 1583 by the Cardinal-Bishop Erard de la Marek. It has a colonnade with pillars somewhat in the Moorish style; anciently the place was the residence of the Prince-Bishops. Another remarkable specimen of architecture is the interior of the Church of St. Jacques, date 1513. In exploring the west end of Liège I came, alongside the Church of St. Anthony, upon a feature not described in guide-books. It was a stone staircase about as wide as the Strand in London, but it went up, up, up, until church spires were left far below—up, until the people at the top looked no higher than umbrellas. Here was something to be explored. When less than half-way up, the spires and turrets of the highest buildings in the city were below the observer, and at the top of the staircase was a *café* called "The Mountain Rest." It turned out to be a staircase upon the side of a steep hill, at the top of which were some of the fortifications of Liège. What lens would do justice to this staircase?

A new departure, I think, might be made in tourist photography by the traveller training himself, not so much to take views of celebrated places, which local photographers, at all events, have obtained already, but to complete various series of pictures, illustrating manners, customs, and events foreign to his own country; then, on his return, by the optical lantern or otherwise, he should convey to others the information which he himself has gained. In Liège, some of the most foreign-looking things I saw were the scaffoldings used in building and repairing houses. These scaffoldings were variously built up, and are indescribable without photographs. In one place I saw a house in a main street undergoing extensive repairs. All the front wall and front rooms had been removed, leaving the roof and back rooms standing. In the eavens thus created a new shop and front rooms gradually arose. As the wanderer wends his way southwards in Europe the scaffoldings grow more mysterious, until in Switzerland they are made so that barrows can be wheeled from the bottom to the top up zigzag inclined planes, built on the principle of the zigzag roads up steep mountains. At Berne, in addition to these novelties to an Englishman, the builders have a special way of raising stones and heavy weights. A kind of squirrel cage is erected high in the air, inside which men perform treadmill exercise, something like squirrels or white mice. The wheel thus turned works a windlass, by which stones and other things required in the building operations are raised. Things like these should be photographed, and a "yarn" spun about them when exhibiting the pictures at home. The interest of observers of photographs can always be enhanced by a little judicious talk. The pictures are most effective when on a large scale and brightened by the glory of colour, as by means of the painted slides of the magic lantern.

Here is another un-English subject for the camera. In Belgium, and in some other European countries, the people do not trouble themselves by building much in the shape of railway platforms. Especially is this the case at the smaller stations, where passengers scramble across one line of rails to get into a r in upon another line of rails. At large centres of

traffic in Belgium it is also common for, say, half-a-dozen trains to be timed to reach the junction at the same time. They remain perhaps fifteen minutes, during which the passengers "sort themselves," and when all are rearranged in their proper trains, off they go. Liège station-in-chief, with three trains waiting at one end, three at the other, and the passengers thronging the space between at the level of the rails, is a subject for an instantaneous photograph. Pictures illustrating the cheerfulness of *café* life in France and Belgium, and the way in which fathers, mothers, and children enjoy themselves in a homely way at such places, would be interesting in England; but to obtain them the magnesium light would perhaps have frequently to be brought into play. The light-hearted French would in many cases enter into the fun of the thing, and politely pose and sit quietly that the Englishman might take home a memento of the scene. In time, such pictures, accompanied by narratives, will become of somewhat less general interest in England, because statistics prove that the number of English crossing the Channel annually is increasing by leaps and bounds. Only the lack of education has hitherto prevented the average English from mixing up with the leading Continental nations to the same extent that the dwellers in those nations intermix with each other. In Switzerland a young man is not thought to be worth much unless he can speak three living languages in addition to his own, and a wise Government has provided for him facilities for learning them almost gratuitously. Hence, also, they can, and they deserve to, get situations in England where an English youth cannot, they having earned their ascendancy by perseverance and honest hard work in good schools.

From what was said in my last about the necessities of the light-footed photographic tourist who intends to visit comparatively unexplored districts, armed with no more baggage than he can himself easily carry, it becomes evident that the weight of his plates or films becomes of major importance. As to paper negatives, it is admitted that they show grain when they are of lantern-slide size, and are afterwards printed as such for projection; therefore, the tourist who has rare subjects before his camera cannot afford to use paper instead of plates. Stripping films deserve attention, but they have yet, for such work, a good or other reputation to make, and the manipulations are more complicated than those connected with dry plates. If plates should prove to be a necessity, it is also an absolute necessity that they should be of thin glass, which in England has not always been very largely on sale at moderate prices, although Mr. J. Traill Taylor recently discovered an exception in London and Birmingham to this rule. At Liège I called at the University, and found that even in the autumn season its library is open, but for a few hours only, and in the daytime. There I saw in a recent number of the *Bulletin Belge* about experiments in Belgium with the Balagny films, which, from reports in French newspapers, would seem to be as good and transparent as glass plates, and nearly as simple in manipulation. The only objection to them which, so far, has come before the public in England is their high price. It seems to be time that their merits and demerits should be exhaustively tested and reported in this country. The number of the *Bulletin Belge* aforesaid stated that M. Lunsden had given a demonstration of the working of these films before the Belgian Photographic Association. The developing bath he used had a glass bottom, so that when he poured off the liquid he could hold the bath and negative up to watch by transmitted light the progress of the development. The films were also strong enough to bear turning over by hand, while wet, to examine the progress. In order to expose them in the camera they were mounted temporarily upon ferrotype plates, which had previously been thinly coated with a warm solution of gelatine and glycerine. To this film, when cold, the films adhere lightly, and the coating serves to hold several films in succession without renewal of the adhesive material. The films are easily detached. In the course of the evening a picture of the members of the Association was taken upon one of the films by the aid of the magnesium light. A slight foginess in the negative was supposed to be possibly due to magnesium smoke or to tobacco smoke, though how the latter came to be present at a meeting of a scientific society is not stated by the *Bulletin Belge*. Thus, the hope of the pedestrian tourist seems to lie—1, in Balagny films; 2, in stripping films; 3, in gelatine emulsions upon thin glass; 4, in getting small batches of thin glass gelatine-emulsion plates sent to meet him at various places by parcels post, and sending home small batches of his finished negatives at the same time. Of these plans, perhaps the first and last are the most promising.

PHOTOGRAPHY IN 1887.

[A Communication to the Yorkshire College Photographic Club.]

I PROPOSE with your permission to classify what I have to say under three heads, namely, progress during the past year; the present position and utility of photography; the claims of photography to rank as a creative art.

A considerable amount of evidence has been accumulated with reference to both the principles and practice of orthochromatic processes, and it may fairly be claimed that the value of these processes has been clearly established, although very much still remains to be done before the methods can be regarded as approaching perfection. For the repro-

duction of paintings orthochromatic methods have become indispensable, and the excellence of the results obtained, when they are combined with photogravure, is truly remarkable. In photographing pottery, flowers, and similar subjects, the advantages are likewise very strongly marked. A more extended series of experiments on the use of plates prepared with erythrosine for landscape work confirms the conclusion previously expressed, that the gain over the ordinary process is more considerable than might be expected from general considerations, whilst at the same time it is much more strongly marked with some subjects than with others. The improvement is most noticeable in the rendering of foliage, water, and distance. The masses of foliage are bolder, and trees of different colour and character are much more clearly distinguished. The distance is rendered more clearly especially during the prevalence of that almost imperceptible blue haze which is frequently so troublesome, whilst at the same time the atmospheric effect is not lost if care is taken not to use a screen of too deep a tint. The gradations of the water are softer and more pleasing, and the reflections, usually so difficult to render, are obtained in a satisfactory manner. Erythrosine is still the most powerful known sensitiser for the less refrangible rays, and is the most useful for general purposes, whilst cyanin is unsurpassed for subjects which contain much* orange and red. Mr. Wellington has recently introduced certain modifications by means of which he is able to increase the stability of the cyanin and the plates prepared with it.

The most noteworthy improvement in the methods of photo-mechanical printing is Husband's *Papyrotint*,† a method of photo-lithography in half tone, the necessary grain being obtained by means of potassium ferricyanide. The transfer paper is first coated with gelatine containing glycerine and a considerable proportion of common salt, and then, after drying, with gelatine containing potassium bichromate salt and a considerable proportion of potassium ferricyanide. After exposure the transfer is treated with water, inked, and transferred to stone. The character of the grain can be modified by altering the proportion of ferricyanide, drying at a higher or lower temperature, and varying the temperature of the water with which the transfer is treated. Even a fine-grained transfer will yield as many as 1200 copies. The results are very satisfactory.

A discussion as to the relative permanence of prints produced by different methods has naturally excited considerable interest, but has been characterised by a considerable amount of reasoning based on false analogies, and the display of an inadequate knowledge of chemistry on the part of otherwise able and skilful photographers. Without at present entering into the question in any detail, it may be useful to point out that a print produced on albumenised paper in the usual way is something totally different from a print produced by development from an emulsion, and the properties and reactions of the one afford no guide whatever as to the probable behaviour of the other under similar conditions.

A most important contribution to the science of photography has been made by Carey Lea, whose papers have been reprinted in most of the photographic journals. His investigations deal mainly with the nature of the invisible or latent image. The two theories which have hitherto divided photographers on this question are generally known respectively as the physical theory and the chemical theory. According to the first the light waves impinging upon the silver salt throw the molecules into such energetic vibration that the molecular structure is very nearly shattered, or, in other words, the attraction of the silver for the chlorine, bromine, and iodine is so far overcome that the developing solution is able to complete the destruction of the molecule by removing the bromine and leaving the silver in the metallic state. According to the chemical theory, the light waves acting on the silver salt in presence of moisture, organic substances, &c., decompose it, splitting off half the chlorine, bromide, or iodine, and leaving a sub-chloride, sub-bromide, or sub-iodide. This sub-salt is at once attacked by the developer, and the metallic silver thus formed constitutes the nucleus upon which the image is built up by the subsequent action of the developer.

" 29.....	London and Provincial	Mason's Hall, Basinghall-street.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday, December 15, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. A. Haddon presided.

Letters were read from Mr. Charles Blackburn, of Didsbury, Mr. J. L. King, and Mr. P. Fincham, expressing regret at being unable to attend at the reading of the paper.

Mr. W. H. HANNAISON read a paper entitled *Historical Notes on the Optical Lantern* [see page 809].

The HON. SECRETARY announced that the discussion of the paper would be postponed until the last Thursday in January.

Mr. W. ENGLAND said that when architectural photographic lantern slides first came out they gave curved lines on the screen at the Polytechnic Institution, the managers of which, consequently, had lenses for projection specially made by Dallmeyer; that was fourteen or fifteen years ago.

Mr. J. TRAILL TAYLOR remarked that at least twenty-five years ago photographic lenses were used in conjunction with the lantern; at the very foundation of the Photographic Society of Edinburgh he read a paper and used achromatic lenses in the lantern. In the last ALMANAC would be found much about lantern condensers and the best methods of intensifying the light by an extra lens and otherwise.

Mr. E. M. STOKES stated that a living painter of the old school of lantern slides, Mr. Hill, had not been mentioned in the paper, nor was Henry Gardner mentioned. The latter is good at landscape painting and general work on slides; he now lives at Birmingham. He remarked that some of the best lantern slide painters of old had been short-sighted, which for such work seemed to be an advantage.

Some historically interesting lantern slides, painted before the days of photographic slides and by the artists mentioned in the paper, were then exhibited for Messrs. Carpenter & Westley by Mr. E. Manning Stokes, a nephew of the late William Westley, and by Mr. T. B. Matthews, a nephew of the late Philip Carpenter. Among these slides was the original one of the man swallowing rats, also the improved form of the same picture subsequently devised by the original artist. One of the exhibited slides of former times had been very delicately painted by a Dutch artist, name now forgotten.

Mr. W. M. AYRES exhibited some unmounted prints on albumenised paper twenty-five years old; they had been toned and fixed in the old hypo and gold bath, and are still in good condition—pure in the whites and deep in the blacks.

Messrs. A. C. Edwards and E. J. Platt were elected members of the Association.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

A COMMITTEE meeting was held on the 15th instant, when the following were elected members of the Association:—Messrs. E. Darlington, A. R. Dresser, F. R. Greenslade, J. Hendrie, W. J. Humphreys, E. A. Rice, E. N. Smart, E. Sampson, Mipess, Coslett, Hawker, Reddy, and Sisman.

Four urgent cases were considered, and substantial assistance given.

Messrs. W. J. Humphreys and H. J. White were elected members of the Committee.

Mr. W. M. Ashman resigned the Chairmanship of the Committee owing to his business necessitating his leaving London.

Mr. W. Bedford was unanimously elected to fill the vacancy.

The meeting then further considered the preliminary stages for the inauguration of the Orphan Fund.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE annual dinner of this Association was held jointly with the Birkenhead Association, in lieu of a general meeting, on Thursday, the 15th instant, at the Neptune Hotel, Liverpool.—Mr. George H. Ratter, President of the Liverpool Association, in the chair.

The party numbered about thirty-two, and a pleasant and social evening was spent.

In the course of the dinner a demonstration took place of what was styled a *New Royal Wet Process*, by Mr. J. B. Sayce, in which the vincus juice played an important part. This process, which is strongly recommended to amateurs convivially inclined, was highly approved of, the only drawback appearing to be its want of permanency.

After the usual loyal toasts, the succeeding toasts were, "The Photographic Associations of Liverpool and Birkenhead," responded to by Mr. J. H. Day on behalf of Birkenhead, and Mr. W. A. Watts on behalf of Liverpool; "Mr. B. J. Sayce, President-elect for Liverpool," proposed by Mr. B. Boothroyd; "The Prize Winners for 1887," proposed by Mr. H. N. Atkins, responded to by Messrs. Beer and Lewis.

During the evening songs were sung and pianoforte selections given by Messrs. Miners, Beer, W. and F. Falton, Day, Tomkinson, Rowman Ralston,

and James Ralston, which added greatly to the pleasure and conviviality of the evening.

In the course of the proceedings a collection was made on behalf of the family of the late Mr. Jennings, which resulted in the sum of 3*l*. 6*s*. 6*d*. being added to the fund.

WALLASEY PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this Association was held at 12, Bradford-terrace, Seacombe, on Wednesday, the 7th instant.—Mr. Wilkinson in the chair.

Messrs. J. Gill, H. B. Sharpe, E. Shubett, and Byrom, were duly elected as members.

The taking of instantaneous photographs by night was then discussed, and the various methods recently mentioned for the instantaneous ignition of magnesium were touched upon.

The Chairman afterwards exposed two plates on a group of the members, using as an illuminant in each case a few grains of gunpowder (not having gun-cotton at hand) and about fifteen grains of powdered magnesium. The results, so far as exposure was concerned, were very good, and plainly demonstrated that by the aid of reflectors extremely successful portraits may be taken at night in an ordinary room. The objection, however, to gunpowder is that it gives off smoke, an inconvenience which does not attend the use of gun-cotton.

DERBY PHOTOGRAPHIC SOCIETY.

THIS Society held its usual monthly meeting in Sykes's Rooms, Victoria-street, at eight p.m. on Tuesday, December 13.—Mr. R. Keene in the chair.

The minutes of the last meeting having been read and confirmed,

Mr. FRANK COOPER read a paper entitled *Photographic Experiences*, which elicited some discussion, Mr. Cooper answering a number of questions put to him on the subject; and he was accorded a hearty vote of thanks.

The CHAIRMAN announced that the annual *conversazione* would be held on January 11, 1888, in the Lecture Hall, when there would be an exhibition of photographs and lantern slides, also demonstrations of photographic printing processes, &c.

It was decided to inaugurate an annual supper, to be provided in the Society's meeting room, upon a date to be fixed during January.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE last meeting of this Society was held at 36, George-street, December 8, 1887.—Mr. Abel Heywood, jun., Vice-President, in the chair.

The minutes of the previous meeting read and confirmed, Messrs. Charles F. Brennan, Warwick Brooks, Alfred J. Bailey, S. Herbert Fry, and M. Pogson, were admitted members.

Mr. ABEL HEYWOOD, JUN., read a short paper on Pumphrey's films, which he had tried a considerable number of during the past summer in Norway. The size he used was quarter-plate, for lantern transparencies. Mr. Heywood stated that though he might be satisfied with the films for silver printing he would not venture on using them again when on a distant expedition, especially if he had lantern transparencies in view. The objections he found to them were that he did not obtain the same refinement of focus as on glass, and the films were much more liable to flaws and blemishes. He exhibited a number of film negatives, with silver prints and transparencies from the same, also silver prints and transparencies from glass negatives taken on the same expedition. Mr. Heywood also exhibited a coloured portrait of himself, taken by Mr. Mayall, London, and coloured by his patent process.

Mr. JOHN SCHOFIELD read a paper and gave a practical and successful demonstration of making lantern slides and bromide enlargements by artificial light [see page 794 in last week's JOURNAL].

The Hon. Secretary exhibited on behalf of Messrs. Ross & Co. an instrument called the "Cuminoscope," for viewing single photographs, and it is claimed that the concave mirror of the instrument magnifies and produces an effect almost equal to stereoscopic. However, the opinions expressed on this instrument were not over favourable.

The Hon. Secretary also exhibited a stereoscope and a number of stereoscopic slides which had been sent by Mr. Harding Warner. The slides were considerably larger than the old form, the photographs being five inches and a half in height by three inches wide, mounted side by side on six-and-a-half-inch square card mounts. These were passed round and examined by the members, and a discussion followed upon the advantages or disadvantages of large-size pictures for the stereoscope.

Mr. W. BLAKELEY could not agree with the Hon. Secretary (Mr. Chadwick), who had stated there was no advantage in large pictures for the stereoscope. He was quite sure he could get a great deal "more subject" on his 7½ × 4½ plates than Mr. Chadwick could on his 6½ × 3½ plates.

Mr. CHADWICK said "more subject" or "amount of subject" was a very unscientific term; angle of view would be far better understood. If, then, a four-and-a-half-inch lens was used on a four-and-a-half-inch plate, and a three-inch lens used for a three-inch plate, the "amount of subject" would be the same in each case, because the angle of view would be the same. The correct way to view a stereoscopic picture was at the same angle at which it was taken; we should then get apparent natural size. Mr. Blakeley had advocated cutting stereoscopic pictures three and a quarter inches wide and mounting them three and a quarter inches apart; in that case few people would be able to see them comfortably, and if we could not see them easily and with pleasure they were not worth looking at at all; but even in Mr. Blakeley's own case, as he had asserted "he could see them *very well*," the picture must be further from the eye than the ordinary distance, and so their size would be reduced. It was quite easy to see a stereoscopic slide four inches deep (or in height), but three inches wide was the limit for the width. For his own pleasure he preferred

one good transparency to a dozen paper slides; he, therefore, did not make paper slides, and anything larger than three and a quarter inches in depth for transparencies would be too heavy and clumsy, &c. When he required "more subject," or greater angle of view, he used a short-focus lens, and three inches was short enough for most purposes in stereoscopic work.

Mr. THOMAS CHILTON promised to bring to the next meeting a number of stereoscopic pictures taken by himself during the past season.

The CHAIRMAN said he was glad to see stereoscopic photography had taken such firm root in the Manchester Photographic Society.

Mr. SCHOFIELD (the Librarian) made a short report of the state of the Society's library.

Mr. J. F. Chapman presented for the Society's library a large collection of modern books on photography.

The Hon. Secretary presented a copy of Vogel's *Progress in Photography* (American edition), and many others were promised by various members.

Mr. A. BROTHERS called attention to the fact that the November meeting was held on Wednesday, November 9, instead of the usual second Thursday, November 10, and spoke of the undesirability of changing the dates of meetings.

The CHAIRMAN acknowledged the undesirability of altering the dates, but in this particular instance it so happened that the date for the closing of the Royal Jubilee Exhibition was November 10, and in making the alteration the Council thought they were considering the convenience of the members, as many would like to be at the closing ceremony of the Exhibition.

Mr. BLAKELEY thought with Mr. Brothers it was very undesirable to alter the date of meeting; for himself he had not had the privilege of being at the Exhibition for the closing ceremony, and November 9 was to him the last day of the Exhibition; therefore, he was debarred from attending the meeting of this Society, and considered "the whole proceedings of the last meeting ought to be repeated."

The Hon. SECRETARY said the date of meeting had only been altered three times in a period of about ten years, and in the present case every member had had nine or ten days' notice of the alteration by printed circular; the meeting which did take place was attended by more than the average number of members, all of whom was congenial and satisfied.

Mr. D. E. BENSON also spoke in condemnation of the alteration of date, and asserted his opinion that the Council had no power in that direction.

Mr. CHILTON thought the subject had been introduced with *very bad taste*. ["Hear, hear," from various parts of the room.]

The meeting was adjourned with the usual vote of thanks.

YORKSHIRE COLLEGE PHOTOGRAPHIC CLUB.

THE meeting on December 13 was devoted to a discussion on *Methods of Enlarging*, the President (Mr. C. H. Bothamley) occupying the chair.

Mr. A. E. NICHOLS described the apparatus which he employed for enlarging or reducing daylight. It consists of two stout wooden rails seven feet six inches long, fastened together by crosspieces; on these rails slide three frames, one of which is fitted with a series of carriers for negatives of different sizes, the second carries the lens, and the third is an easel on which the paper or plate can be fixed. A series of flat boards about twelve inches long slides along the rails, and prevents the access of any light from below. Laths pass from the upper part of one sliding frame to the next, and a cloth is thrown over these to keep out the light. The frame carrying the negative is placed against a window, and tilted at such an angle that unbroken sky illumination is obtained.

Mr. C. H. BOTHAMLEY described the usual method of daylight enlarging by means of an ordinary camera, the negative being placed in the camera and fixed against a window, and illuminated by means of a reflector, whilst the enlarged image is produced by the ordinary object being fixed in its usual place in the camera front.

Mr. F. W. BRANSON exhibited and explained a complete form of apparatus for enlarging by means of the oxyhydrogen light. The condenser was nine inches in diameter, and the objective was a Ross 8x5 rapid symmetrical. The condenser was fixed, but the distances of the light and the object from it could be readily adjusted by a sliding motion. The illumination of the field was perfectly uniform as far as the eye could judge, and a half-plate negative enlarged six diameters was perfectly sharp to the corners with a stop $\frac{1}{11}$.

Mr. BOTHAMLEY briefly explained the optical principle involved in using a condenser, and insisted on the necessity of having the light, condenser, and objective always fixed, or of being able to adjust the distances of both the light and objective from the condenser. He pointed out that the ordinary lanterns for projection were not very suitable for enlarging purposes, on account of the small range of adjustment. He also exhibited and described an apparatus for enlarging with either an argand gas lamp or the oxyhydrogen light.

Dr. E. H. JACOB had obtained good results with an argand oil lamp used in ordinary projection lantern, but had found it desirable to adopt some form of apparatus permitting of more ready adjustment. An efficient apparatus can be made out of very simple materials, involving little expense beyond the cost of the condenser, the camera lens being of course used as the objective. He considered that when working with paper it was possible to use a much greater quantity of yellow light than was commonly employed.

In reply to Mr. Whitham, the SECRETARY (Mr. Harry B. Hall) had had experience in the making of enlarged paper negatives which could be used for printing by any process, and had obtained very satisfactory results.

Further discussion of a conversational character followed, in which the previous speakers, the Rev. W. Hancock and Messrs. Whitham and H. Pocklington, took part. There was a general consensus of opinion that if enlarging was done at all, it was not worth while to use anything bigger than a quarter-plate camera in the field; that Eastman paper was uniformly good, and easy to work, and gave excellent results with suitable negatives; but that Morgan & Kidd's paper was more rapid, and gave a better rendering of half

tones when used with negatives which are good printing negatives for other purposes; that when an enlarged negative is required, it is much better to make an enlarged transparency, and print the negative from that by contact, any retouching being done on the enlarged transparency, or negative, or both, and not on the original negative.

The annual lantern exhibition will take place on January 27, 1888, and the annual exhibition of pictures, &c., on February 14 in connexion with the *conversazione* of the Yorkshire College Students' Association.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE second ordinary meeting of the current session was held in the Professional Hall, 20, George-street, on December 7.—Mr. W. Forgan in the chair.

One lady and nine gentlemen were elected ordinary members, and six gentlemen were nominated for election in January.

Dr. ALEXANDER HUNTER made some descriptive remarks upon places in the Highlands which he had recently visited, and where good subjects might be had for exposures when members were holidaying in the north. He gave a good idea of the spots he referred to by handing round a considerable number of large water colour sketches made by himself during the past summer.

This being the occasion when the annual exhibition of members' work takes place, a large and interesting collection of prints were arranged upon the walls. This year the exhibits were not so numerous as on some past occasions, but some very fine technical work was shown, while the picturesque was evidently well kept in view in many examples. Some very good cloud effects were shown, obtained by double printing, which seems to be almost essential where the best results are aimed at. Landscapes formed the bulk of the exhibits, and were well represented in forest, lake, and fell. Several members sent frames of figure studies, which deservedly attracted much attention. They chiefly depicted fishing village scenes, occupations, and life. While there was no direct work of large size exhibited, save in one instance, a number of gelatinobromide enlargements gave pleasing variety to the display. As usual, silver prints constituted the majority of what appeared, and of these the smaller sizes did not fail to hold their own. Not the least interesting and clever, because of the great difficulties encountered in securing them, were the marine subjects hung. In a creditable number of instances the pictures of shipping were admirable, the feeling of breeziness and wave motion being capitally caught. The collection was not confined to members residing in the city, but contributions came from those at a distance as well, even as far as the banks of the Rhine. The largest work shown was a presentation to the Society by Mr. W. Crooke, being a copy in platinum of the group taken on a twenty-five-inch plate at Craigmillar Castle during the late visit of the "Convention" party from Glasgow. It is a very welcome addition to the Society's properties, and will ever be interesting on account of its subject. The frame is the gift of Mr. Thomas Warlale. Mr. Graham, of Derby, presented twelve copies of a remarkable instantaneous picture of a flight of sea gulls, which will be balloted for at a future meeting of the Society. A large number of portraits of past and present members were displayed, and the Society's new portrait album was laid open to view. The PRESIDENT invited the members to add to the collection it already contained by prints, if possible, executed in some of the permanent processes.

A number of cameras and dark slides were arranged upon the tables, and were the objects of much inspection during the evening.

Mr. A. H. Baird exhibited a Brown's patent camera and dark slide. A feature in this slide is that it offers a means of taking two pictures upon one plate. When this is desired a dark screen covers half of the space occupied by the focussing glass, the slide is pushed half in and the door half drawn out, after which the second exposure is made by pushing the slide fully home and uncovering the other half of the plate. The sliding front in this camera carries the bellows with it when moved up or down.

Mr. H. Auld showed a Gotz camera which contained several very good points. The power of adjustment of the focus so as to suit widely different lenses is very considerable, and a circular eccentric front gives great latitude of movement. The slides are of the "solid" make and beautifully designed. The tripod head seemed of a new pattern.

Mr. E. SHAWCROSS also described his camera, which possessed some useful arrangements in view of portability.

The PRESIDENT intimated the approach of the popular evening season, and urged members to prepare their transparencies in good time. The Council also were making arrangements for a public lecture in Queen-street Hall with lantern illustrations, which would be intimated in the usual course. A distribution of prints at an approaching meeting was also intimated and contributions of prints solicited for the same.

Correspondence.

✎ Correspondents should never write on both sides of the paper.

"ALKALINE DEVELOPMENT."—"A NEW METHOD OF INTENSIFYING BEFORE FIXING."

To the Editors.

GENTLEMEN,—In reply to the letter of your correspondent Signor A. Gil de Tejada, referring to my article which appears under the above title in this year's ALMANAC, may I be permitted to state that the second part of the title was selected by the Editor as a description of the process.

I should be sorry to usurp any part of the credit which may be due to Signor Tejada, whose article on *Alkaline Intensifying* in THE BRITISH

JOURNAL PHOTOGRAPHIC ALMANAC for 1880 I had not seen previous to writing my own.

I can only say that if by our united efforts photographers are induced to exchange the present system of development (in case of unknown exposure) for a better and more convenient way of working, I shall only be too glad to yield to Signor Tejada the honour of having been the first to suggest the improvement.

I find on comparing Signor Tejada's method of working with the one I have proposed, that although the theory is the same there is a considerable difference in the means used to effect the desired object. There would also probably be, in many instances, a very material difference in the practical results.

One of the distinctive features in the method I have described is the enormously increased latitude which it allows in the exposure. This was recently demonstrated at the Photographic Club, when a good printing negative with clear shadows was easily obtained on a plate which had received twenty times the normal exposure, *the fact that the plate was over exposed being unknown to the operator before commencing development.*

This method of developing a negative so as to obtain detail first and density afterwards, is simply an adaptation to the alkaline development of gelatine plates of the old method of redeveloping or intensifying before fixing which was commonly used in the wet collodion process. It seems not improbable, judging from the results obtained, that the modification now proposed will prove equally useful in the gelatino-bromide process.—
I am, yours, &c., B. J. EDWARDS.

The Grove, Hackney.

MOUNTS.

To the Editors.

GENTLEMEN,—In reference to the paragraph on p. 788 of present week's issue of THE BRITISH JOURNAL OF PHOTOGRAPHY, which mentions a probable difficulty in getting mounts through with the photographer's name on same, I think that if an imprint is added at foot of card as follows, "Manufactured in Berlin (or Paris) for J. Fallowfield (or others) as a foreign product," it would fully cover any possible objections the Custom House might raise.

It might be mentioned that it is now generally known these goods are of foreign manufacture, and I also know the authorities have been made aware of this fact, as I had two cases stopped by the Customs because they bore the imprint, "Fallowfield, London," but they were released after a delay of about fourteen months. This I take to be an admission of admissibility of these goods as recognised articles of foreign make, and that no deception was intended.—I am, yours, &c.,

H. WHITE (pro J. FALLOWFIELD).

35 and 36, Lower Marsh, and 86, Oakley-street, Lambeth, S.E.,
December 16, 1887.

THE PHOTOGRAPHIC SOCIETY.

To the Editors.

GENTLEMEN,—I have just read your report of the proceedings at the last meeting of the Photographic Society of Great Britain, and regret very much that I was unavoidably absent, as I might have saved the President from the extreme annoyance—to use a gentle expression—to which he was subjected, by making the statement which I will now, with your permission, lay before your readers.

At the meeting on November 8 I read out as usual the name and address of each candidate for election, with the name of the member proposing him from personal knowledge. The Chairman then stated, as usual, that all the candidates would be balloted for *en bloc*, but that if there were any considerable number of black balls (one in five excludes) a ballot would be taken for each candidate separately. The attendant then took round the ballot box, and while the voting was in progress Mr. Wollaston handed me a card with the following words written in pencil, "— is a mistake," naming one of the candidates. I at once got up, followed the attendant, took from him the certificate of the candidate in question, and not seeing any mistake in it I showed it to Mr. Wollaston and asked him what was wrong. He then told me that he objected to the candidate. I said, "Oh, is that it; well, then, put in your black ball," or words to this effect. He replied that the ballot box had already passed him. Subsequently, after the Chairman had opened the ballot box, and finding no black balls at all had declared all the candidates duly elected, Mr. Wollaston complained that sufficient notice was not given that the candidate in question was about to be balloted for. It was suggested by some one that the candidates' certificates should be posted up beforehand so as to give members an opportunity of examining them. General approval was expressed of this plan, and the matter then dropped.

In what I have here stated I wish to emphasise the fact that no protest of any kind reached me *before* the ballot began; that after it had begun, Mr. Wollaston left his seat and handed me a card bearing the four words quoted above, and that I took them to imply some clerical error in the candidate's certificate. No one could suppose at first sight they were

intended as a formal protest against his nomination, and I submit that they do not constitute a protest at all. I wish further to say that the system of election of candidates which was followed on this occasion was that which has always been in use in this Society, and that there was no attempt to hurry them through. The names were, I think, read out sufficiently clearly for every one to hear, and several minutes elapsed between the time of naming the candidate in question and the ballot being started.

Mr. Wollaston is reported to have said at the last meeting (December 13) that he handed in a written protest to Mr. Cocking, written in ink in his presence, an hour before the meeting (on November 8) began. It is impossible to prove a negative, but Mr. Cocking has accounted to me for the whole of his time after five o'clock on that evening, when the Exhibition closed, till 6.15, when the Council meeting began at which all the candidates' certificates were signed. At eight o'clock the Council adjourned for the meeting upstairs, and Mr. Cocking assures me he has no recollection of seeing Mr. Wollaston at all till then, or of receiving any document from him. It should be noted also that Mr. Wollaston asked a question of the proposer of the candidate he objected to, implying a doubt as to his identity, *after* the ballot was over.

I am glad that the majority of the meeting on December 13 regained sufficient confidence in the honesty of the President and Secretaries to rescind their hasty vote, even in the absence of the above statement of facts.—I am, yours, &c., W. F. DONKIN, Hon. Secretary P.S.G.B.
December 17, 1887.

RE THE "PERFECT" PHOTOMETER.

To the Editors.

GENTLEMEN,—Our attention has been called to a letter from Messrs. Marion & Co. in your issue of the 16th instant, and in fairness to ourselves and to the Stereoscopic Company, who make their statements upon facts given them by us, we must explain that we are the sole licensees of Decoudun's photometers since September 23, so far as England is concerned, having a legally signed agreement between Decoudun and our representative in Paris to that effect, upon consideration of our taking a certain large quantity. This being the case, we offered the sale of this article to the London Stereoscopic Company for London and to other important houses in the country, on the conditions of their likewise taking from us considerable quantities to retain in their hands the exclusive sale in their districts. Decoudun has further undertaken that he will not sell to any other house shipping to England, and if he finds that any sold by him to commission houses are sent to England he will discontinue supplying such houses.—I am, yours, &c.,

A. STALEY (pro CHARLES, REYNOLDS, & Co.).

26 and 27, Milk-street, Cheapside, London, E.C., December 19, 1887.

N.B.—As stated by Messrs. Marion & Co., Decoudun, Paris, is the maker, and, further, the Stereoscopic Company have never sold one without his name being upon it.

To the Editors.

GENTLEMEN,—With regard to Messrs. Marion & Co.'s letter in your issue of the 16th regarding the "Perfect" Photometer, we quite admit that the inventor is M. Decoudun, of Paris—not *Decoudesor*, as they state—and that the patentee's name is only stamped on every photometer we sell. As to their statement that they hold stock of it, we immediately called upon Decoudun's licensees here, who had guaranteed us exclusive sale for London, for an explanation as to how any other London firm could have acquired any, and they stated that so far since the date of their license no firm except ourselves had received any deliveries, and that if any had reached this country since the date of their license for Great Britain they must have been obtained in contravention of the express arrangements made with M. Decoudun. As we have secured the sole license for London, we are only following the usual custom of advertising it as our speciality. That the principle of its use should have been suggested by others, as they state, so far back as 1884, only shows how long a good idea may lay dormant until some one is smart enough to take it up.—
We are, yours, &c.,

THE LONDON STEREOSCOPIC AND PHOTOGRAPHIC COMPANY, LIMITED.
54, Cheapside, London, E.C., December 20, 1887.

Exchange Column.

*. No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Will exchange 7x5 wide-angle rectilinear lens for half-plate "Optimus" rapid rectilinear.—Address, E. RULL, 90, Summer-road, Peckham, S.E.

I will exchange a binocular lantern in mahogany case, with brass front, jets, and dissolver, for a 12x10 camera with three or more double slides of good make.—Address, J. K. TOWNSEND, Woodbine Villas, Carrington, Nottingham.

Answers to Correspondents.

* * *All matters for the text portion of this JOURNAL, including "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C.*

Communications relating to Advertisements and general business affairs to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

PHOTOGRAPHS REGISTERED:—

J. Stuart, Glasgow.—Photograph of R. B. Cunningham Graham, Esq., M.P.

A. F. McKenzie, Birmingham.—Photograph of the Right Hon. A. Peel, M.P., Speaker of the House of Commons.

* * **TOO LATE.**—In our next number, and also in that for January 6, 1888, we shall publish a list of societies which have elected their officers for the ensuing year since the date of our going to press with the ALMANAC.

RECEIVED.—J. M. F.

J. R.—See leading article in ALMANAC.

C. W. W.—Dried blood albumen may be obtained at most drysalers or dealers in dyers' or calico printers' materials.

J. T. D.—1. By proper treatment the grain of the paper will not show.—2. The lens will not answer *well*; a common French portrait lens will be preferable.

A. F. M.—In vignetting an enlargement the vignetting mask must either be placed very much out of focus or be kept in motion during the exposure. The latter is the preferable way.

WILLY EDELSTEIN.—England, Brothers, 7, St. James's-square, Notting Hill, publish Wilkinson's treatise on photo-lithography and kindred processes. This is the only one in the English language.

J. O. V.—The plates mentioned will prove quite rapid enough for every purpose. The light in Egypt will at the time of your visit equal that at mid-summer in this country. But little trouble will be given by the Customs officers.

H. C. S. inquires as follows: "Would you please say if shadows on a wall caused by the sun or any bright light are capable of being developed, or if there is any reason to suppose they can be? The wall is of ordinary stone or papered, but not prepared in any way."—According to the present knowledge of the photographic art, the answer is in the negative.

THE "HALF-INCH" PINHOLE.—G. B. B. writes:—"Seeing that Mr. Forgan has not come forward with an explanation as to the monstrous—nay, Brobignagian—pinhole he recommended in his paper to the Edinburgh Society, might I suggest that a hole the four-hundredth part of an inch in diameter was meant instead of the appalling one mentioned?"

JUSTICE writes:—"Referring to your article on the new film in last week's JOURNAL, it appears to me from your description, and from specimens I have seen, to be the same thing as exhibited at the Camera Club some fourteen months ago as the invention of a Mr. Froedman, of Dublin. If so, surely a word of credit is due to the inventor, who has worked many years to bring it to perfection."

A. E. EMEN.—The size proposed for the studio is very circumscribed. Twelve feet is much too short. Better increase the length to at least eighteen feet by removing the fowlhouse shown in the plan. If this be done have the two ends of the building and the south side opaque. The north side should be glass, except about four feet at either end; then the sitter can be placed at the east or the west end as occasion may require.

R. (Dublin) writes:—"In your issue of the 16th instant you draw attention to a new film as a basis for photographic negatives, from the reading of which one would suppose that the 'gelatinous preparation' which has been substituted for the translucent paper is the invention of the manufacturer, whereas it should have been stated that the inventor and patentee is Mr. Froedman, of Dublin (who has devoted much time and labour to attain this object)."

SPECIAL X.—If you wish to secure greater rapidity in your plates than you are now obtaining we should recommend you to keep to the formula you are employing, but to boil for a longer time. You must, however, bear in mind that in going for excessive rapidity you will probably encounter greater difficulties in working. To obtain the greatest sensibility in plates while retaining their other good qualities taxes the skill of our most experienced plate makers to the utmost.

D. MC.—The cost of a provisional specification is 1*l.* only, and that of a patent, together with the provisional specification for four years, 4*l.* This is the cost if you take out the patent yourself. Of course, if you do it through a patent agent there will be his charges in addition. These are sometimes well incurred if the invention is likely to become an important one, as a layman does not always state the claims in the way they should be stated. Patents are often invalid through the claims being improperly put forth.

APPRENTICE asks: "Will you kindly give me a recipe for mounting bromide prints on paper about the thickness of foolscap without cockling? I have some, cabinet size, to mount on circulars."—We fear there is no way of absolutely avoiding cockling except, perhaps, making the paper and the print equally wet and then mounting them in that condition with starch. If the paper cannot be wetted then the best plan will be to mount the prints dry with a solution of gelatine containing a large proportion of alcohol.

F. S. C. (Bordeaux) writes as follows: "1. Could you tell me if, by boiling one hour by Abney's formula, and after digesting at a low temperature with the small quantity of ammonia Abney recommends, it will give the rapidity of Beernaert's plates?—2. Does the augmentation of iodide in the emulsion give rapidity? Is there a secret as to rapidity?—3. What would be the cost, about, of a small coating machine installation?"—In reply: 1. We have had no experience with the plates named, so cannot say; but great rapidity can be obtained by the method indicated.—2. Opinions are somewhat divided as to whether iodide increases the sensibility or not. The only secret is skill and experience on the part of the maker.—3. This depends upon the particular machine. Our correspondent should obtain prices from the different manufacturers.

S. M. writes as follows: "Recently there has been a good deal in THE BRITISH JOURNAL OF PHOTOGRAPHY about mounting photographs on glass, which leads me to inquire if photographs could not be mounted on glass simply by putting them on when wet, then applying the squeegee, without any mountant whatever? Sometimes when copying unmounted photographs I have put them while wet behind glass, and had to be careful not to let them dry on, to prevent adherence to the glass. That leads me to think the same plan might be adopted in mounting 'Rives,' &c. Be so good as to give your opinion on it."—We are fully aware that prints on albumenised paper if allowed to dry in optical contact with glass, with water only as a medium, are very difficult of removal; but whether this system of mounting would answer as well as the usual one with gelatine we, from personal experience, are unable to say. Perhaps our correspondent will give the plan a trial and give us the benefit of his experience.

THE JENNINGS'S FUND.—Collected at a dinner of the Liverpool Amateur and Birkenhead Photographic Associations, and remitted by the President, 3*l.* 6*s.* 6*d.*

PHOTOGRAPHIC CLUB.—The next meeting of this Club will be a lantern meeting, on December 28, 1887. Visitors are invited. Discussion on lantern matters.

CHARLES KNIGHT (Newport) sends us two photographs taken by the Flashing Magnesium Light. One of them is the interior of a smithy, showing the blacksmith at work. This is the best of the flashing class that we have yet seen.

THE LANTERN.—The *Cyclist* Christmas number. Certainly a goodly annual, replete with matters interesting to the cycling fraternity, and having a large number of cleverly drawn comic illustrations. It is published by Iliffe & Son, Fleet-street.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The usual monthly technical meeting of this Society will take place on Tuesday next, December 27, at eight p.m., at the Gallery, 5*a*, Pall Mall East. Open at seven p.m. for journals and conversation.

LANTERN SLIDES—A SUGGESTION.—Any one making lantern slides by copying from books, carols, hymn tunes, or music, will find the negative, at least to my mind, a more effective slide than the positive printed from it, the former giving, of course, a dark background with the words, "expressed in burning light."—W. T. F. M. INGALL.

DEAD BLACK FOR LENS TUBES, INSIDES OF CAMERAS, &c.—Triturate lamp-black with thin starch either in a mortar or on a piece of glass with a knife, thinning with water to the desired consistency. Mr. F. York says this is a capital and cheap substitute for Indian ink for blocking out or writing on cardboard and stencilling.

THE indebtedness of science to photography is one of the themes on which the Astronomer Royal for Ireland is eloquently discoursing in lectures which he is at present delivering in the provinces. As an astronomer Sir Robert Ball could not fail to take notice in this connexion of the remarkable work now being carried on as a memorial of Henry Draper in America. This was enthusiastically acknowledged, at the June *conversazione* of the Royal Society, by Mr. Norman Lockyer, who took great pride in showing some Draper photographs which have been of the greatest aid in spectrum analysis. Mr. Draper's widow devoted all her husband's photographic instruments and an adequate endowment to the continuation of his work, and Sir Robert Ball makes the emphatic statement that the results obtained by Professor Pickering and others are such as to constitute one of the noblest monuments an astronomer could desire. As the Astronomer Royal for Ireland says, some of the faintest and most distant stars have now been analysed with a minuteness and accuracy which a few years ago it was thought impossible to realise in the case of our own sun. Now that men of science have got the length of making the sun and stars write the story of their own constitution on photographic plates, who shall assign a limit to their future achievements?—*Daily News*.

HOW TO CONVERT GOLD RESIDUES INTO CHLORIDE OF GOLD.

PHOTOGRAPHERS who, like the correspondent whose letter appeared in our issue of the 16th inst., have only a small quantity of gold residue to deal with annually, would, in many instances, find it more satisfactory to treat it themselves rather than to send it to the refiner, particularly if they be afraid that they will not receive a fair return. The conversion of the gold in residues from old toning baths into fresh chloride to be used again, is really a very simple operation. It requires no special appliances nor exceptional skill, all that is necessary being neatness and care in the manipulations, for, it goes without saying, that if any of the metal be lost in the operations the proceeding may, in the result, prove anything but profitable.

Assuming that the waste has been saved and the gold thrown down in the ordinary manner with sulphate of iron, the residue will, at this stage, consist of metallic gold, chloride of silver, and extraneous matters, principally fibre of paper detached from the prints while toning. The first thing, therefore, is to separate the gold from the other matters. Here is the method of procedure.

Presuming that the whole of the metal has already been precipitated in the usual way, the residue is thrown on to a filter, placed in a funnel, and closely drained. It is now, filter and all, transferred into a good sized Florence flask. If any reduced gold is adherent to the sides of the vessel which contained the waste—and probably there will be a considerable quantity—a little aqua regia—one drachm of nitric acid to five drachms of hydrochloric—must be poured in and run round the sides. This will detach or dissolve the deposit, which must then be added to the contents of the flask. An ounce or two of aqua regia, according to the quantity of residue, are now poured into the flask; this must be done cautiously, as violent effervescence sometimes occurs, which without due care may lead to waste. When the ebullition has ceased the flask should be gently heated over a spirit lamp to nearly, or quite, the boiling point. The whole is now allowed to cool.

The flask is then nearly filled with water and well shaken, and afterwards the solid portion is allowed to subside. Next, the clear portion is carefully decanted on to a filter placed in a clean bottle. If any doubt exists as to whether the whole of the gold has been dissolved, fresh aqua regia should be added and the flask boiled again. If not, the flask must be again filled with water, and the whole of its contents emptied on to the filter and closely drained. A little fresh water may then be passed through the filter to ensure the entire removal of the gold. The filter and its contents may now be added to the silver residues, as what remains is principally chloride of silver.

The bottle now contains the whole of the gold, as a chloride in solution. But the solution is of an indefinite strength, and, moreover, it is too impure for photographic purposes, hence we must again precipitate the gold in the metallic state. A little of a freshly-prepared and filtered solution of protosulphate of iron, which has been rendered *strongly* acid with sulphuric acid, is now added so long as any further addition causes turbidity. But it is unadvisable to add more than is necessary, as it will have to be got rid of afterwards. After vigorous agitation, the precipitate is allowed to subside. This may take many hours, or a day or two, but sufficient time must be allowed for it to settle down compactly. The supernatant liquid is now decanted and the bottle filled up again with distilled water, agitated, and again allowed to subside. This must be repeated several times in order to remove all traces of iron.

After the last decantation the precipitate is transferred to a clean china saucer, or an evaporating dish, and dried by any convenient means—in the kitchen oven, for example. At this stage considerable care should be taken to avoid waste, as we are dealing with pure gold, which is worth four guineas an ounce. When the powder is dry it must be collected and carefully weighed, and then transferred to a small flask. It is next dissolved in aqua regia, diluted with twice its bulk of distilled water, no more being employed than is absolutely necessary to bring it into a state of solution. Heat may be used to assist the solution if time be an object. When the metal is all dissolved the solution is to be brought to a definite strength, or the salt may be crystallised. This, however, is quite unnecessary, as it entails extra trouble without yielding any corresponding advantage; therefore we advise its being retained in solution.

Supposing the dried metal weighed 200 grains it would be equivalent, roughly, to 400 grains of the chloride, and much more than this quantity of many samples now met with in commerce. If the bulk be made up to twelve and a half ounces with distilled water, each drachm of the solution will contain four grains of the chloride. Carbonate of soda is now added so long as it produces effervescence; this is done to neutralise any great excess of acid that may be present. But, as a neutral solution does not keep so well as an acid one, a few drops of hydrochloric acid, just sufficient to render it decidedly acid, must be added. In this condition the solution may be retained without the gold becoming precipitated.

When solutions of chloride of gold have to be kept for any great length of time, we prefer to keep them in a more concentrated form than the usual one grain to the drachm strength, as they are less liable to decomposition. The strength given above is the one we always adopt ourselves.

HEALTHY DARK ROOMS.

THE topic of healthy dark rooms is one that comparatively few years ago was perpetually cropping up at the various meetings, in our correspondence columns, or elsewhere. Yet, nowadays, how often do we hear of it? Practically speaking the question is a forgotten one; but that there is any valid reason for this neglect of a once burning topic we fail to see. The "fumes" of ether and alcohol are no longer present, but there are dark rooms still in existence, and without alteration, that colloid called into existence thirty years ago. The colloid has gone, the conditions as to ventilation remain; indeed, we are inclined to believe that from a sanitary point of view this is a distinct retrogression. We can, without need of proof, readily acquaint ourselves with the facts of the case as to the presence or absence of ether or acetic acid in the atmosphere, but the more deadly carbonic acid may be present unobserved, in actually poisonous quantities. When the unhealthfulness of the old dark room was assumed from the prevailing odour, it was in all probability an example of a correct conclusion from wrong premises; the converse now holds good—a wrong conclusion from correct premises. We are not aware of the existence of any account of distinct pathological experiments upon the inspiration of small quantities of ether or acetic acid, but the literature of pathology and sanitation abounds with facts as to the injurious consequence of the inhalation of small quantities of carbonic acid or of carbonic oxide, and we would, in the most urgent manner, draw the attention of all dark-room workers or their employers to the vital necessity for ventilation in those chambers, and to the fact that their healthfulness must not be assumed because of absence of chemical odour. We simply express the views of all authorities on the question when we assert that when air contains more than a certain proportion of carbonic acid its continued respiration is highly injurious to health; and we further say that we are of opinion that in far too many instances the overstepping of this limit is of daily occurrence. It is no part of our present plan to give working details of ventilating arrangements, nor of the construction of suitable dark rooms; we wish to give a few data from which these may be constructed by those who desire, and which will enable any one to ascertain with little trouble the condition of the air he is breathing.

The two factors of insalubrity are, of course, primarily the products of respiration, and, next, of the combustion of coal gas. For the nonce we only say of the sulphur compounds that accompany the latter that they add so much more noxious an element to the sum of injurious constituents of the atmosphere of an inhabited room that, unless the apartment be both lofty and spacious, it is almost suicidal to inhale it, and that such products should invariably be led away by chimney or flue.

Air containing only from .09 to .1 per cent. of carbonic acid is perceptibly impure, and Dr. Parkes has suggested that .06 per cent. be considered the standard, beyond which air must be called impure.

As to the extent to which air is altered by the respiration of one adult, it may be stated that every hour from sixteen to eighteen cubic feet are inhaled, from .5 to .7 cubic feet of carbonic acid gas being produced and exhaled in the time; he thus fouls a thousand feet of air, if free from carbonic acid to start with, really three thousand in practice—far more than the whole cubical contents of many dark rooms. In round numbers a foot of coal gas burnt per hour in an ordinary burner produces about the same ill effect as one man in regard to the

carbonic acid gas produced; most burners burn three or more feet. The above mentioned three thousand feet per hour is, further, the quantity that is usually assumed to be necessary for removal by ventilation every hour.

The space allowed in various public buildings in this country per head is as follows:—Barracks, six hundred; military hospitals, twelve hundred; civil ditto, eight to twelve hundred; Poor Law Board dormitories, three hundred; but in these various buildings special attention is given to ventilating arrangements. Thus the Army Sanitary Commissioners on Barrack Ventilation recommended a square inch of inlet area for every sixty cubic feet of room space, special shafts being arranged for both inlet and outlet of air.

As a rule, the door and window are the dark room ventilators, and both almost wholly kept closed in working hours. It is, however, estimated that an ordinary closed window is sufficiently loose to allow from five to eight cubic feet of air per minute to pass through, and a door to allow from fifteen to twenty. There is also a large amount of osmotic action through brick walls always taking place, and this assists ventilation. Thus Pettenkofer made an experiment in a room in his own house containing between two and three thousand cubic feet; and, when all openings in doors and windows were pasted up air-tight, about one-third that quantity of fresh air entered the room. This is the bright side of the matter, the beneficent process of nature operating to nullify man's carelessness. Still, it is evident that, in the case we are considering, special provision has to be made if health be not sacrificed.

After these statistics we may return to the first aspect of our subject, the need for some mode of readily ascertaining the character of the atmosphere of the dark room at any particular moment. We do not think it necessary to mention more than one, Dr. Angus Smith's, method, by lime-water. Assuming .06 as the limit of impurity, his method is to put half an ounce of lime-water into a bottle of ten and a half ounces capacity, and then to shake violently for a minute or two. There should be no precipitate: if a milkiness be seen, it is a proof that the atmosphere has passed the stage that divides healthfulness from harmfulness. To ensure the bottle being filled with the particular air under suspicion, it will not be enough to keep the bottle empty ready for use; it should be kept filled with water, and emptied immediately before use. The water will then be replaced by the air of the particular room where the emptying took place.

In this connexion, a patent based on an exceedingly ingenious idea has lately been taken out. We have on a former occasion described to our readers how phenol phthalein, colourless of itself, is turned rose coloured by caustic alkalis, but is unchanged by their carbonates. The patentee utilises this property in his new apparatus. From a vessel containing a weak caustic soda solution of this salt there comes every one hundred seconds, through a siphon arrangement, a red drop on a prepared white thread about half a yard long, and trickles down it. Behind this thread is a scale, beginning with "pure air" (up to .07 per cent.) at the bottom, and ending with "extremely bad" (.4 to .7 per cent. and more). In pure air the drop continues red down to the bottom; but as it loses colour when it absorbs carbonic acid, the sooner the colour disappears the greater the proportion of carbonic acid present, the scale indicating that proportion. This seems something more than a toy, and should be a very valuable contrivance for dark-room purposes. But, whatever the method adopted, we believe we have sufficiently shown the grave importance of the subject,

and the necessity for ascertaining the extent and increasing the power of removal of impure atmosphere in the dark room of the photographer.

COLLODIO-CHLORIDE.

THERE is one other application of the soluble gelatine transfer paper to which we did not allude in our articles on *Home-Made Stripping Films*, partly because it scarcely came under that heading, and also because the process is so nearly forgotten, or has been so little used, that a separate article may well be devoted to it.

Collodio-chloride, though it has been before the public now for nearly a quarter of a century, has never apparently secured a very strong or lasting hold, in spite of the indubitable facts of the beauty of its results as well as their permanence, as well as the applicability of the emulsion to a variety of purposes. The reasons are perhaps, in one way, not far to seek: it was not sufficiently different from other printing methods in sensitiveness, character of result, and comparative permanency, to induce the general body of photographers to leave the already beaten track, though some few have during a number of years worked the process regularly, if not exclusively. The two best known of its steadfast upholders and exponents have been: in Great Britain, Mr. George Bruce, of Danse, whose exhibited pictures for many years past have been entirely printed in collodio-chloride; and on the Continent, Dr. Liesegang, who has long endeavoured to popularise the process.

Perhaps the not least important reason why the process has remained in abeyance so long is to be found in the fact that no regular supply of the emulsion has been in the market, and photographers have therefore been compelled either to resort to the manufacture of the article on their own account or to use it by fits and starts as an intermittent supply offered; needless to say that the proverbial "conservatism" of professional photographers stood in the way of one, and the unsatisfactory influence upon regular business of the other, alternative. But as the manufacture of the emulsion is one of the simplest chemical operations, and there exists at the present time a large class of amateurs and others who are not averse to experiment on new or untried processes, especially if they offer any advantages over known methods, we have little doubt some of our readers may be inclined to try their hands with this one.

As its name suggests, collodio-chloride is an emulsion of chloride of silver in collodion; or, speaking more accurately, of citro-chloride, for chloride of silver alone will not give that necessary vigour and brilliancy of result. It is used for direct printing, or "printing-out," without development, and may be applied to paper, cardboard, ivory, opal, glass, or, indeed, any support to which collodion is applicable. The sensitive surfaces retain their good qualities for a very long time, certainly longer than ready sensitised albumen paper or gelatino-chloride; but the emulsion, though generally tolerably permanent, often exhibits a tendency to gelatinise or solidify from the action of the citric acid, and citrates upon the pyroxyline. There is, however, no difficulty in getting it to keep perfectly for a few weeks, and as the operation of making a quantity only occupies a few minutes, and it will keep almost indefinitely when spread, little reason exists for rejecting the process because the emulsion will not keep. If the same principle were applied to gelatino-bromide there would soon be a general return to the practice of wet collodion.

The great point in favour of collodio-chloride has been its close resemblance to albumenised paper in its behaviour, treatment, and results, with the added advantage that it can be utilised not only for paper work but upon glass or opal, or for any chance job that may crop up, even to making reproduced negatives, for which purpose it is peculiarly well suited. A few months ago a somewhat novel application of the process was brought before one of the London societies, namely, the production of transparencies by transferring the collodio-chloride image from paper to glass; and this connects it with our recent articles on stripping films, for it then becomes a veritable stripping film.

A weak point in the use of this emulsion upon glass, opal, or other impermeable support, is to be found in the composition of the preparation itself. In order to confer the property of rendering the force and vigour necessary in a "printing-out" process, it is absolutely essential that the collodion shall contain, in addition to its haloid, a due proportion of silver nitrate, or other soluble silver salt, as well as free acid—preferably citric—which serves the double purpose of keeping the emulsion and films and assisting to "organify" them. The presence of these substances, though entirely unobjectionable when paper is the support, because they are absorbed by it, gives rise to difficulties when the emulsion is applied to non-absorbent surfaces, since they are forced to crystallise in the collodion film, and possessing, together with the decomposition salts, more or less hygroscopic properties, are liable to cause irregularities on the resulting pictures if kept for any length of time after the surfaces are coated.

The difficulties are not insuperable, as the application of a preliminary coating or substratum of a partially absorbent character serves to considerably mitigate, if it does not entirely eradicate the evil, and at the same time acts beneficially in other ways, especially in causing the emulsion film to adhere to its support.

The following will be found a good formula for the emulsion:

Ether.....	2½ fluid ounces.
Alcohol (methylated)	2½ "
Pyroxyline.....	40 grains.
Chloride of calcium	12 to 15 "
Citric acid.....	15 "
Nitrate of silver	60 "

The pyroxyline need not be of any special "high temperature" kind, any good sample for wet collodion purposes and fairly soluble will answer well; avoid equally, both extremely powdery as well as "horny" contractile specimens.

Place the pyroxyline in a ten-ounce bottle, and pour upon it the ether; when thoroughly saturated add one ounce of alcohol, and shake well until dissolved. Now weigh out the silver nitrate, dissolve it by heat in a small glass flask in half a drachm of distilled water, and add one ounce of the alcohol, a little at a time, warming after each addition in order to prevent the precipitation of the silver. In another flask dissolve the chloride of calcium and citric acid in the remaining half ounce of alcohol.

To sensitise the emulsion take the hot alcoholic solution of silver and pour it, about a drachm at a time, into the thick collodion, and shake the latter thoroughly after each such addition. When the whole has been added the mixture will assume an opalescent, milky appearance, from the precipitation of a portion of the silver in extremely minute crystals. Allow it to stand in this state, with occasional shaking, for an hour or two, then add the chloride of calcium, citric acid, and remaining

alcohol, and shake vigorously for two or three minutes, and afterwards at occasional intervals. The emulsion will be ready for use, after filtration, in about an hour's time.

Those who are accustomed only to films of gelatino-bromide, or even of collodio-bromide, will be astonished at the extreme transparency of this emulsion when spread upon glass, notwithstanding the thickness of the layer of collodion. It is, in fact, not only perfectly transparent, but exhibits only a slight brownish opalescence when viewed by transmitted light, and gives little promise of possessing the power of darkening to any depth. This is due to the comparatively small quantity of silver converted into chloride, as well as to the natural transparency of the latter haloid; but the darkening power of the mixture is very great, and depends mainly upon the soluble organic silver compounds it contains. An emulsion less heavily charged with pyroxyline would be easier to use were it not that a considerable "body" is necessary to prevent the soluble matters from crystallising in the dried film.

This preparation may be used with almost any good sample of paper, though necessarily the finish of the surface will depend upon that of the paper, while the tone of the image will vary according to the nature of the sizing, an acid or gelatine sizing giving a redder colour than others. Upon glass or other neutral surface the colour before toning is a rich reddish purple, which in the gold toning bath rapidly changes to blue; consequently the bath should be of only moderate strength, any of the ordinary formulæ for albumen paper or the sulphocyanide bath answering well.

The gelatine-coated paper already described forms a most admirable support for collodio-chloride; and if properly prepared and in good condition is as easy to coat as glass itself. The paper having been first rendered perfectly flat is pinned to a light board, as described in a previous article, and coated in the same manner as glass; hung up to dry spontaneously it is ready for use in a few minutes, but it is as well to give it a final "airing" before a fire. In coating glass or opal it is absolutely necessary to dry by gentle heat, and if the plates are to be kept any length of time they should be preserved in a perfectly dry atmosphere with chloride of calcium or some similar desiccator, otherwise uneven markings appear on the surface from the attraction of moisture. These disappear to a great extent, or altogether, during the operation of toning and fixing, but are liable, if the plates have been long kept, to leave permanent markings behind. The danger is lessened by giving the glass or opal a preliminary coating of gelatine.

This difficulty of irregular markings, as well as the necessity for a special printing frame for use with glass plates in order to enable the progress of the printing to be watched, renders the making of transparencies direct upon glass an inconvenient operation. But if the emulsion be spread upon soluble gelatine paper it may be printed in the ordinary manner, and the picture afterwards transferred to glass as already described, thus enabling the operator to produce the most charming transparencies with scarcely more trouble than an albumen print.

Some little experience will, however, have to be gained in judging the density of the image, as it will appear far more intense while on paper than when transferred to glass, even when examined by looking through it. The printing must be carried to such a depth that, when examined as a positive by reflection, all the half tones are lost, and even the higher lights discoloured.

The paper is somewhat difficult to manage when wetted, owing to the difference in expansion of the paper and collodion film, which causes a strong tendency to curl up into a firm roll.

A little careful management will overcome this trouble, but we shall probably have a few words to say on this subject on another occasion.

It was stated at a meeting of the Physical Society by Mr. Hilger that there was now less need for liquid prisms, seeing that glass could be made with a mean index of about 1.8. He also stated that Dr. Perten had recently supplied him with a perfectly colourless Canadian balsam which would not tarnish the face of spar.

In the Report of the New York Pharmaceutical Association may be found such a crushing report upon the facts in relation to the purification of water by congelation, that the subject—which, from its interest to photographers and the process having often been recommended for obtaining a substitute for distilled water, has often been treated by us—may be almost considered exhausted, especially in the light of recent facts which have been brought before our readers. Notwithstanding the weight of such authorities as Professor Tyndall and the late Dr. W. A. Miller, who lean to the ordinary view, it is shown that ice and ice-water are very far from being necessarily pure. Thus, when urea in a little under one per cent. proportion, .83 exactly, was dissolved in water, the ice obtained from the solution contained just .5 per cent. When 1.5 per cent. glucose was dissolved, the ice held .96 per cent. Arsenic dissolved (by the aid of ammonia) to .178 per cent. gave .048 per cent. in the ice. The opinion of Professor Nichols, writing in 1882, is given, and it is equally condemnatory of the popular idea. Ice frozen from water containing salt dissolved will only, he says, contain "less" of the salts, while with organic matter the process of freezing may actually concentrate the impurities into the ice.

At no previous period in the history of photography has the art been so extensively employed in the production of Christmas and New-year's cards as this year. Silver printing, platinotype, collotype, carbon, Woodburytype, and gelatino-bromide, have all been pressed into service in obtaining the requisite supply, the latter two processes particularly lending themselves to the rapid production of large numbers at a rapid rate. Lithography has also been extensively utilised for reproductions from photographic originals. The subjects published have been varied, and include landscapes, copies of works of art, and portraits. Many of the latter, however, bear unmistakable evidence that they were not originally taken for the purpose to which they have since been applied. Evidently they are portraits, and were taken as such, and for no other purpose. It may, perhaps, be gratifying to some parents to see their pretty children's portraits exhibited in the shop windows for sale to strangers, to be afterwards sent with seasonable greetings to people of which they have no knowledge whatever. With other parents the case may be widely different.

CONSIDERABLE annoyance has, we are informed, been caused in some families by the free use which has been made of the portraits of some of its younger members without consent. This is too bad. In many instances the pictures are not photographs at all, but lithographs reproduced from them, in the closest imitation possible, with, perhaps, a background more or less appropriate to the season introduced. In most cases, however, the likeness is so well preserved as to be unmistakable. Indeed, it is the portraits which are the only interest, and if it were not for them the pictures would be commercially valueless, for the poses are invariably of the hackneyed studio type. Anyhow, the sitters, or their parents, have no remedy at present. If a new Copyright Act be passed, and it is framed on the same lines as all the projected ones have been, the system of publishing private portraits without the sitter's consent will receive its death-blow.

A CONFERENCE on the Merchandise Marks Act was held one day last week at the offices of the London Chamber of Commerce, at which there was a good attendance of delegates from the provincial chambers of commerce. It was unanimously agreed to form an association to promote the carrying out of the Act without damage to British commerce, and with this object in view a provisional Committee has been appointed.

LITTLE photography will be done by amateurs, we imagine, during the next two or three weeks, but there is no reason why it should not be practised at home and interesting pictures secured. Excellent figure studies and family groups, many of which could not be got together at any other season, can still be taken, and in an ordinary room, with rapid plates, when the light is fairly good, and when it is not, artificial may be substituted. The magnesium flash light affords a ready means of obtaining satisfactory negatives of such subjects when daylight fails. Some interesting, amusing, and even comic pictures might often be secured in the drawing-room during the festive season with this source of illumination. For example, a camera placed in an obscure corner of the room, with the lens focussed on an object under the mistletoe, and the light flashed at a certain time, would often secure a far more natural picture than could possibly be obtained by any other means. Fancy a group with the staid Mr. A. kneeling at the feet of the charming Miss B. "crying forfeits." What an amusing picture it would be. With magnesium powder burnt on guncotton, the light is so momentary that the individuals have not time to move, or to alter their expression, before the picture is secured. Of course, when this class of photography is indulged in, a certain amount of discretion must be used, otherwise what was intended as a harmless joke might turn out unpleasantly.

It would be interesting to know the number of opal glass "Christmas and New-year's cards" which have come to grief in transmission through the post during the last few days. If we may judge from our own experience as recipients, it has been large indeed. Many of these little tokens of remembrance have been sent through the post simply in the cardboard boxes in which they were purchased, with, perhaps, a thickness or two of brown paper wrapped round them, with a result that might well have been imagined. A fragile thing like a picture on opal glass, protected only by one or two thicknesses of cardboard, is not equal to the obliterating stamp of the Post Office when it is vigorously or hurriedly applied. It is a pity that the stationers who sell these pictures do not supply them in a rigid case for packing them in, which shall be equal to the exigencies of the Post Office. Some do, we know.

ATTEMPTS will, no doubt, be made to photograph the interiors of many churches before the Christmas decorations, which have absorbed so much time to arrange, are removed. As a rule, photographs of these subjects are rarely satisfactory. This arises from the circumstance that the light is usually very bad at this time of the year, and from the non-actinic colour of the evergreens. Hence the negatives are usually very much under exposed; and, furthermore, there is frequently a large amount of halation, so that the result is disappointing generally. Much of this might be obviated if the negatives are given a very much longer exposure, and the plates are backed. In no case should an interior be attempted in which there are strong contrasts of light and shade, particularly when a prolonged exposure has to be given, without previously backing the plates—a point too often neglected by amateurs.

THE DEVELOPMENT OF TRANSPARENCIES.

THE development of a transparency, whether for lantern or decorative purposes, is an operation differing very materially from the production of a negative, notwithstanding that the chemical principle involved as well as the materials employed are identical. In the case of the negative, we are concerned in getting out the details in the least exposed or darkest parts of the picture, and in giving to the highest lights just that degree of density which confers "sparkle" without rendering them hard or "chalky," and these two main points being attended to, the half tones about which we frequently hear so much, may be pretty well left to take care of themselves, while a slight veiling of the shadows or degradation of the absolute clearness of the film is of little moment, or even considered by some operators an improvement to the printing qualities of the negative. What we have to do in fact is, with a given exposure to get as much out of the plate in detail and brilliancy as we can.

In the development of a transparency, we have equally thrust upon

us the necessity for getting out the minutest details in the least exposed portions of the picture—in this case the high lights—while we must have sufficient force in the shadows, and this without losing transparency, or what is tantamount to it, burying their details and so causing heaviness instead of brilliancy. With a good negative to work from it is perhaps not very difficult to secure these two extremes, and in that case here, also, the half tones may be trusted to look after themselves; but when the negative is not all that is desirable without "dodging"—if it be a trifle hard, or, on the other hand, inclined to be flat—the chances are that the same qualities will mark the transparency unless either by careful arrangement or happy accident the exposure and development are so suited to one another as to effect the necessary modification.

It is, in fact, a more difficult operation to produce a perfect transparency—if such a thing exist—so far as accuracy of gradation is concerned, unless the negative be equally "perfect," than to make a negative from nature, the latitude in development being far more limited in the former than in the latter case.

But where the transparency is concerned, we have to consider in addition to the proper range of "tones" the purity of the high lights, or, in other words, the absolute clearness of the unexposed portions of the film. Time was when a perfectly white sky in a paper photograph was considered a good quality, but that was in the days when absolute whiteness was perhaps one shade better than the murky, uneven tints that too often did duty for the sky in landscapes. Next, white skies came to be preached down as inartistic, and an evenly but slightly tinted blank was considered the proper thing until the practice of printing in real skies became general, or of securing sky and landscape at the same time became at all possible.

But, so far as I am aware, a tinted sky or veiled high lights have never been recognised as either desirable or permissible in a transparency with any claims to quality, whether for merely ornamental, for stereoscopic, or for lantern purposes, least of all, if there be any question of degree, for the last. So that in the development of transparencies we find ourselves additionally handicapped by having to preserve absolutely clear films while combining delicacy of gradation with depth and brilliancy of image.

The old system of development consisted in giving the shortest possible exposure—i.e., the shortest exposure that would penetrate the high lights of the negative—and developing rapidly with a strong but adequately restrained solution, so as to bring up the picture quickly to full strength at one operation. This plan certainly favoured "clear glass" high lights, and under favourable conditions also gave pluck and contrast in combination with proper gradation. But this was in the days when negatives were made with collodion, and themselves possessed more of the combination of those three qualities than their modern successors do; they, in a word, had more "sparkle" and suited such treatment if of good average quality, but were pronounced unsuitable for transparency work if the treatment did not agree with them.

The modern gelatine negative differs very considerably in character from those of the old collodion days, whether wet or dry; I am not going to imply that it is inferior, nor do I say it is the reverse, but simply it is different. I can well understand old wet-plate men looking back to their negatives of former days with feelings of regret, for certainly no more perfect type of negative to look at and for rough, straight-away printing has yet been seen—certainly not from gelatine plates. But after all the negative is only a means to an end, and if a less prepossessing *looking* plate with careful treatment will give a better result, we are bound to recognise its advantages. Print a copperplate and a wood block with the same amount of care, and the wood block would "have the pull;" but not so if the copperplate were properly worked.

The main difference in modern negatives is the presence of far more minute detail—I am speaking of the now recognised type of a properly exposed gelatine plate—with less of the contrast—fewer notes in the gamut, as someone described it—that went to make the so-called "sparkle" of the wet plate. And so it happens that to produce the finest results in printing a different course must be adopted to that which served in years gone by. It was long ere this was recognised, hence, perhaps, the outcry there was some years ago on the subject of the "want of sparkle" in gelatine plates. But since more attention

has been given to printing matters, I venture to say that quite as good work has been turned out from gelatine plates as from collodion, speaking merely of the finished print from a technical point of view, while as regards the class of subjects possible with gelatine and their general rendering there can be no two opinions.

If the different character of modern negatives requires modified treatment when paper prints are in question, surely some variation in manipulation may be ventured on when glass transparencies have to be made. And if we examine ever so slightly into the details of the production of the latter, there appears all the more reason for such a course. Whatever class of plates may be employed, collodion or gelatine, their superior sensitiveness to albumenised paper increases their tendency to softness rather than "sparkle;" consequently, if paper prints from gelatine negatives are, with ordinary treatment, blamed for their want of force and general robustness, transparencies under similar conditions must suffer the more.

No one, I imagine, who has tried transparency making upon gelatine plates—even the slow and specially prepared ones—can have failed to recognise the fact that to produce results which will at all compare in quality with paper prints from the same negatives, the utmost care must be bestowed not only upon the exposure but upon the development as well. By quality, I mean here simply quality of gradation, from purity of high lights to depth and transparency of shadows, and not in any sense comparison of tone or colour. The old system of giving a short exposure and quick development gives unsatisfactory gradation and bad colour, and as the exposure is lengthened, so is the tendency to veil and general flatness increased, however the development may be modified. Variations in development, indeed, seem to end chiefly in keeping away absolute *fog*, but so far as materially modifying the gradation of the picture is concerned, they appear beyond a certain point to be useless.

The best results I have been able to obtain upon gelatine plates, after "ringing the changes" in every possible direction, have been produced by first of all paying careful attention to the exposure. That is a point upon which very little can be said that will be of any use as a guide beyond that it must be sufficient without going to excess. Perhaps it is safer to err slightly in the direction of under than over exposure. The next point is to use a modified developer in which the main difference lies in greatly reducing the proportion of pyro—say, to one grain or even half a grain to the ounce, according to the character of the plate—while the quantities of bromide and ammonia remain at about the normal, the bromide being always present in sufficient force to hold the development well in hand without exercising too great a check.

With such a solution, and supposing the plate not to have been over exposed, a thin, clean image, full of detail, but utterly devoid of density, comes up easily and gradually, and must be stopped the instant the amount of detail required is visible by reflected light. With most plates this image will be so delicate as to be nearly, if not quite, invisible on looking through the plate, while examined by reflected light it presents little or no contrast in strength between what should be the deep shadows and the more delicate gradations of the lights. If now the plate be washed and treated with a fresh solution, containing at least three grains of pyro to the ounce, the normal quantity of alkali usually employed with that "make of plate, and double or treble the ordinary dose of bromide, the effect will be magical. The image rapidly gains in force, until what at first looked flat and hopeless develops into a well-modelled and vigorous picture, with as much clearness in the lights as can be obtained from a film of gelatine.

The treatment of collodion emulsion plates is very similar, indeed, it was the behaviour of those plates under that treatment that induced me to apply it to gelatine. In the case of collodion, however, it is of more importance to reduce the ammonia than the pyro in the developer, and the bromide may be altogether omitted. The development of collodion and gelatine plates respectively differs in this respect, that with the former the proportion of alkali used in the early stage of development has more effect in ruling density than pyro, with the latter the reverse is the case. Hence, in order to obtain the thinnest possible image in all its detail, I reduce the quantity of alkali. For an emulsion giving ordinary density with tolerable ease, I use, say, two grains of pyro, two grains of carbonate of ammonia, and if any at all,

not more than two or three minims of a ten-grain solution of bromide of potassium to each ounce of solution. This will bring out in the course of thirty seconds, if the exposure have been sufficient, a fully detailed image so extremely delicate as to be quite invisible in the light usually employed for gelatine plates, and difficult to watch even in a full yellow light when the eye is accustomed to gelatine.

I may say here that the matter of exposure is of less importance in the case of collodion, or rather, that so long as sufficient time is given there need not be much fear of over doing it, as the development may be stopped instantly when the proper point is reached. Here, again, vigour is obtained by the application of a stronger but energetically restrained solution, containing, say, three grains of pyro, fifteen to twenty of carbonate of ammonia, and from half a drachm to a drachm of a ten-grain bromide solution to the ounce. Under this solution the feeble, scarcely visible image rapidly gains strength, and its action may be continued until the requisite density is obtained without the slightest chance of any fresh detail, or, if the emulsion be all right, any veil appearing.

But instead of intensifying with alkali I greatly prefer silver, which not only gives strength but also *tone*, and that in a manner that alkali seldom or never does. It is, moreover, as rapid, as clean, and in every way as convenient as alkaline pyro, if the solutions are at hand, and possesses none of the terrors it seems to do for gelatine workers. Make two solutions, the first consisting of—

Pyro	6 grains.
Glacial acetic acid	1 drachm.
Water	4 ounces.

Flood the plate with a small quantity of this (after first washing well) and return it to the developing glass and add, say, one drop to each drachm of a fifteen-grain solution of nitrate of silver, slightly acidified with nitric acid. Remember that the smaller the quantity of silver added the warmer and finer will be the colour, but the action will be slower. With the quantity named no difficulty will be felt in intensifying and toning the thinnest image.

H. Y. E. COTESWORTH.

HISTORICAL NOTES ON THE OPTICAL LANTERN.*

AMONG the questions other than historical suggested for discussion by this meeting, is, Supposing a first-class Italian painter were to execute a fine work of art upon a lantern slide, is the average optical system of the present lanterns good enough to do full justice to his work upon the screen? Probably as the lantern is now becoming a popular household instrument, a limited portion of its users would not object to incur large expenses to obtain high-class artistic slides of ideal or real subjects. Could not such ideal subjects be executed in monochrome on a large scale by skilled artists, then be reduced as lantern slides by photography, and, lastly, be coloured by artists? I should like to ask whether the three-wick lamps of commercial lanterns are always so mounted as to be easily centred in relation to the optical axis of the lenses? also what objection there is to invariably fixing a small lens near the three-wick lamp, to nearly double the amount of light the lamp will cast upon the ordinary large condenser? Can those who have invented apparatus to make oxygen continuously near the lantern, and no faster than the lantern uses it up, exhibit the said apparatus at work before this Association? Cannot oxygen for the purpose be made as required, in the wet way, without heat, as suggested years ago by Dr. Emerson Reynolds? In many private homes, the various disadvantages connected with making and storing oxygen in bags or cylinders will operate against the use of oxygen with the lantern until some simple process is devised to give off the gas just as fast as the burners use it up, so that no storage is necessary.

W. H. HARRISON.

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION EXHIBITION.

THE fifth annual exhibition of photographs by the members of the above Association was opened on Saturday, the 24th December, and remains open to the public for a fortnight, closing on 7th January.

The Executive of the Association has made a fresh departure this year. Instead of, as in previous years, holding the exhibition in the galleries of the Fine Art Institute, in Sauchiehall-street, where the meetings of the late Photographic Convention were held, they have seen

* Concluded in abstract from page 811.

proper to utilise their own premises at 180, West Regent-street, and so far as the accommodation is concerned it is ample for present requirements, but should the Association go on progressing in future years as in the past, much larger premises will again be required.

The growth of the Association has been most marked during the five years of its existence. Commencing with a membership roll of about thirty, it has steadily progressed from year to year until now its members number 168, and to keep pace with this large and continuous addition the Council has had to provide additional accommodation for the members, the original rooms being crowded to excess at many of the Association's meetings. To overcome this they have lately made considerable additions to their rooms, and now they possess a fine suite of three large apartments at the above address.

Entering the premises situated on the top storey, the visitor finds on the left a very commodious dark room containing lockers, half a dozen developing sinks, with every other facility the most fastidious taste could desire. Passing into the public rooms we enter the council room, where the Tuesday evening's informal meetings are held, and where all the latest gossip of the hour is freely discussed over the friendly pipe of peace. These Tuesday evening meetings have become quite a feature, and are largely attended. To the right of the council room we enter the large room of the Association, and which has quite recently been added. This is an excellent room, and is capable of seating fully 200, being well lighted by day and night. Much taste has been exercised in the way of adapting it for the present exhibition, the wall space being coloured with a suitable tint, so as to show off the various pictures to the best advantage. A very efficient mode of hanging the pictures has been adopted by running a beading round the entire room, and from which hooks are suspended carrying the various frames, thereby dispensing with nails. In striking contrast with past years, the hanging of the pictures on the present occasion show to great advantage. Profiting by the experience of the past the Hanging Committee were wise enough to allow themselves ample time for their work, which has been done with much care, and free from all haste and scurry, no picture being above six feet or below two feet from the floor.

Comparing the present exhibition with that of 1886, we find a falling off in the number of pictures. Last year, we believe, there were about 160 frames, this year the number does not exceed 130, and on glancing over the list of exhibitors one is struck with the number of many local amateurs who are not represented. We miss Mr. Goodwin, the enterprising Secretary, who by the way was prevented from doing much work last summer through illness, but who, we are pleased to say is now nearly himself again. Then, again, Mr. Wm. Lang, F.C.S., is not represented, but doubtless his hands are full to overflowing with the arduous task he has to perform of taking charge of the Photographic Section of the International Exhibition, and which, by the way, is going to be a big success. Then, again, the following are conspicuous by their absence:—Miss Gibson, Miss Thom, Mrs. Ramsay, the Misses Coulson (five) who in past years contributed largely, W. H. Turner, Wilfred Smith, W. F. Finlayson, James Elder, P. Falconer, R. Cutting, John Parker, R. Dalglish, Alex. McDonald, W. Ovenstone, A. J. W. Reid, and others.

On the other hand, we notice many new aspirants for honour, among whom may be noticed D. R. Clark, W. Remson, John Morrison, jun., W. McLaren, R. Knox, Leyson T. Merry, J. R. Berger, W. R. Buchanan, D. Glen, D. S. Macnair, and Dr. McCorkindale. Why the number of exhibitors this year should be fewer than last, seeing the membership is much larger, is a question we have heard frequently mentioned and discussed. The late summer, so far as weather was concerned, was all that could be desired, and without doubt much excellent work was done by many who are not represented. We believe the solution of the question lies in the fact that most of the members named are keeping their pictures back for the International Exhibition.

The Executive have this year again had the prizes awarded by two independent judges. The gentlemen who have this year performed these arduous duties are Mr. Wm. Young, artist, and Mr. James Paton, photographer, Greenock, and they came to their various decisions without any differences of opinion worth speaking about.

The following is the list of their awards:—

COMPETITIVE PICTURES.

Class 1 (Landscapes).—First prize, silver medal, Hugh Reid; second, bronze, John Dore; third, bronze, John Rennie.

Section B (Small Landscapes).—First prize, silver medal, Arch. Watson; second, bronze, R. B. M. Stewart; third, bronze, John C. Hutcheson.

Class 2 (Figure Studies).—First prize, silver medal, Arch. Watson; second, bronze, David R. Clark.

Class 3 (Instantaneous).—First prize, silver medal, J. C. Oliver; second, bronze, Arch. Watson.

Class 4 (Portraits).—First prize, silver medal, W. S. Anderson; second, bronze, Hugh Buchanan.

Class 5 (Groups).—First prize, silver medal, J. C. Oliver; second, bronze, David Irving, jun.

Class 6 (Animals).—First prize, silver medal, James Fleming; second, bronze, Leyson T. Merry.

Class 7 (Still Life and Interiors).—First prize, silver medal, D. McCorkindale; second, bronze, John Morrison, jun.

Class 8 (Enlargements).—First prize (a protest has been lodged against this award on account of the infringement of the rules); second, bronze medal, J. C. Oliver; third, bronze, D. S. Macnair. Should this protest be sustained, Mr. Oliver will take first and Mr. Macnair second prize.

Class 9 (Transparencies).—First prize, silver medal, W. S. Anderson; second, bronze, James Fleming.

Class 10 (Developed Prints).—First prize, silver medal, Arch. Watson; second, bronze, J. C. Oliver.

With regard to the protest lodged against the judges' award in the enlargement class, it appears that the rule against any touching of the finished pictures is alleged to have been infringed by Mr. D. R. Clark, the allegation being that in one picture at least the print shows unmistakable signs of being worked up. The matter will be brought before the Council at an early date, and their decision will be duly notified in our next.

Speaking generally, the exhibition, as a whole, is not superior to past years. Without doubt the landscape classes are most excellent, and the judges only arrived at their decision after much thought and trouble, so equal are many of the exhibits. Mr. Reid, who has this year been successful in the large landscapes, deserves great praise for the excellence of his pictures. Technically they are perfect, and his success is very popular with the members of the Association. Mr. Watson takes no less than five medals. In the small landscape class, his picture of *Spring-time* is just one of those delightful pictures the eye never tires of looking at.

In the large landscape class Mr. W. S. Anderson is well represented, and although the judges have for some reason or other not seen fit to award him a medal, in our estimation there is no better landscape in the room than his *On the Braes of Loch Lomond*.

Mr. W. Hume also contributes a charming set of three little bits, which are well worthy of notice.

The figure studies is a poor class taken as a whole, and the judges had little difficulty here. In the portrait class Mr. W. S. Anderson takes first prize and Mr. Buchanan second.

We regret to notice that this year the element of retouching has entered largely into the exhibits, and in very many cases it has been carried to excess; as an exception, however, to these remarks, Mr. Oliver's pictures stand alone.

One of the largest exhibitors over the various classes is Mr. D. R. Clark, but his pictures lack softness, and have the appearance of being much under exposed, and in several instances are faulty from false lighting.

In the still life class the judges have seen fit to go past Mr. Sheriff's charming *Studies of Flowers*, much to the surprise of many. In our estimation this gentleman's exhibit is far and away ahead of anything in the class.

In the transparency class Mr. W. S. Anderson takes first prize; as a whole, however, the exhibits are not of much merit, none of the collodion transparencies being toned.

Mr. Oliver is to be congratulated on securing the medal for the most artistic picture in the room; his *Waiting for a Bite* is a gem, and the judges had an easy task in coming to this decision.

In the non-competitive class Mr. R. B. M. Stewart shows two exceedingly fine enlargements of the yacht *Thistle*, taken from negatives obtained on board the *Vanguard* during the Convention trip at Largs Regatta.

Perhaps the best class in the exhibition is the enlargements. Among so many examples of excellence it is difficult to select those for special mention after the awards of the judges, but we cannot refrain from again speaking of the excellence of Mr. W. S. Anderson's set of three. A finer bit of work than his centre picture, *An Autumn Haze*, we have never witnessed, still somehow the judges think otherwise. In this class Mr. J. Ure Primrose comes out strong also, his portrait enlargement of *Old Mr. McFarlane*, the negative of which (half-plate) was taken inside an old hut at Kilcreggan, is well worthy of notice. During the continuance of the exhibition the Council has arranged for several popular meetings. The optical lantern will be brought into requisition, and the transparencies will be furnished by different members of the Association.

THE FADING OF SILVER PRINTS.

If we assume prints upon albumenised paper to be liable to fade from at least three different causes, and if photographers in numerous instances are known to be more or less careless in relation to one or two of the three causes, the fading of so large a proportion of such prints is explained.

To one of the probable causes of fading I think that too little attention has been given, namely, to the occasional imperfect coagulation of the albumen by the various solutions, and to the presence of this or some other organic matter in the print liable to relatively rapid decomposition, liberating at the same time sulphurous gases to attack the silver. That the organic matter of a finished print is not always in good condition is an inference to be drawn from a statement made by Mr. J. Hubert a few days ago at a photographic meeting, to the effect that when damp finished prints are allowed to lie upon each other in a pile for too long a time, they give off a bad smell. He also stated that he had found that if they were left long enough under such conditions the image would become spotted.

Supposing those prints to have been dried in the ordinary way, they would have been relatively, but not absolutely, dry; in fact, while exposed to the atmosphere at all they could never be perfectly dry, hence it is reasonable to assume that after they were quickly dried the same changes would have taken place in a long time which, while they were wet, took place in a short time. Here, then, we have a cause of decay not necessarily due to imperfect toning, fixing, or washing.

The evil smelling organic matter must have been either albumen or something else. My reason for believing it to be imperfectly coagulated albumen is that some time ago I had occasion to thoroughly coagulate films of plain albumen upon paper, and did it by means of that powerful agent for the purpose—phenol, better known as carbolic acid. When this was properly done, the paper, after drying, curled up with more vigour than I have ever yet seen done by a photographic print: its surface had become waterproof, and could not be evenly wetted; a drop or two of water might stick on the film here and there. Thus a properly coagulated film presents characteristics not seen in photographic printing, and we may safely conclude that such films if allowed to rest upon each other a reasonably long time in a damp state would not acquire a bad smell, or exhibit a tendency to generate micro-organisms.

My suggestion, therefore, is, that a little carbolic acid should be put in the final washing water of albumenised prints; that they should next have all superfluous moisture removed by blotting paper, then be soaked for at least ten minutes in a solution of methylated spirit, to each quart of which two drachms of crystallised carbolic acid have been added. After removal from this bath they might be allowed to dry. Blotting paper free from hypo is on sale in the market; the methylated spirit may be of the commonest, but free from resin.

For many years I have not produced a print upon albumenised paper, believing that the sooner the process dies out the better; hence I have not tried the preceding remedy for one probable cause of fading. Any one can easily try comparative experiments in the matter who is in the habit of producing photographs by the process.

A little phenol will go a long way in arresting decay. In chemical nature it is so much like creasote, that in early times chemists were in doubt whether they were not the same substance in different forms. Professor Allen Miller says:—"Kreasote produces the immediate coagulation of albumen. It is the most powerful antiseptic known. Meat that has been plunged into a solution containing one per cent. of kreasote gradually becomes dry and hard on exposure to the air, and acquires the flavour of smoked meat, but does not become putrid. . . . Much of the kreasote of commerce is simply carbolic acid." For the purpose I have suggested phenol is as good as creasote, and cheaper. Mr. William Crookes made a careful report upon the powerful antiseptic properties of phenol, when he tried it under the sanction of the Cattle Plague Commission. Its poisonous nature should, however, not be forgotten by its users.

An advantage from giving prints a final soaking in methylated spirits and phenol will be, that they will afterwards dry more quickly. Another advantage is, that the aqueous washings having dissolved out everything soluble in water, the final treatment will dissolve out anything which may be soluble in spirit.

A second cause of the fading of ordinary albumenised prints is, as Mr. W. K. Burton recently pointed out so clearly, an insufficient deposit of gold; the less gold a sample of paper requires to tone it the worse is that paper for producing permanent prints, and it should be rejected. Mr. Burton tested his views experimentally, by proving that the more complete the toning the better did the prints resist the action of bichloride of mercury, but it may not be generally known that the editor of this periodical tried analogous experiments twenty-

one years ago. He cut a print into four parts; one he over toned in alkaline gold, the second he partially toned to a purplish sepia tint, the third was simply fixed, the fourth was toned to a proper tint, and kept as a standard of comparison. The first three were suspended in a box two feet and a half square, in which a minute gas jet of about the size of a pea was constantly burning; the only ventilation was through a round hole one inch and a half in diameter. He reported: "The untuned print was almost entirely destroyed in three days. The partially toned one resisted tolerably well for five days, as far as the half tones and shadows were concerned, but the high lights or whites had already become yellow. Two days more rendered it a ghastly spectacle of the 'sere and yellow leaf' both in the half tones and shadows. The over-toned print has yet (after eight days) shown no symptoms of decay, except in the high lights, which have become yellowish."

Come we now, in the third place, to the cause of fading with which it is most difficult to deal, namely, the traces of organic salts of silver left in the film, some compound probably of albumen and the metal. This usually causes the slow destruction of the print, years being necessary for the operation, and the decay can then be largely arrested by treatment with bichloride of mercury, which, be it noted, is a powerful antiseptic and coagulator of albumen. Had the print been washed in phenol at the outset, as already suggested, is it not probable that the subsequent treatment with bichloride of mercury would have been unnecessary?

Is it absolutely impossible to escape the presence in a finished print of this insidious organic salt of silver? Mr. Carey Lea claims to have done something of the kind, but his conclusions were formed upon but few experiments; other samples of paper or albumen might not have given the same results. He sensitised his paper upon a forty-grain acidulated bath, then fumed it for five minutes with ammonia, printed it, and toned and fixed by the old, much-condemned process of one operation. He says:—"Two ounces of hyposulphite of soda were dissolved in eight ounces of hot water, and chloride of gold corresponding to one grain metallic gold was added while hot. The bath was used two or three hours after mixing. This bath toned to a rich purple-black." On testing the prints with sulphide of ammonium they were found to contain no silver in the whites. Sulphide of ammonium will yellow a film of plain albumen, but that yellowness disappears on drying, hence, in applying this test, the prints must afterwards be allowed to dry before the result can be accurately known.

If acid chloride of gold be added to hyposulphite of soda, the result is to liberate a little tetrathionate of soda, which is liable to set up sulphur toning; hence the chloride of gold must be neutralised with chalk before it is added to the hypo.

The worst of the old-fashioned toning and fixing bath was that it would go on toning with sulphur after all its gold had disappeared, thus subjecting economical or careless photographers to undue temptation. When properly utilised, and the prints soaked a little in clean plain solution of hyposulphite of soda afterwards, the results were good and the tones rich.

Experience with gelatino-bromide plates proves that when they appear to the eye to be fixed they are in reality not fixed, and must be left in the solution as long again. Doubtless something of the same kind occurs with chloride of silver in albumen, but is there not so perceptible; if the prints have had their full time in clean hypo of the proper strength, they are likely to be more permanent than would otherwise be the case. Probably much fading of prints is due to too short a time in the fixing bath, or to that bath being too weak in consequence of the operator having mixed it by guess instead of by weight and measure. Photographic results are influenced by such apparently slight causes that it is not wise to do anything by guess where it can be avoided.

Another possible cause of fading may be left in the film by insufficient fixing, that cause being an insoluble double salt of silver. Hyposulphite of silver is so unstable as to be destroyed almost as quickly as it is formed; but two double salts of silver may be formed during fixing, the one soluble and the other insoluble in water. The latter is freely soluble in ammonia, also in sufficient excess of hyposulphite of soda, when proper time is allowed. The final fixing bath should always be made alkaline with ammonia. W. H. HARRISON.

PHOTOGRAPHY IN 1887.*

CAREY LEA has hitherto been one of the most enthusiastic supporters of the physical theory, but it is extremely interesting to find that the investigator who has shattered the chief argument in favour of this theory is—Carey Lea! We have here an excellent illustration of the fact that a

* Concluded from page 812.

truly scientific man has little respect for even his own pet theories if they are found to be inconsistent with the facts. Carey Lea observed that if a film of silver iodide obtained by treatment with a solution of iodine is exposed in the camera and is developed immediately, an image is obtained; but if the exposed plate is put on one side and not developed until some time afterwards, no image is obtained, the latent or developable image having gradually disappeared. He now finds, however, that silver iodide has the property of absorbing and retaining a certain quantity of free iodine. In the experiment described the silver iodide retains some of the free iodine contained in the solution by means of which it has been prepared, and when an exposed plate is allowed to remain undeveloped, this small quantity of free iodine gradually combines with the subiodide which has been formed, and reconverts it into the ordinary iodide. The fading of the latent image is, therefore, the result of a chemical and not a physical change.

Carey Lea finds that by the action of certain reducing agents he can obtain from silver chloride, bromide, and iodide by purely chemical means and without the action of light, coloured products identical in composition and properties with the coloured products obtained by the action of light on the same salts, and therefore, in all probability, of the same chemical nature. These products vary in composition according to their mode of formation, but always contain less bromine, chlorine, or iodine, than the ordinary salts, whilst they are much more stable than the so-called subsalts. Carey Lea regards them as compounds of the subsalts with a large excess of the unaltered ordinary salt, and proposes to call them photo-salts, that is, photochloride, photobromide, and photoiodide.

He also finds that certain reducing agents, and notably sodium hyposulphite, will produce on a sensitive film an invisible effect which, like the effect produced by light, can be developed into a visible image. The latent images produced by light and by the reducing agents behave in precisely the same manner towards reagents such as nitric acid and the haloid salts of potassium. What destroys the one, destroys the other. What does not affect the one, does not affect the other. It is fair to conclude, therefore, that the latent image is of the same nature in both cases. Moreover, just as light can produce both direct and reversed images, so the reducing agents can produce direct and reversed images, and the conditions under which reversal takes place are similar in both cases. Light can, in fact, reverse the image produced by the reducing agents, and *vice versa*. In both cases, continued action results in the formation of visible photo-salts. The formation of an invisible or latent image is the initial stage of a reaction which, when prolonged, produces a visible effect, and it follows that the invisible and visible images differ in degree only, and not in kind, as Abney has always contended.

An invisible but developable image can be formed on film of silver tartrate, silver oxalate, and other silver salts. If before development the film is treated with hydrochloric or hydrobromic acid, so that the whole of the silver salt is converted into chloride or bromide, the latent image is not destroyed, but can still be developed; the resulting image is even more intense than that obtained when the salt is not converted into chloride or bromide. It follows that the alteration in composition or constitution which renders the silver salt amenable to the action of the developer can be transferred from one salt to another, and Carey Lea regards this as evidence of the general existence of subsalts of silver corresponding with most if not all the ordinary salts.

It should be pointed out that the existence of definite subsalts of silver is still a disputed point amongst chemists. We may, however, take Carey Lea's results as proving that the production of the latent image by the action of light is an instance of a chemical change produced by a physical agent, and that the material of which the latent image is composed is chemically different from the salt which has not been affected by light, but the exact constitution of this material has still to be determined.

In this year of Jubilee it is not altogether inappropriate to attempt some sort of general estimate of the present position of photography, especially as the art may be said to have begun with Her Majesty's reign. To the majority of people photography is simply a useful process for obtaining "likenesses" and "views." Of its artistic capabilities, and of the extent to which its results, direct or indirect, permeate our everyday life, they have not a suspicion. It is even not too much to say that a large proportion of photographers—of amateurs, at any rate—have little idea of the multitudinous uses to which the art is put. There are few things more remarkable in the history of applied science than the rapid development of photographic processes during the past thirty years, and it is not extravagant to claim that this is an age of photography as much as it is an age of steel or of electricity.

Even if it were merely a method for producing likenesses we should find it very difficult to dispense with it now, but its utility is far more wide-spread than this. The physicist and meteorologist use it constantly as a means of accurately and anatomically recording observations; the astronomer finds that he can photograph stars and nebulae otherwise outside human ken; the microscopist, instead of spending hours upon hours in delineating a complex structure, attaches his microscope to a camera and makes the structure produce its own image; the anatomist and physiologist employs the drop shutter and the sensitive plate as the only available method of analysing the rapid movements of man and other animals. We have already evidence that the day is not far distant when cameras attached to balloons will not only give us an accurate plan of a vast stretch of country, but may enable contending armies to provide

themselves with maps of the country through which they are marching, and also to ascertain the exact distribution of the enemy's forces. To-day no explorer's outfit is complete if it does not include a camera, and the records of distant lands obtained in this way far out-value any amount of written description and pencil sketches. At the last exhibition at Pall Mall there was no exhibit more remarkable than Mr. J. W. Lindt's series of photographs in New Guinea, a country hitherto very little explored. Take only two instances. We are accustomed to think of lake dwellings as belonging altogether to prehistoric times; but here was a lake dwelling of to-day, stretching with its inhabitants over the broad waters of a lagoon. Not very far away was a picture of a hut-like human dwelling, perched like a gigantic nest in the branches of a tree. Now, if a traveller had come home and simply described these things, would it not have been insinuated that he was making an unscientific use of his imagination? The evidence of photographs is upon another footing.

It is, however, in the form of photo-mechanical printing processes that the utility of photography is most strongly marked. Photogravure, especially when used in conjunction with orthochromatic processes, is rapidly distancing its older rivals, engraving and etching, as a method for the accurate reproduction of drawings and paintings of all kinds. Collotype, when used in the hand-press, yields results little if at all inferior in point of delicacy; when used with the steam press, produces excellent results with such great rapidity and at such a low rate that it forms an economical process for the illustration of catalogues and for similar purposes. To photo-zincography we are mainly indebted for the accuracy and cheapness of our smaller scale Ordnance maps. Photo-zinc blocks, both for line and half-tone subjects, are very largely employed indeed. With the former excellent results are obtained, even in the reproduction of drawings full of complicated detail; but a great deal has still to be done before half-tone blocks can be regarded as equally satisfactory. In this, and indeed in almost all photo-mechanical printing processes, we, in this country, are still behind our foreign competitors. All the processes alluded to, and likewise photo-lithography and Woodburytype, are very largely used for the illustration of books of all kinds, the block processes being generally adopted for ordinary work, since the illustrations can be printed along with the type. The great increase of illustrated periodicals may in fact be attributed, in a great measure, to the development of these processes. Both line and half-tone blocks are used, for instance, with great success by such publications as the *English Illustrated Magazine*, *Harper's Monthly*, and the *Century Magazine*, to say nothing of unknown periodicals like *Punch*.

Photographic prints are largely used in the form of transfers in the decorative arts, and notable for the decoration of pottery, and photo-etching processes are used for such purposes as the engraving of the rollers used for calico printing, &c. Another application of photography, which at first sight might seem of minor importance, but is really of very great practical value, is the reproduction of engineer's drawings and plans by the cyanotype or Prussian blue process. And lastly, this summary would be incomplete if no reference were made to the extensive employment of photography all over the civilised world for the detection of criminals and the prevention of crime.

One of the great advantages of many of these processes is the cheapness of the results and the rapidity with which they can be produced, two very strong recommendations to popular favour in these times of high pressure.

So far photography has been treated entirely as a method of reproduction, a register of facts, and from this point of view its value is indisputable. How far can it claim to be regarded as a method of creation, or, in other words, as a fine art? This is a question of an entirely different character, and one on which I speak with much diffidence. In fact, I should not venture to deal with it at all were it not that I am able to refer to photographic pictures which are, or ought to be, well known, and which may safely be left to speak for themselves.

In order that any method of production, pictorial or otherwise, may serve as a process of fine art, it must not be automatic and mechanical, but must be so far under the control of the man who employs it, that he can bring the result into more or less complete agreement with the conception existing in his mind. Now, to talk of photography as a merely mechanical art, is simply to display ignorance which self-respect would seek to conceal. The character of plate; the time of exposure; the manner of development; the time of the year; the hour of the day; the point of view; the introduction of figures or otherwise, their pose and grouping; the character of the lens used; the method of printing, and the modification made in it—all these are under the control of the operator, and upon these the character of the result depends.

It is quite true that much of the photography that one meets with is not artistic, but that is equally true of very many paintings and drawings, and it does not follow that photography is incapable of artistic results, as many people too hastily assume. In this, as in so many other instances, it is not so much the method as the man who uses it, that determines the excellence or otherwise of the result.

The reasons for refusing to photography the rank of a fine art in 1873 were summed up by no less an authority than Mr. P. G. Hamerton, in the following statements:—(1), It is false in local colour, putting all the lights and darks of natural colours out of tone; (2), It is false in light, not being able to make those sub-divisions in the scale which are necessary to attain relative truth; (3), It is false in perspective, and

consequently in the proportions of forms; (4), Its literalness and incapacity for selection and emphasis are antagonistic to the artistic spirit. He finally summed up the matter by asserting that photography was not a fine art and could not be made one.

However true these criticisms may have been in 1873, they are not applicable with anything like the same force, if indeed they are applicable at all, to the photography of the present time. It is in the highest degree probable that they will be altogether inapplicable to the photography of the future. The first objection—i.e., the falsity in local colour, which was perfectly sound at that time—has, to a great extent, been removed by the introduction of orthochromatic methods, and the defect may fairly be expected to disappear entirely as these methods are developed. The correct rendering of gradations of light and shade, apart from the effect of colour, is a matter of exposure, development, and the character of the emulsion, and it is not difficult to find examples in which a wide range of tones is represented in a very satisfactory manner. Falsity in perspective, and in the proportion of forms, is apparent only, and depends on the position of the eye from the picture. Whenever it is met with, it results from the use of short focus lenses, and can be easily remedied by the use of lenses of sufficient focal length. Three objections out of the four have been deprived of their foundations by improvements in the methods of the art, and by increased knowledge of its capabilities. The remaining objection is of a somewhat different order.

It has been contended that art is but an accurate representation of nature, and if this be true, how can the rank of fine art be denied to photography? To take only two examples: What other method can represent with equal success the intricate grace of a leafless tree, or the ever-changing beauties of the clouds? But this definition would not be generally accepted as satisfactory. It would be denied by many that art was necessarily a representation of nature at all, and even if the need of truth to nature were admitted, the truth of idealised, and not of literal, representation would be implied.

What the artist really tries to represent is not so much the thing itself, be it animal or landscape, sea or sky, as the impression which the thing produced on his mind; and in order to convey this impression to the observer, he selects this and rejects that, emphasises one point and tones down another. He likewise endeavours to put into his picture that undefinable something which is recognised as characteristic of the best work, and which for want of a more precise term, is generally spoken of as "feeling" or sentiment. Upon the extent to which photography lends itself to similar treatment and the production of similar results, its title to the rank claimed for it must largely depend.

In the matter of selection and emphasis it must be conceded that photography is much less elastic than painting. A photographer cannot always leave out an unsuitable object; he cannot alter form; he cannot at will increase the apparent size of a thing. It would be wrong to conclude, however, that he is altogether at the mercy of his subject. In portraiture, the pose, background, mode of lighting, and in fact almost everything, is under his control. In outdoor work the point of view can be altered, and the conditions of lighting selected, in order to get the best result. The introduction of a figure suitably posed and lighted will often give the required emphasis. Careful and thoughtful printing will likewise do much towards the attainment of the same end. Selection and emphasis in photography may be comparatively difficult, but it is not impossible.

To put sentiment into a photograph is more difficult than to put sentiment into a painting, because the methods and conditions are less elastic. This "feeling," however, is painfully absent from many paintings, and may, in fact, be taken as characteristic of high-class work only. To obtain it in a photograph may, therefore, be looked upon as a considerable artistic achievement. And can it not be done?

Is there not sentiment, and sentiment in a high degree, in many of Sutcliffe's studies? The cold, misty, autumnal evening, with the breeze which will soon tear the few remaining leaves off the trees; the wild, wintry-looking sky, harbinging of the wind that shall sing the dirge of the wreck on the beach; the rapidly coming twilight, bringing rest from toil to both man and beast; are not these successfully and admirably rendered? Take as another example Tolley's *On the Lonely Shore*, with its harmonious composition and chiaroscuro. Observe how true the picture is to its title and the idea which the artist wished to convey, and notice especially the emphasis which is gained by the skilful introduction of the figure. Again, in Green's photograph of *The Head of Buttermere*, what a capital picture is made out of the simplest materials, and how admirably the height of the mountain, the loneliness, and the general atmospheric effect are portrayed! And last, but not least, is there not feeling and harmony to at least the same extent as in many paintings in many of Emerson's studies in the Norfolk Broads? These examples are not cited for the purpose of making invidious distinctions, but because they are recent and are familiar to most lovers of photography. Are they not enough to show that in landscape work at least the best photography—and it is on the best that judgment must be based—is truly artistic? What painter has done anything much better than Mayland's wonderful photograph, *There's Sorrow on the Sea*.

When we pass to *genre* pictures and portraiture, surely the case is still stronger. Here the photographer has matters more under his control. Is there not artistic treatment of a very high order indeed in H. P. Robinson's *Dawn and Sunset*, *When the Day's Work is Done*, and *Wayside*

Gossip, to say nothing of his numerous other productions? Are not Sutcliffe's studies of fisher folk as admirable as the majority of similar studies done with the pencil or brush? Do we not yet remember Malby's *Strengthening the Understanding*, and Gridley's *The Good Flask*?

In portraiture it must be admitted that the great bulk of the work done is bad—bad technically—worse artistically—but then this is equally true of much portrait painting. The capabilities of an art are, however, judged from its best results, and not from the worst. Photography is the method of portraiture for the million, and this alone would insure its continued existence. But it has higher claims, and people rightly set considerable value on a photographic portrait by one of our most eminent artists in this branch. Truth, which is of great importance in these cases, is not difficult to obtain, nor is it excessively difficult, by proper treatment, to throw into the picture some of that sentiment and character which is essential to all good portraiture. Referring now to examples in the late exhibition at Pall Mall, it is safe to say, in the first place, that those who examined Mendelssohn's grand head of Mr. Perigal will not soon forget it. Is there not, too, a peculiar charm about Hollier's portrait of Miss Terry, in spite of some criticisms which might be made respecting the lighting of the face and its background? To go a little further back, some at least will remember Byrne's *Lady in a Grecian Dress*. It is not very rash to assert that there is much "fine art" in these examples and in many others which might have been mentioned if these had not come first into mind, as in not a few of the portraits which are seen at the Academy. How many painters of to-day have done anything more vigorous and characteristic than Debenham's head of F. Barnard?

It is not necessary to cite further examples. The claims of photography to be recognised as a fine art are, as a matter of fact, being gradually admitted—a result due entirely to the labours of the minority of the craft, who bring to their work sound, artistic training and a careful study of its difficulties and capabilities. Already the leading newspapers criticise the exhibition in Pall Mall on the same footing, so far as the pictorial part of it is concerned, as they criticise an exhibition of drawings or paintings. It is unfortunate, however, that the critics do not always display even a decent knowledge of the art which they criticise, and particularly of the special technical difficulties which have to be contended against.

I should be sorry to weaken the argument by seeming to claim too much. It would be ridiculous to assert that photography is entitled to equal rank with painting. Some things it can do which painting cannot do, but in most respects it is undoubtedly inferior to the older art. It lacks at present, and probably for some time to come, the power and mystery of colour. It is much less elastic, and, whilst answering to a very considerable extent to the will of the artist, it does not, at present at any rate, leave him that complete control which is essential to the production of the very highest work. Moreover, it imposes strict and somewhat narrow limitations both as to choice of subject and the mode of treatment. Limitations of a similar kind are, however, inseparable from other graphic arts, and painting itself is not altogether untrammelled. To admit, as we are bound to do, that photography does not rank with the very first of the fine arts is a very different thing from admitting that it is not a fine art at all. Such an admission I, and think you also, would altogether decline to make. Holding then this belief, let us not be satisfied with mere technical efficiency, but let us each endeavour, by systematic cultivation of whatever artistic faculty may be in us, by careful and painstaking study of every subject we undertake, to make good individually our claims to be in reality, and not merely in name, artists in photography.

C. H. BOTTLAMLEY, F.I.C., F.C.S.

"MEMENTO MORI."

It is often said that lords of the soil and the voluptuous plutocracy occasionally find time hang heavy on their hands. This is probably quite as true as the statement of the good Dr. Watts that the satanic denizen of another place obligingly furnishes the idle with plenty of mischief. Once upon a time a satiated imperial personage offered a prize for the invention of a new and original pleasure. History refuses to tell us how many entrants there were; probably in those remote centuries there were no unemployed, or a close and exciting competition might have resulted instead of, as we are entitled to conclude, no contest. The issue would be different to-day under our high-pressure regime of ceaseless change and novelty. The recently deceased heir to an English marquise, who was an amateur photographer, was wont to distil amusement from persuading his friends to feign death, so that he might photograph them in a position of monumental recumbency. The eccentric earl's inner object never transpired. His pictures impressed one with the fancy that the "sitters" were calmly chewing the cud with closed eyes, which, as we often hear mention of the meditative cast that steals over their features, is an aspect that must be met with in the really defunct. We have here an illustration of the strange and several uses to which photography is applied. The still juvenile fact that it is possible to accurately transfer the features of the dead to paper by scientific means will merit, in company with the twin truth as to pictures of the living, the notice of the

future analytical historian as he reviews the conditions of nineteenth century existence, and may afford food for the pencil of the apocryphal person from New Zealand when, having finished his sketch of the ruined basilica at the top of Ludgate-hill, he proceeds to explore the remains of the second Babylon, like another Schliemann in another Mycenæ.

It is almost if not quite a truism to assert that there is no stage of life in which photography does not perform a useful, necessary part, while in death its services are capable of much more extended application than is at present the case. Shakespeare's—or Bacon's—Seven Ages are now depicted by an eloquent substitute for words; for the modern prototype of the Melancholy Jacques may moralise over photographs of the entire septet, from the "infant mewling and puking in the nurse's arms," down to the doddering dribbler in his second childhood; and when silence comes he may have the camera carried to the very edge of the tomb, and secure the only unalterable expression the human countenance has at its command. It is singular that in these days of ultra-realism post-mortem photographs are not in greater request. The notion of obtaining them does not, presumably, occur to the average mind until too late for concrete embodiment; but if fashion once turned her fickle footsteps in this direction it is difficult to predict to what lengths the innovation would go. Like the gentleman in Lord Lytton's play of *Money*, Mr. Photographer would do "anything to oblige"—especially in these hard times. One of the peculiar experiences related by Mr. Hubert in a discursive but candid paper read by him before the London and Provincial Association last winter, was that of being suddenly called upon to photograph the dead body of a little girl, and latterly Mr. Cowan drily informed the same Association that he once photographed a corpse by combined natural and artificial light. To the hysterically inclined these gruesome confessions may impart a shudder, and but that the Christmas literature provided for us by the proprietors of the JOURNAL takes the austere shape of the ALMANAC, one might have suggested that with such a theme a thrilling photographic creeper could be written, and the commission handed to Mr. Wilkie Collins or Dr. Conan Doyle, whose graceful pen seems to have quite forsaken these pages for the lurid literature of the bookstall. Or if that idea was received with cold disdain, what could be more instructive and entertaining at this festive season of the year, when ghosts are in such great demand, than the adventures of a well-conducted impalpability, constructed, not of the time-honoured thin air, but of such spectral and serviceable materials as Ag Br and Drescher's Extra Hard? Sculptors, painters, and novelists have ghosts, and very substantial ones some of them are; but these privileges of the higher arts are denied to us, who should therefore seize the chance of securing something novel and striking that would stand the rigid analysis to which no respectable ghost ever thinks of objecting.

We are not in the habit of perpetuating the features of the departed as such in so great a variety of ways that we should despise the assistance of photography if it were once generally called into use. Painters show us great people and sovereigns lying in state; sculptors stick chilly effigies of dead warriors and ecclesiastics on the tops of cathedral tombs, and the worker in brass executes tablets that are enduring—but ugly. Each of these methods conduces to glorified untruthfulness, being done to order or paid for by results. Lower down that ladder the first step of which is bronze, and the others silver, gold, titles and diadems, canvas or Carrara canonisation is out of the question. Nor does the familiar album of the middle-class parlour table, plethora of portraits as their originals were when living, often contain a last memento of them after the heart has made its final beat. Surely, if it were generally known that we had in our midst ready and accomplished experts like Messrs. Hubert and Cowan, willing at a moment's notice to step round and execute a commission of this ghostly description, our albums and walls would at last boast something worth inspection. By never having the departed photographed we miss a great deal worth possessing. Here, in the aforesaid family album, are the features of that generous uncle who, true to his promise, remembered us in his will. How consoling to have a replica of the last benevolent smile of one who had kept his word and left us—a suit of mourning wrapped up in his best wishes! Furthermore, we might value a picture of the family misanthrope who had a sour visage all his life and a beatific one after it; of the unhappy wretch who always looked at the camera as if it were a lion in his path, and now basked in the sweet sheen of post-mortem peace; of the artificial cynic, whose features were their natural clothing for the first time; the painted belle, minus her rouge and pencillings; the worried man without his care; the small debtor absolutely undaunted by the threat of the coffee-coloured paper; the hypocrite without his mask of sanctity; the lively man who at length was grave and severe, &c., &c., &c. Again, if we yearned for something colossal, did

not Messrs. Eastman and Walker prove to us the other day that we can do without the sculptor and the painter, and have no more ruinous bills for brass and marble? We can have a paper enlargement which is permanent—whilst stone and brass are not, or rather sculptors and tablet-workers do not say they are, so, of course, they cannot be! What a pity somebody wasn't before me with this astounding discovery a year ago, when that inquisitive Langholm *savant* published his experiences; we could then have talked to him on the subject of relative permanence with greater confidence and the certainty of confuting him and others who were sceptical of the staying powers of bromide and platinum-type images!

Dead men tell no tales, and also possess the inestimable virtues of keeping still and wearing a natural expression, so that a post-mortem photograph might at least be depended upon for accuracy of resemblance and freedom from movement. In place of the little yellowed prints one sees under glass at some cemetery headstones, which prints are usually photographs of the deceased when living, we could substitute something more realistic; renew it as often as necessary, and thus have the departed or their counterfeits always with us. An expiring man would be soothed by the reflection that he would go down to posterity in something more than name. Even the poor devil who cannot soar above a joint-stock grave, might have a glazed carbon print on the lid of his "common elm," if it were considered necessary to supplement the painfully bald information of the brass plate. Professional photography as an industry is languishing: it might receive a welcome fillip if it became known that, like the undertaker, the photographer was prepared to take a share in executing the last sad offices for our dear brother. Mr. Mould, the undertaker, it will be remembered by readers of *Martin Chuzzlewit*, was always studiously attentive to those upon whom he considered it probable he would be shortly called to wait in his professional capacity; is it within the precincts of possibility that the portrait photographer in addition to his other troubles may, like Mould, some day conceive it his duty to be attentive to those upon, &c.? If it is, we shall have the consolation of knowing that such photographs will be far less ghastly, disagreeable, and untruthful than those now prevalent of many living people, than which nothing could well be worse. However repulsive some of us may consider the question of post-mortem photography, it is inextricably bound with two or three matters of public policy. Should the practice become general it might be the forerunner of the abolition of such standing horrors as the Paris Morgue, for the French authorities could have the unclaimed suicides photographed, and the pictures shown only upon request just as well as exhibiting the bodies to the gaze of morbid sensation seekers. In like manner, to come nearer home, some future legislator might propose a short Bill abolishing compulsory inspection of corpses by coroner's juries, as an officially certified photograph of the remains would serve as well as viewing them—a practice which to many sensitively balanced minds is an unmitigated terror, and in every respect as indefensible as it is barbarous. Photographs of the departed hung upon our walls might also be made to serve a purpose akin to that of the corpse at the feasts of the ancient Egyptians, by perpetually reminding us that, unlike the results obtained upon the rival printing surfaces already mentioned, life is neither permanent nor indestructible, and that the mortal clay is sadly given to yellowing and fading under the influences of agents more or less inimical to its longevity than H₂S is to photographic prints.

MARSTON MOORE.

WHAT IS HYDROQUINONE?

THE above question having been put to us by a number of our friends, we thought it would not be uninteresting to give our readers a brief review of the chemistry of this new developing agent and some statement of its general properties.

A few words may not be out of place here in explanation of the method of spelling the word as given above. Some writers in English use the term "hydrokinone;" but in looking into the matter we find this is simply an adoption of the German word without much change, whereas the correct English word used by the best scientific authorities is "hydroquinone." The reason for the latter method of spelling appears to us to be a good one: it is because the body under discussion was formerly obtained from quinic acid, one of the substances associated with quinine in Peruvian bark. We therefore prefer the word hydroquinone rather than hydrokinone, and for like reasons we reject the word hydrochinone, also used by some authorities.

Hydroquinone belongs to a class of organic bodies that the chemist calls diphenols, and hence it is sometimes called quinol; but the former name is that more commonly used. It was first obtained by Caventou and Pelletier, about the year 1820, as a product of the dry distillation of quinic acid, a compound found in Peruvian bark and a

by-product in the manufacture of the well known alkaloid quinine. The above chemists did not make a thorough examination of the body, and called it pyroquinic acid because they obtained it by heating quinic acid. Some time afterwards Wöhler found that he could obtain the same body by combining hydrogen and quinone (a product of the oxidation of quinic acid with manganese dioxide and sulphuric acid) and gave it the name it now bears, hydroquinone. He further found that hydroquinone could be best prepared by passing sulphurous acid gas through a warm saturated solution of quinone which has some of the undissolved substance suspended in it.

It is very interesting to note how the researches which had for their object the artificial production of the alkaloid quinine have also given us a long list of new chemical compounds that are gradually becoming useful to man as their properties are studied. Hydroquinone is one of these bodies, and although we cannot make quinine from it, yet there appears to be a great field for it in its applications to photography.

After hydroquinone as a product of the dry distillation of quinic acid had been studied, it was found to be obtainable from other sources. The leaves of the bearberry (*Arbutus uva ursi*) contain it combined with glucose, also the leaves of wintergreen (*Pyrola umbellata*). From both these sources it can be obtained by boiling the aqueous extract with dilute acids. But further study showed it to be related to benzol, the product of coal tar, and a process was soon devised to manufacture it from aniline, which is a derivative of benzol and the source of so many interesting organic compounds. The method of procedure is as follows.

One part of aniline is dissolved in eight parts of sulphuric acid and thirty parts of water, and to the cooled solution two and a half parts of potassium bichromate dissolved in water are gradually added. To the brown fluid thus obtained potassium sulphite is added, and the whole mixture is finally shaken with ether. The ether is allowed to rise and the fluid below is drawn off and rejected. By distilling the ether solution a residue is obtained which is dissolved in the smallest quantity of hot water; sulphurous acid and animal charcoal are then added, and the solution is boiled and filtered. On standing the hydroquinone separates out in hexagonal rhombohedral prisms.

The substance thus obtained sublimes in monoclinic plates, which on solution in water again gives the crystals mentioned above. It has a slightly sweet taste and melts at 169° Cel. It is readily soluble in hot water, alcohol, and ether (at 60° Fahr. one part takes seventeen parts of water for solution). It reduces silver nitrate solution, and also alkaline solution of copper sulphate. It forms a compound with sulphurous acid gas, which may account for the fact that it works better in a developer which contains sodium sulphite. It may possibly be still further improved by adding sulphurous acid to this solution of sulphite and hydroquinone. The result of its oxidation is quinone, the product mentioned above, which is also obtainable from aniline by oxidation.

We have given our readers a brief review of the principal chemical properties of this exceedingly interesting developing agent. It is not as energetic as pyrogallol in its reducing power, but the results obtained are softer and the negatives are less liable to be stained. Furthermore, the fact that the reducing action of the developer is less energetic, allows of its better preservation, and the same solution can be used for the production of a great many more negatives than a similar solution with pyrogallol as the active agent. At present the price of hydroquinone is considerably higher than pyrogallol, but should there be a demand for this new agent it will be manufactured cheaply, and the reduction in price will be similar to that which took place when pyrogallol became a popular developer.

We recommend all our readers to try this new developing agent, and even at the present prices the advantages and comfort obtained in its use fully compensate for the extra expense incurred in using it.

—Anthony's Photographic Bulletin.

A LADY'S VIEWS ABOUT RETOUCHING.

In an age of all-abounding vanity the lover of his species must experience an inward satisfaction in learning, through the medium of the Woolwich County Court, that there exists a lady who declines to pay for her portraits on the plea that they were too good-looking. The photographs were "touched up." They made her younger than she was. Her hair was straight, while in the manipulated sun-pictures it was wavy. In vain did the artist plead that in "touching up" the plate he only met a customary requirement of his clients to look a little better than their best. The Spartan lady scorned the insinuation. She did not wish to be "flattered and titivated up." Like Oliver Cromwell, she desired the Sir Peter Lely of Woolwich to present her face to the world as years, good-nature, and a frankness better than beauty have made it. If there were wrinkles, she wished them; and if her hair was straight, whatever might be the prejudices of the Woolwich matrons in favour of waviness, straight must her locks go down to posterity. Unlike Topsy, she was not one of

those who preferred "wool to har." Unfortunately, however, the judge decided against her, though, for the credit of maligned human nature, one might have wished that a lady so little dominated by the weaknesses of her sex could have won the case she so valiantly defended. But his Honour, after a long experience of the average woman as she appears in county courts, had come to the conclusion that she goes to the photographer not to get a likeness, but a picture. Accordingly, in default of the Cromwellian lady giving the artist specific orders to make her appear "just as she was," he was compelled to come to the cynical conclusion that she desired him to take the "ordinary course of procedure," namely, to "make the customers look their best." From this point of view the rejected portraits were "reasonable likenesses," and must be paid for at the same rate as if they had been all that the courageous lady required. We regret to record the decision, for it adds one more piece of judge-made law to the fringe which is almost daily getting round the photographic art and its applications. Henceforward the science which we had faintly hoped was to preserve the lineaments of man and his surroundings with a fidelity which admits of no prevarication is to play the flatterer like the pencil of the painter or the chisel of the sculptor. And what is more, the judge has ruled, and county-court law it must ever be, that the sun, or the servants of the sun, are to flatter the sitters, touch them up beyond recognition, and turn back by a stroke of the brush the dial of time, unless the client declares in advance that he or she desires the Orb of Day to be uncompromisingly truthful.

All this is pitiful, but we fear it is fact nevertheless. The sun, especially in a day of spersensitive plates, is capable, almost without an interval of reasonable time, of imprinting on a sheet of glass every passing mood of the person who passes before it. The result may not be a portrait. It is not an average likeness. It is simply a photograph of the appearance which the person presented at the moment when the light was let in on the chemicalised plate, be that the usual or the unusual aspect of the sitter's countenance. This is his business, not the sun's. Hence that wooden figure, and that supernaturally grim countenance, which in the early days of the art we had learned to recognise as the "photographic face," have almost disappeared from the family albums. Before the sitter has time to pose he is "taken." He—or more likely she—is trying to look her best, is wondering whether her hair is smooth, or his shirt-front unruffled, when a click is heard, and the gentleman in the velvet jacket blandly informs his victim that all is over. No longer are the dismal minutes of torture required, or the sacrifice to duty compelled to fix his occiput in the iron head-rest of collodion days. Almost ere he knows that he is before the face of the exposed plate the mischief is done. But for that very reason it is seldom satisfactory. The customary frown has not had time to be replaced by the unwonted grin, or the crow's-feet show with a needless amount of fidelity. Thus have arisen a race of subsidiary artists whose business it is to improve on nature. These are the "touchers up," and that the profession is an important one a glance at the columns of any photographic journal will afford the scepticist the most convincing proof. The fact is that the photographer has inherited many of the traditions and most of the prejudices of the old portrait painter. The defiant attitude beside a sham marble pillar and a red curtain, with the forefinger on a copy of the *Elegant Extracts*, which pretty clearly marks the date of the earlier efforts of Daguerreotypy, was a survival of a former day. The touching up is another. The photographer has never—as it was at one time thought he would—entirely displaced the painter. For he could never flatter with the ease which the fashionable portrait painter always did, and always will do. However, by means of touching up he is doing his best to pander to the weakness of mankind. There was at one time—perhaps is still, though by this period he must have made a fortune—an ex-Confederate general who prospered amazingly in Mexico owing to his skill as a photographer enabling him to take a very pale portrait, the great ambition of a Mexican being to look as like a white man as art will allow. The photographer has begun to learn—and a photographer's autobiography would be an entertaining book—that no man or woman ever believes himself or herself to be as plain or as prosaic-looking as he or she actually is. Hence the "customary procedure," with the occasional revolt of the emancipated woman, and the county court to follow.

In former days it was not so easy to reject a canvas once it was done. Yet the annals of painting afford not a few instances of that form of revolt. Cromwell's injunction to Lely stands by itself, and even then it is by no means certain that the courtly painter carried out his instructions to the ultimate "pimple and wart." He, probably enough, interpreted the Lord Protector's injunction as intended mainly for the use of the coffee houses frequented by the Cropheads. When an ugly old peer refused to pay for a portrait which was only too truthful, Hogarth threatened that if it was not removed in three days he would add a "tail and other appendages," and sell it "to Mr. Hore, the wild-beast showman." Du Bost went further than this, for in default of getting paid for his work he exhibited the portraits of an offended client and his wife as *Beauty and the Beast*, an act which so enraged the lady's brother that he cut it in pieces. On the case being tried before Lord Ellenborough it was decided that as the picture was a libel the plaintiff could only recover for the loss of the paint and canvas. This story is on a par with that of the modern artist who, being refused his price by a wealthy Manchester man on the plea that he had taken a shorter time to paint

his portrait than had been stipulated, settled the question by devoting the departed days to lengthening, little by little, the ears of his patron. In later times, when another plutocrat refused the portrait of his daughters, the painter simply exhibited them as *The Three Graces*, and found exceeding profit in so doing. Libels on his enemies have always been a favourite trick of the enraged artist. Thorsvaldsen made a godless German sculptor sit for the portrait of the impenitent thief on the Cross. Horace Vernet, after his dispute with Rothschild, depicted him as the plunderer running away with the spoils in the famous *Prise de Smala* at Versailles; and Gros, to wreak his vengeance on Marshal Bessieres, who had cut him, set the soldier among the plague-stricken people in Egypt holding his nose. Guido represented Pope Innocent as a demon; and three or four years ago there was a huge pother in Paris over M. Jaquet painting Alexandre Dumas as *Le Juif de Bagdad*. All this is very amusing—and very wicked. But the modern sensitive plates, which will in an instant perpetuate in the most minute details anything which passes before them, ought to be more truthful and less libellous. They will even show little incidents which the photographer did not observe with his unassisted eye, and no doubt, skilfully managed, might be introduced into a court of law as evidence of a faction fight in Ireland, or a street riot in London, which there would be no controverting. Even a bird in flight, a racehorse in full gallop, or an express train passing a station, can be caught. Here touching up is impossible, for any tampering with the plate could be at once detected.

—Observer.

THE CRYSTAL PALACE PHOTOGRAPHIC EXHIBITION.

As promised last week, we now give the schedule of classes:—

ART DIVISION.

Class A (Outdoor Photography).—Section 1, Pure landscapes; 2, Landscape, with figure; 3, Architecture, (a) exterior, (b) interior; 4, Instantaneous photographs, including marine subjects.

Class B (Indoor Photography).—Section 1, Direct portraiture; 2, Home portraiture; 3, Enlargements.

Class C (General).—Section 1, Groups; 2, Combination pictures; 3, Photographs mounted in optical contact; 4, Ceramic photographs; 5, Orthochromatic photographs; 6, Photo-mechanical pictures; 7, Micro-photography*; 8, Bromide prints by contact; 9, Carbon pictures.

Class D (Transparencies).—Section 1, Photographic transparencies for decorative purposes; 2, Photographic lantern slides.

Class E (Stereoscopic Photography).—Section 1, Stereoscopic slides—paper; 2, Ditto, glass.

APPARATUS DIVISION.

Class A (Woodwork, &c.).—Section 1, Cameras and fittings, including detective cameras; 2, Appliances for paper and film photography; 3, Tripods and studio stands; 4, Studio furniture, including upholstery.

Class B (Optical).—Section 1, Lenses; 2, Instantaneous and time shutters; 3, Finders and view meters; 4, Enlarging apparatus; 5, Lanterns; 6, Appliances for artificial illumination; 7, Stereoscopes.

Class C (Cheap and Popular Sets).

Class D (Dry Plates and Films).

Class E (Surrounds).—Section 1, Mounts; 2, Frames specially suitable for photographs; 3, Albums and cases.

Class F (General Appliances, and Plant).

Class G (Cycles fitted for Photographic Purposes).

LANTERN DIVISION.

Regulations and other information respecting the Competitive Lantern Entertainments, which will take place during the exhibition, may be obtained on application to the Executive Committee.

PATENTS COMPLETED.

PHOTO-CHEMICAL PRINTING.

No. 1681. WILLIAM WILKS, Bromley, Kent.—February 2, 1887.

My invention has for its object the production upon paper or other surfaces of photographic pictures, or images in platinum—that is to say, pictures or images of which the colouring matter or pigment is platinum. It differs from the processes of photo-chemical printing described in the specifications of my former patents, viz., No. 2011, dated June 5, 1873; No. 2500, dated July 12, 1878, and No. 1117, dated March 15, 1880, in which processes (as far as they relate to platinum) the paper or other surface is coated with a solution of a salt of platinum, and sometimes other salts, and also with a solution of ferric oxalate. These solutions are applied, either separately or mixed, to the paper, and in all cases the sensitive coating of the paper contains a salt of platinum and ferric oxalate. After exposure to light, the prepared surfaces are treated with one or other of the developing solutions described in the said specifications.

* Is not this a misprint for photo-micrography? The two terms convey a totally different meaning.—EWS.

Hitherto no means have been known by which the salt of platinum could be employed entirely in the developer or developing solution, instead of wholly or partly in the sensitive coating of the paper, or other surface as above set forth. I have, however, now discovered a process by which I can accomplish this result. For this purpose I apply to paper, or other suitable material, which has been rendered sensitive by a coating of ferric oxalate and afterwards exposed to light, a developer containing salts of platinum and certain soluble phosphates (or other salts, in which the ferric oxalate image produced by exposure to light is insoluble, or nearly so), with or without the addition of potassic oxalate, potassic tartrate, ammoniac citrate, or other salts which tend to increase the rapidity and vigour of the development. By this process I avoid the necessity of using salts of platinum in the sensitive coating of the paper or other surface. I thereby greatly diminish the cost of the process and can obtain good results without heating the developer.

Moreover, I obtain a slower developing action, so that it is possible to watch the progress of development, and to arrest it at any desired moment by washing the print in a solution of acid.

According to my present invention I use paper, wood, woven fabric, or other material, the surface of which I prepare and render sensitive for photographic purposes by the application of a coating or coatings containing ferric oxalate, with (or without) the addition of a salt of lead or of mercury, or mixture thereof, and without any salt of platinum.

I first prepare the paper or other surface by the use of this coating as herein-after specified. I then expose it to light under or behind a negative, and then develop the picture by means of one of my improved developing solutions hereinafter specified, or other suitable solution containing a salt of platinum.

For preparing or coating the paper or other material, I employ for ordinary purposes an aqueous solution of ferric oxalate containing in each fluid ounce about sixty (60) grains of ferric oxalate $\text{Fe}_2(\text{C}_2\text{O}_4)_3$; but I may use less or more of the latter according to the result desired to be obtained. I am of course aware that there are other salts of iron sensitive to light, but the oxalate is best for my purpose. I sometimes mix or dissolve in the ferric oxalate a salt of mercury or of lead or a mixture of these salts; for instance, I dissolve in one fluid ounce of the ferric oxalate solution above described, from one grain to three grains of mercuric chloride. Or I apply solutions of a salt of lead or mercury or a mixture of these salts to the paper or other surface either previously or subsequently to coating the same with ferric oxalate. I find the mercuric salt very useful where a warm tone or effect somewhat resembling that of sepia is desired.

I do not confine myself to aqueous solutions of the above-named salts.

The paper thus coated, after being dried, is ready for use. If two coatings are applied to the paper or other surface, it should be dried between the application of the first and second coatings. After its exposure to light under or behind a negative, I apply to it the developing solution.

I prepare an improved developing solution or developer as follows, that is to say:—I use solutions of various soluble phosphates. I have been most successful with the following, viz.:—the monosodic or disodic, the monopotassic or dipotassic or the mono-ammoniac or diammoniac orthophosphates, or mixtures or combinations of these salts with one another, and with or without the addition of other salts, such as potassic oxalate, ammoniac citrate, and others. In all cases I add to these solutions or mixtures of solutions a salt of platinum. I mix a solution of this salt with the above-named solutions or I dissolve the platinum of salt in them. The platinum salts most suitable for my purpose are the ammoniac, potassic, and sodic chloro-platinates, the ammoniac, potassic, and sodic bromo-platinates, or mixtures of them, and in some cases I use a very small quantity of a platinum salt, such as ammoniac, potassic, or sodic chloro-platinate.

I usually prepare this developing solution as follows, that is to say:—I dissolve in one fluid ounce of water, one hundred (100) grains of di-potassic orthophosphate, forty (40) grains of potassic oxalate and ten (10) grains of potassic chloro-platinate; or I make it in another manner, viz., by dissolving in one fluid ounce of water, one hundred (100) grains of diammoniac orthophosphate, thirty-five (35) grains of ammoniac citrate, and ten (10) grains of ammoniac chloro-platinate; or I make similar developing solutions with the salts previously mentioned. I make also developers containing only phosphates and salts of platinum, that is to say, I may make a developer by dissolving in one ounce of water about one hundred (100) grains of mono-potassic, or di-potassic orthophosphate, or mixtures of these salts, and ten (10) grains of potassic chloro-platinate.

The developing solution is applied to the paper or other surface (after the same has been exposed to light) by pouring it over the same, or by immersing the paper therein, or by floating the paper thereon, or by means of a brush, or otherwise. It is applied cold, warm, or hot, as desired. A cold solution usually takes longer to effect the development of the picture than a hot one. The strength of the solution may be varied; usually the best results are obtained by strong solutions of the phosphates and other salts; the platinum salt will ordinarily be used in the proportion of from five to ten grains of the salt to one fluid ounce of the developer.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I wish it understood that I claim—1. The process or method in which I sensitise the surface of paper or other material by the means herein specified, then expose the surface to light, and then develop the picture or image by the use of a solution containing a salt of platinum, as above set forth. 2. The production or development of photographic pictures or images in platinum, by the application of a salt of this metal to a surface which has been previously rendered sensitive by the application of a ferric salt and exposed to light. 3. Paper, or other material, which has its surface prepared and rendered sensitive for photographic purposes by the application of a ferric salt and a salt of mercury, or of lead, or of both mercury and lead, as above set forth.

IMPROVEMENTS IN BEARINGS FOR PHOTOGRAPHIC ROLLING PRESSES, ROLLING MACHINES, AND THE LIKE.

No. 1830. WILLIAM EDWIN MOSS AND JOHN MITTON, Birch-passage, Alfreton-road, Nottingham.—February 5, 1887.

In the improved system indicated by the title of our said invention we adopt a

more simple plan of construction than has hitherto been introduced, the cost of production being likewise thereby lessened, whilst at the same time friction is reduced to a minimum.

In photographic rolling presses, rolling machines, and the like, each bottom bearing, constructed according to our invention, consists of two friction rollers working in recesses or slots and revolving on pins attached to the body of the machine. The top bearing is formed by two friction rollers, but to a loose cap, and is arranged in the same manner as the bottom bearing.

IMPROVEMENTS IN WASHING PHOTOGRAPHIC PRINTS AND IN APPARATUS THEREFOR.

No. 12,292. ARTHUR MARRIOTT, 13, Swann-street, Loughborough, Leicester.—
September 10, 1887.

This invention relates to the washing of photographic prints by the action of cold water, and it has for its object the improved construction of apparatus whereby this operation can be automatically performed in a more expeditious and thorough manner than heretofore.

The invention comprises the use of a cylindrical vessel of suitable dimensions, and constructed of any suitable material at, or near, the lower end of which is fixed a water-tight bottom; at the bottom of this vessel, and rotating close to it is a water wheel with a convenient number of arms; this wheel is a little less than the inner diameter of the vessel and is secured to a vertical axis working freely in a lower bearing secured to the bottom, and an upper bearing formed in a bar placed across the top of the vessel.

This wheel is driven by a number of water jets set at a suitable angle on the bottom of the vessel, each jet being supplied with water from a central reservoir underneath the bottom provided with a supply pipe, or by any convenient arrangement.

Immediately above this water wheel is a false bottom resting on bearings secured to the sides of the vessel. It is formed in the shape of an air propeller with a convenient number of propellers, and to prevent the prints from slipping through them the space between each is filled with a perforated metal plate, placed in a vertical position.

To prevent the prints from collecting in the centre by the action of the water, the centre space above the false bottom is occupied by a hollow perforated cone; and to prevent the vessel from overflowing, there is an opening in the side, near the bottom, connected with a pipe, which is carried up the side to a convenient height, and then bent down again in the form of a syphon. At the upper bend of this pipe or syphon is a small air inlet provided with a tap, and by opening or closing this inlet the pipe may be used as an overflow pipe or as a syphon to empty the vessel.

The action of the apparatus is as follows:—The prints to be washed are placed in the vessel above the false bottom, and the water entering by the jets turns the water wheel, the action of the water wheel forces the water through the false bottom in waves in a circular direction, and the whole of the water in the vessel is kept moving by this action, the prints are gently turned over and over, and are kept constantly in motion until they are removed.

IMPROVEMENTS IN TELESCOPIC FRONTS AND OBJECTIVES FOR OPTICAL LANTERNS.

No. 14,809. ALFRED WRENCH, 39, Gray's Inn-road, London, W.C.—
October 31, 1887.

My invention consists of an improved combination telescopic front for optical lanterns, and is constructed so that the tube which carries the lenses called the objectives may be moved to any desired position to suit lenses of various focus by means of rackwork adjustments. I first make a wide ring, provided with a bridge bearing and pinion, the ends of the pinion having suitable mill-heads to turn it by. This combination is called a jacket (No. 1), and into this jacket I slide a tube provided with a suitable rack, which gears into the before-named pinion. At one end of this tube I fix a jacket (No. 2), and I make a second tube (No. 3), with a rack and jacket fitted to it, to slide into No. 2 tube. Into this tube and jacket (No. 3) I slide a third tube with a rack only fixed to it (No. 4), and into this tube I fit a barrel (containing the lenses, which may be of any suitable combination) having at its front end a pivoted plate or shutter of the usual description. The jacket No. 1 has a suitable screw thread at one end to screw it into the front of the lantern, and the length of the jacket is preferably one inch. The tube and jacket No. 2 is preferably four times the length of No. 1, and the tube No. 3 is increased in length and amount equal to the length of its jacket. The tube No. 4 is also the amount of jacket longer than No. 3. It will be seen that when placed together, i.e., the various tubes slid inside each other, the total length is only that of the tube No. 4, but when extended (or racked out) the total length is about three times that of tube No. 4.

Although I employ three rackwork tubes to form my improved combination front, it is obvious that two, or any larger number, might be employed without departing from the nature of my invention. I am also aware that a telescopic front, with one rackwork objective, and that a barrel to slide into a single rackwork objective, is not new, but my invention of two or more rackwork tubes in combination, forming a telescopic front, is new.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—In a telescopic front for optical lanterns the combination of a jacket and two or more tubes, each with a rack and pinion adjustment, forming a telescopic lantern front substantially as described; the combination of two or more tubes with rackwork adjustments, and an extra tube with a rack arrangement for the barrel to fit into it; the general combination forming my improved telescopic front for optical lanterns substantially as described.

AUSTRALIAN AWARDS.—We learn that Messrs. Watson & Sons are so fortunate as to have been the recipients of no fewer than seven awards for photographic and optical goods sent this year to the Adelaide Exhibition; two for photographic apparatus being of the first order of merit, those for microscopes, surveying instruments, telescopes, mathematical instruments, and lines for lanterns, securing awards of the second class.

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST Tuesday night, at the ordinary weekly meeting of the above Society, held at 5A, Pall Mall East, London, Mr. William England, Vice-President, occupied the chair.

Mr. W. F. DONKIN said that he had been trying hydroquinone as a developer for lantern slides: he had brought a sample of the developer mixed more than three weeks ago, and which had developed three or four dozen plates; they would see that it was still nearly colourless. The hydroquinone cost 2s. 4d. per ounce. He prepared the solutions as follows:—

Solution A.

Hydroquinone	1 drachm.
Metabisulphite of potash	$\frac{1}{2}$ ounce.
Water	8 ounces.

Solution B.

Sodium carbonate, recrystallised	5 ounces.
Ammonium bromide	50 grains.
Water	1 quart.

Mix A, one part, with B, three parts. With a fully exposed plate the development occupied ten minutes. Supposing a plate to have been but just exposed enough, it was possible to go on developing without the slightest trace of fogging. The developer did not discolour; it seemed as if it could be used indefinitely, so might be as cheap or cheaper than pyro. He used Fry's special bromide lantern plates.

Mr. W. H. HYSLOP asked if he did not get yellow stains sometimes.

Mr. DONKIN thought he obtained traces of such with over exposure and quick development.

Mr. LEWIS M. BIDEN had tried the developer; on one occasion he left a plate in it for three hours, and no fog resulted; nevertheless, he had produced fog with it sometimes.

The CHAIRMAN remarked that Mr. Donkin's slides before the meeting were very bright and clear.

Mr. DONKIN had only tried one experiment with the developer upon stripping films; it answered admirably.

Mr. HYSLOP had developed plates with hydroquinone and sulphite of soda, which plates had been exposed for sixteen, thirty-two, up to one hundred and twenty seconds; there was no difference in the results except in the case of the first one. On Mawson's plates he could only get green stains with it.

Colonel W. L. NOVERRE brought samples of the paper and substratum of Eastman's stripping films, which substratum had a ghost of the developed image upon its surface, as mentioned by him at a previous meeting. He thought the residual image to be due to a partial removal of the substratum by hot water.

Mr. T. BOLAS thought that perhaps the products of oxidation of the pyro caused the stain and rendered the film beneath insoluble.

Mr. W. BEDFORD suggested that two white paper spots should be gummed on the top front surface of each slide, to be placed at the bottom, next the light in the lantern. He also thought that each exhibitor of slides at the Society's meetings should bind his slides with paper of a distinctive colour or pattern, to favour easy sorting.

Mr. HYSLOP thought that success in taking yachting photographs depended much upon the operator being a sailor. With the captain's consent he would go to the wheel and move the steamboat into different positions, then explain to the helmsman what positions he wanted when the racing commenced; he would then go nearer to the yachts than he would be likely to take the risk of doing for a landsman; this enabled a larger view to be taken. His views of the *Thistle* were taken at probably not a greater distance than 100 yards, with a Dallmeyer's single landscape lens of 30 inches focus, and upon 18 x 14 plates; he used a double Kershaw shutter, but could not say that he quite approved it, because if a sea came over it, it had a tendency to stick afterwards. He had not found the damp or other influence of sea air to injure plates at all, even in long voyages, but he had not carried them into places of high temperature. When possible he had the machinery of the boat stopped for a moment while making the exposure, to stop vibration.

Mr. BIDEN knew of an instance of cockroaches eating the gelatine of a damp negative.

The CHAIRMAN thought that a single lens was better than any other, whenever it was possible to use it; he never used anything else upon his views of Swiss mountains.

Mr. BEDFORD was of the same opinion. He had seen several photographs taken by the flashing magnesium light, but in them the flashes had not been rapid enough to anticipate movements by the sitters.

Mr. HYSLOP's experience was the same.

Mr. SHEPHERD had found pyroxyline for enamel collodion to answer about as well as gun cotton for igniting the magnesium. He thought the fineness of division of the magnesium powder to have much to do with the rapidity of the flash.

Mr. BOLAS knew of provincial photographers who were using the flashing light in their business, and for dark interiors with success, even when living figures were included.

Mr. DONKIN thought that various portions of the compound could be placed at different distances, and ignited at the same moment by an electrical current passing through minute lengths of platinum wire, so as to get diffusion of light.

Mr. W. E. DEBENHAM had photographed a meeting of the Pharmaceutical Society more than twenty years ago, by a flashing magnesium light from a powder mixed for him by Mr. Larkin.

Mr. BEDFORD had seen a cat successfully photographed by it, but she could not be induced to sit a second time.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, December 22, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. J. Traill Taylor presided.

Mr. NORMAN MACBETH read a paper upon *The Construction and Requirements of Portrait Art* [this will appear in a future number].

The CHAIRMAN supposed that the 50 x 40 size mentioned in the paper had its analogue in the photographers' 5 x 4 plate. Photographers were slaves to the plate makers in the matter of sizes; a 7 x 5 plate was much wanted; in America it is largely used as a standard size. He used 8 x 5 plates because they would cut into other good sizes. Did Mr. Macbeth think it well to have platforms which could be rotated slightly after the sitter was posed?

Mr. MACBETH replied that the plan would do; he preferred a square platform, the line being often advantageous.

Mr. F. A. BRIDGE had been impressed when at Edinburgh with the peculiar lighting of Mr. Macbeth's studio; all the illumination came from very high up, but the effect was fine; he had never been in a finer studio.

The CHAIRMAN said that Mr. Macbeth had spoken of the advantage of having blinds rising from below; the late Mr. Tunny, of Edinburgh, had tried that plan with advantage. A better plan was to have blinds coming both from above and below.

Mr. MACBETH stated that his studio was twenty-two feet high, and that its platform was covered with grey baize cloth; the recess or cave below the window was very useful when copying pictures.

The CHAIRMAN remarked that it was an approximation to the "tunnel studio" of this country.

Mr. BRIDGE spoke of a West-end artist photographer who so arranged matters that his camera looked at the sitter through an orifice in dark grey curtains.

Mr. W. M. ASHMAN knew a photographer who had similar heavy curtains running upon lengths of gas piping. Too high a light caused occasional difficulty in lighting the dress and feet of the sitter properly; most photographers had not time enough with their sitters to do all suggested by Mr. Macbeth.

Mr. MACBETH thought that there was great necessity for the use in studios of lenses of longer focus than usual.

The CHAIRMAN remarked that Mr. Reutlinger produced charming pictures with a low studio.

Mr. J. HUBERT thought it to be of great importance to get an atmospheric effect between the sitter and the background, also that the shaded part of the face should be against the lighter part of the background when stereoscopic effects were desired. He disliked front light, which had a tendency to destroy delicate half tones.

Mr. A. COWAN thought that electric lighting would furnish any kind of illumination the artist might desire, a translucent screen being used as an adjunct; he had not seen equal results from magnesium.

The CHAIRMAN supposed that it might be different if magnesium were properly burnt.

Mr. W. COBB said that it was most reprehensible to pull the sitter about and lecture him just before the exposure.

Mr. COOKE remarked that with sitters who were like lumps of wood there was no alternative. He had seen a revolving platform in a photographer's studio at Hull; it was turned by means of a long handle.

Mr. HUBERT said that the operator must be an artist, or not all the "proportions" and instructions in the world would enable him to make a picture.

Mr. NISBET stated that photographic poses for busts and half-length figures were generally very good; but for full-length figures they were usually inferior to those seen in paintings.

Mr. ASHMAN had noticed at recent public exhibitions that some artist painters were introducing photographic poses.

Mr. W. M. AYRES thought that artists would have to learn from photographers.

Mr. MACBETH did not wish to assume the position of a teacher, but a man ought to speak his mind if any progress were to be made at all, and he had merely stated his own experience from a desire to advance the interests of photography; although a painter, he had been a photographer as long as many present, for he began work with the camera thirty-three years ago. The camera had brought to his eye many items previously overlooked. His taking up photography had brought down upon him some obloquy from artists; both parties should exercise kindness and forbearance to each other to advance the interests of art. Photography was far from being equal in experience to art. Photographers should study every effort made by artists to be original. There was a great limit to the exercise of art in photography, the operator being bound by an instrument, so that when he began to use his mind he found it difficult to get what he anticipated. In placing the sitter upon a platform he had been carrying out his own views; in the portraits by Raeburn the wonderful breadth was produced by the high horizontal line. He liked a high window, a good long studio, and lenses of long focus, and he thought that the magnesium light would do great things for photography in the future.

Mr. COOKE asked Mr. Ashman whether Millais copied photographic poses.

Mr. ASHMAN did not know, but painters now frequently introduced what were strictly photographic poses; such poses were not to be found in the National Gallery.

Mr. HUBERT said that as photographers had a great number and variety of sitters they had more experience in posing than painters, who sometimes might not have more than one sitter in a month, hence it was excusable if painters copied photographic poses.

CAMERA CLUB.

An exhibition of lantern slides was given at the above Club on Thursday, December 22, pictures being shown by Messrs. Dresser, Mason, Davison, Gale, Hussey, Finney, and England.

Mr. Dresser's slides were on gelatino-bromide plates (chiefly Fry's), the subjects being animals at the Zoological Gardens. Mr. Mason's and Mr. Davison's slides were of landscape and seascape, also on gelatine dry plates (Mawson's). Mr. Gale exhibited a selection of his wet collodion work from those recently adjudged the medal at the Pall Mall Exhibition. Mr. Hussey's slides were some collodio-bromide (Brooks's emulsion), and some gelatino-bromide, and included excellent landscape work. Mr. Howard Finney showed gelatino-chloride transparencies, and Mr. England slides made on specially rapid chloride plates. These plates were said to be so fast as to permit of reduction in the camera.

The lantern was worked by Messrs. Hussey and Lionel Clark, and Mr. Hussey employed a new regulator (introduced by Mr. Oakley) upon his oxygen bottle.

The subject for January 5 is *Pheidias and Photography*. Paper at eight p.m., by the Rev. F. C. Lambert.

NORTH STAFFORDSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION.

The monthly meeting was held on the 7th inst.,—Mr. W. E. Leek in the chair.

It was decided that ladies should be admitted free as members, the annual subscription payable by gentlemen to remain 5s., as at present.

It was resolved that all the business of the Association be conducted by the Council alone, and that under no circumstances should any business matter be intruded upon the monthly meetings, which should in future be devoted entirely to matters photographic and entertaining.

The prints sent in for competition for a prize offered by Mr. Drummond having been examined and voted for, a photograph by Mr. Leek was found to be the winner.

The CHAIRMAN then offered a prize for artistic merit in a photograph, the competition to be held at the next meeting.

Messrs. Beech, Stanway, Varcoc, Lobly, and Dr. Crapper were elected members.

Correspondence.

✂ Correspondents should never write on both sides of the paper.

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

"Audi alteram partem."

To the EDITORS.

GENTLEMEN,—I also very much regret Mr. Donkin's absence from the last meeting of the Photographic Society of Great Britain, for I might have saved him from the annoyance of endorsing statements which are readily disproved.

I do not dispute that the names of all the candidates were distinctly read out by Mr. Donkin, but the simple question remains:—"Was he justified in including in the list the name of any candidate against whose nomination a formal written protest had been duly lodged without calling attention to the fact?" His reply to this is that no protest had come to his knowledge: hence, obviously, his difficulty in understanding the drift of the words quoted:—"—is a mistake," and I am glad to find that he is, therefore, personally exonerated from all blame in this matter. He only, however, succeeds in shifting the onus on to other shoulders.

After this statement, it need be no surprise to Mr. Donkin that no black balls were found in the ballot box, as none of those who were aware of the protest (and there were several) for one moment imagined that the name of the candidate against whom objection had been taken would be run in with some forty others. I may add, that personally, I had no opportunity of voting owing to my having left my seat to speak to Mr. Donkin on the subject, and before I had time to return thither, all candidates were declared "duly" elected, although Mr. Donkin says, "there was no attempt to hurry them through."

I was correctly reported as having stated that I handed in a written protest to Mr. Cocking late in the afternoon of the day of meeting; and in order that there shall be no possible mistake in the matter, I will enter into details of what then occurred.

Notwithstanding Mr. Cocking's attempt to account to Mr. Donkin "for the whole of his time from five o'clock . . . till a quarter to seven," &c., and thus inferentially any receipt of the protest, I did undoubtedly, at his request, occupy his own seat at his desk at or about five p.m., he at the time standing at my elbow, and then and there sign the nomination forms for several candidates, during which process I came upon the name of the candidate in question, which led me to ask Mr. Cocking who he was. He replied, and I believe with truth, that he did not know. I then said:—

"If he is, as I have reason to believe, connected with. . . . I shall enter a protest against his nomination." Mr. Cocking appeared somewhat excited about my strong expression of disapproval of the candidate, and after a few minutes conversation he produced a half sheet of paper upon which I wrote the protest, laying it upon the top of the pile of nomination forms in his presence. All this took place, and was witnessed by two gentlemen, neither members of the Society; and yet Mr. Cocking assures Mr. Donkin that "he has no recollection of seeing Mr. Wollaston at all till then (viz., eight o'clock), or of receiving any document from him!" Comment is needless.

I submit, sir, that it is clearly the duty of the officers of the Society, and not mine, to ascertain what became of the document which was duly lodged in the hands of the only official of the Society in attendance. And failing the production of the same, or an explanation satisfactory to the body of members, it is my intention, as a public matter, to demand a re-nomination of the proposed member, in order to give any member the opportunity if he so desire, of exercising his right to vote "Aye" or "No" in this particular case.

I do, and shall ever question the legality of the second vote (under coercion), that the minutes of the meeting of November 8 as entered were correct, for as a matter of fact they were not.—I am, yours, &c.,

Lennie, Chislehurst.

S. G. BUCHANAN WOLLASTON.

MANCHESTER PHOTOGRAPHIC SOCIETY.

To the Editors.

GENTLEMEN,—The latter part of the report of the last meeting of the Manchester Photographic Society is not correct. Mr. Chilton did not use the words ascribed to him, and it is quite certain he did not speak in italics.—I am, yours, &c.,

Manchester, December 28, 1887.

A. BROTHERS.

DUNDEE EXHIBITION.

To the Editors.

GENTLEMEN,—Will you kindly allow me to point out to your readers, through your columns, the fact that the date for receiving entries for the above exhibition has been altered, in response to the expressed wishes of many intending exhibitors, to the end of January, 1888.

As the greater part of the space is already applied for, it would, however, be advisable that those who have not already entered should do so as soon as possible.—I am, yours, &c.,

JAMES RATTRAY, Hon. Secretary.

82, High-street, Dundee, December 24, 1887.

Exchange Column.

* * No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Will exchange candle ruby lamp for argentometer.—Address, R. S. JOHNSON, 64, Wellington-road, Northampton.

Will exchange a half-plate bellows-bodied camera with two double dark slides, all in good order, for a Hughes's triplexion lamp, in good order.—Address, J. DONALDSON, 42, St. Vigean's-road, Arbroath.

Answers to Correspondents.

* * All matters for the text portion of this JOURNAL, including "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C.

Communications relating to Advertisements and general business affairs to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

PHOTOGRAPHS REGISTERED:—

B. J. Taylor, Sheffield.—Photograph entitled "The Doll's Doctor."

A. T. Mackenzie, Birnam, Perthshire.—Two photographs of the Right Hon. A. Peel, M.P., Speaker of the House of Commons.

A. PUMPHREY.—Received.

W. L. NASH.—We have expressed your wish to the gentleman named.

H. B. BRAIN.—The ball and socket system was applied to the lens and camera thirty years ago by Mr. George Shadbolt.

T. BRAYWOOD.—Read an article on the subject in the ALMANAC for 1888, and if you wish further information write again.

S. W.—Magnesium in the state of powder can now be obtained at most photographic warehouses. The price is about 2s. 6d. or 3s. per ounce.

A. Y. E.—You certainly can have nothing simpler than the gelatino-bromide paper process. There is no process so simple and easy as this for making enlargements.

TYRO.—Any one selling pictures of the class you desire renders himself liable to fine or imprisonment, or both, under Lord Campbell's Act. No wonder your letter was returned.

B. CROSBY.—The most convenient form of furnace for burning-in small enamel pictures is a gas muffle furnace. Mr. Fletcher, of Warrington, supplies an excellent one for the purpose and at a very moderate price.

WERNER & SON.—A bath for electro-silvering can certainly be made by adding a solution of cyanide to one of silver nitrate until the silver cyanide, at first copiously thrown down, is redissolved. Any ordinary battery will answer.

R. STEWART.—We must repeat what we said lately to another correspondent, that Hardwick's *Manual* (J. & A. Churchill) is the only work that will satisfy your conditions. Articles on retouching will be found scattered over the present and last year's volume of this JOURNAL.

W. S. A. says: "Having a quantity of the silver cuttings, I have burnt them and sifted to fine powder; how should I proceed to obtain the silver from it in its metallic form?"—Mix the powder with its own weight of a flux composed of equal parts of the carbonates of soda and potash, place in a clay crucible and fuse at a strong heat in a melting furnace, and do not hurry the operation. After the crucible has cooled the silver will be found as a button on breaking the pot.

E. S. H.—For the 5 × 4 camera the rapid lens mentioned in the postscript will prove very useful, especially as one of the pair may be used as a single lens. Obtain also another of about seven or eight inches focus. This may be either a single or a combination lens. For the larger camera obtain a doublet of about ten inches focus, capable of dividing so as to give a focus of twenty inches, and a similar lens of about seven inches, which may be used either in its entirety or divided.

W. HINKS asks advice on the following:—He says some olive oil has been accidentally dropped on a bromide enlargement which has been expensively finished in "black and white," and asks if there is any method by which it can be removed without injury to the picture.—The oil can no doubt be taken out by alternately moistening it with pure benzole and blotting it off with clean blotting paper. Some little patience may possibly be required, but in the end the treatment will be effectual.

H. B. (Subscriber).—You are evidently mistaken, no such article appeared in our ALMANAC for 1887. There is an article by the gentleman mentioned but it is on a different subject. The acetate toning bath will yield excellent brown tones and the lime bath a good black with the right kind of negative; but more depends upon the paper and the character of the negative than upon the particular toning bath employed. With an ordinary good sample of paper and a suitable negative almost every tone desired may be obtained with any toning bath.

SUBSCRIBER (Newcastle-on-Tyne) writes: "I have a photographic album which I am afraid has been lying in a damp place, for the leather back has turned to a milky-white colour on one side; perhaps it is something in the tanning of the leather. Can you suggest any treatment that will restore it? I may say that the album is of the best, and not a cheap article."—If the album be a valuable one we should recommend our correspondent to place it in the hands of a practical bookbinder. We imagine that it has simply become mouldy, but we cannot say without seeing it.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, Wednesday, January 4, 1888, will be on *Winter Photography*.

PEOPLE'S PALACE, MILE END.—Among the Boxing-day attractions here were included two dioramic lectures by Mr. F. A. Bridge. The views—consisting of a series of *Windsor Castle*, *Jane Conquest*, *The Women of Mumble's Head*, *The Curfew*, statuary, instantaneous effects, &c.—were exhibited on a very large scale, and were much appreciated.

LENS FORGERY.—We have been shown one of the clumsiest forgeries of lenses we have yet seen. A gentleman advertised in our columns for a 2b Dallmeyer portrait lens, and has received (on approval) a miserable old and old-fashioned French half-plate lens, having engraved thereon the name of Mr. Dallmeyer, although not in the same style or lettering as the genuine article. Let buyers beware of purchasing lenses from those of whom they know nothing or who object to having them sent to the maker for verification.
